# Active Alignments of Lens Systems with Reinforcement Learning\*

Matthias Burkhardt, Tobias Schmähling, Michael Layh, and Tobias Windisch

Abstract-Aligning a lens system relative to an imager is a critical challenge in camera manufacturing. While optimal alignment can be mathematically computed under ideal conditions, real-world deviations caused by manufacturing tolerances often render this approach impractical. Measuring these tolerances can be costly or even infeasible, and neglecting them may result in suboptimal alignments. We propose a reinforcement learning (RL) approach that learns exclusively in the pixel space of the sensor output, eliminating the need to develop expert-designed alignment concepts. We conduct an extensive benchmark study and show that our approach surpasses other methods in speed, precision, and robustness. We further introduce relign, a realistic, freely explorable, opensource simulation utilizing physically based rendering that models optical systems with non-deterministic manufacturing tolerances and noise in robotic alignment movement. It provides an interface to popular machine learning frameworks, enabling seamless experimentation and development. Our work highlights the potential of RL in a manufacturing environment to enhance efficiency of optical alignments while minimizing the need for manual intervention.

#### I. INTRODUCTION

The assembly of optical devices requires precise positioning when joining their individual components. This requirement is essential in a wide range of products, including cameras in mobile phones, fiber optics, aerial and medical imaging and optical projection systems for microlithography [1]. One particularly sensitive process is an alignment, where two components must be precisely positioned relative to each other to achieve high precision. A prominent example is the positioning of a lens system relative to an imager [2]. The compound product must be assembled in a way that the optical performance is maximized. While high-cost lenses are often designed to ease the alignment with an imager, achieving optimal alignment with low-cost components presents a significant challenge. All of these components typically offer many degrees of freedom, each influencing multiple performance metrics in complex and interdependent ways. Often, it is unclear how the position has to be modified in order to reach a performance satisfying predefined quality constraints. Additionally, variations of the components make the relations between the position and the optical performance diffuse and noisy. These challenges have been widely studied in the literature [3], [4], [5], [6].

Fig. 1: Schematic presentation of a single alignment step, where a lens system consisting of three single lenses (left) has to be positioned relative to an optical sensor (right).

The classic way to deal with such problems involves extensive scans during the alignment of each optical system individually, where any degrees of freedom are varied and evaluated separately. To make those scans robust against manufacturing tolerances within the components, many possible positions are scanned by a structured walk through the alignment space, for example along coordinate axes. Often, these algorithms solely rely on hand-crafted features obtained from the high-dimensional sensor output, where sensor and movement noise make it hard to conduct deterministic algorithms. Speeding up optical alignments has thus been a fruitful application of machine learning methods in the past, see [7] for a review. Some approaches predict next alignment moves from misaligned settings in a supervised fashion [8], [9]. A detailed study for Fast-Axis Collimating Lenses can be found in [10]. In their basic form, however, active alignment problems are no supervised learning problems. This is due to the fact that first, symmetries and offsets in the optical layout make it hard-or even impossibleto set up a supervised dataset from the sensor observation to the optimal sensor image. Second, training models via supervised learning cannot account to minimize the number of alignment steps. For instance, sometimes a step into the wrong direction has to be taken in order to explore symmetries in the robotic movements. Thus, more naturally, optical alignments are modeled as an RL problem which canonically allows training models to find short trajectories to optimal positions. RL algorithms have demonstrated the ability to learn complex relationships for various challenging tasks [11], [12], [13]. There has also been plenty of research using RL for process control in manufacturing (see [14] and references therein). For the alignment of laser optics or interferometers, RL has already been applied successfully as demonstrated in [15] or [16], respectively. Particularly when

applied to real systems, RL comes with its own intrinsic challenges [17], like sparse and delayed rewards [18], data inefficiencies [19], and reproducibility issues [20], rendering high need for research when applied to new tasks.

In this study, we formulate optical alignment problems as an RL task, where optimal robotic alignment movements are learned solely in the pixel space from a high-dimensional sensor observation (see Figure 1). The alignment goal is reached when the difference between the observed image and a given reference pattern falls below a predefined threshold. We study different reward functions to motivate RL agents to find optimal alignment positions in as few steps as possible. To the best of our knowledge, our work is the first that treats an optical alignment task as a *Partially Observable Markov Decision Process* (POMDP). More specifically, our main contributions are:

- We formulate active lens alignment problems as POMDP tangible by RL algorithms.
- We introduce the Python framework *relign*<sup>1</sup> for simulating active alignment scenarios using the physically based rendering framework Mitsuba [21].
- We provide an interface compatible with the Gymnasium API [22] for benchmarking state-of-the-art methods on representative alignment tasks, including RL models and black-box optimization techniques.
- We show that RL algorithms can solve real-worldinspired alignment problems more efficiently than other methods based on machine learning, even under presence of manufacturing tolerances and noise in robotic alignment movements while maintaining high accuracy and low inference time.

Our approach not only speeds up the optical alignment process significantly, it also renders the need to design handcrafted features obsolete.

## **II. ACTIVE ALIGNMENTS OF LENS SYSTEMS**

## A. Problem Formulation

An optical alignment process joins multiple components to maximize optical performance. In this work, the component to be aligned is a lens system consisting of a fixed number of single lenses  $L = (L_1, \ldots, L_k)$  that need to be positioned relative to an optical sensor. This situation is typical when manufacturing cameras. The goal of an alignment is to move L to a position  $s = (x, y, z, R_x, R_y, R_z) \in \mathbb{R}^6$  relative to a sensor, typically with an automated robotic alignment system, such that the optical performance is maximal.

The main challenge is that in each alignment, the process has to adjust to new conditions, mainly due to variances within *L* and when gripping *L*. The first type of variances is a randomized offset arising from the placement of *L* in the alignment station. This can be modeled by a randomized starting position  $W_{\text{off}} \in \mathbb{R}^6$  representing a random translation and rotation offset. When connecting to the robotic alignment system, the movement is typically not optimal, meaning that when a movement  $a \in \mathbb{R}^6$  in a state *s* is executed, the new

Fig. 2: Impact of  $W_L$  on lenses. Here, the arrows depict normal vectors of the lenses to visualize noise in the rotations.

state is not s + a but the slightly distorted state  $s + W_{\text{dist}} \cdot a$ with  $W_{\text{dist}} \in \mathbb{R}^{6 \times 6}$ . Moreover, the new state can be clipped, for instance because a boundary condition is met. We refer to Section Section IV-B for more details on how  $W_{dist}$  is constructured and how the boundary behavior is modeled. Another type of variances comes from the production of Litself, which cannot be changed by the process during the alignment. That is, each single lens  $L_i$  in L has an individual tilt and position offset in comparison to the *ideal* lens system (see Figure 2). We denote the offsets of each lens within L by  $W_{\rm L} \in \mathbb{R}^{k \times 6}$ . Other variances not considered in this work are dispersions in the geometries of the single lenses, like their curvature. Here, the variances  $W = (W_{off}, W_{dist}, W_L)$ characterize an alignment completely and we assume that these are sampled from an unknown distribution  $W \sim \rho$ . We further assume that the variances W are latent to the alignment process, i.e., cannot be measured while aligning. As a result, it is not possible to directly compute the position where optical performance is optimal using the physical equations of e.g. geometrical optics.

## **B.** Performance Measurements

To quantify the optical performance at a given state s, collimated light is sent through L and measured at the sensor with width w and height h, yielding a high-dimensional image  $O_W(s) \in \mathbb{R}^{w \times h}$  of light intensities. The sensor output  $O_W(s)$  is noisy, and retrieving  $O_W(s)$  multiple times for the same position s always yields slightly different observations. We call this noise sensor variance. In many industrial applications, hand-crafted scalar features are extracted from  $O_W(s)$ , typically involving the optical transfer functions, for which quality bounds have to be reached during the alignment. Here, however, we study problems where a generic reference output  $O^*$  independent of W is given such that the alignment task is the identification of a state  $s^*$  where the sensor output matches the reference, i.e.,  $O_W(s^*) \approx O^*$ . The reference pattern can be considered as  $O^* = \mathbb{E}[O_{W^*}(s^*)]$ , that is the sensor output without noise  $W^* = 0$  in the positioning of L and its lenses at the optimal position  $s^*$ . In practice, the choice of the light field used for creating a test pattern at sensor level is dictated by the specific application requirements, such as whether the camera needs to achieve sharp focus in the near or far field. A common example is the Siemens star [23], which is widely used for evaluating optical performance of digital cameras [24]. Numerous methods exist to measure the quality of an optical image based on projected patterns such as a pattern of Siemens stars and

<sup>&</sup>lt;sup>1</sup>Code under https://github.com/hs-kempten/relign.

Fig. 3: Visualization of  $(s_i, s_j) \rightarrow \min_{s_k, k \neq i, k \neq j} ||O_W(s) - O^*||$ for each tuple  $\{i, j\} \subset \{x, y, z, R_x, R_y\}$ .

slanted edges as described in ISO 12233 [24]. Given a reference pattern, the optimization problem

$$\underset{s \in S}{\operatorname{arg\,min}} \| O_W(s) - O^* \| \tag{1}$$

has to be solved for a given situation  $W \sim \rho$ , where  $S \subset \mathbb{R}^6$ denotes the set of allowed positions. Here,  $\|\cdot\|$  denotes a vector norm, like the Euclidean distance, and we interpret the input matrices as vectors. Figure 3 shows some 2Dprojections of this optimization problem for the alignment situations introduced in Section V. Typically, a threshold  $\theta \in$  $\mathbb{R}_{\geq 0}$  is given such that any *s* that satisfies  $\|O_W(s) - O^*\| \leq \theta$ is considered as *optimal*. However, as *s* can only compensate positional offsets of *L* given by  $W_{\text{off}}$  under distortions given by  $W_{\text{dist}}$  and not the variances  $W_L$  inside *L*, some lens systems may have  $\|O_W(s) - O^*\| > \theta$  for all positions *s*.

#### C. Alignment Algorithms

As the variances W are unobservable by the alignment process, most active alignment algorithms explore the state space S iteratively by selecting states and searching for directions where the score  $||O_W(s) - O^*||$  attains its minimum. Once positioned at a new state, a new sensor signal is observed. An *alignment algorithm* computes a series of subsequent actions  $a_1, \ldots, a_n$ , step by step, starting from a randomized initial position  $s_0 = W_{\text{off}}$ . Each action is an element of a set of allowed actions  $A \subset \mathbb{R}^6$  and generates a sequence of states  $s_i = s_0 + W_{\text{dist}}(a_1 + \ldots + a_i)$  such that  $s_n$  is optimal, i.e.,  $||O_W(s_n) - O^*|| \le \theta$ . The computation of  $a_i$  must be based on a subset of the i-1 many images  $O_W(s_1), \ldots, O_W(s_{i-1})$  obtained so far. In Section V-B, we state the alignment algorithms used in our benchmark study.

# III. APPROACH

# A. Alignments as a POMDP

In this section, we describe how RL algorithms can be used as alignment algorithms as defined in Section II-C. Specifically, we consider active alignments as an *episodic* POMDP, where each episode is the alignment of a given lens system L. As defined in Section II, S represents the set of states, and A denotes the set of actions. In the alignment of L, including variances  $W = (W_{off}, W_{dist}, W_L)$ , selecting a at s results in the new state  $s' = s + W_{dist} \cdot a$ , yielding a reward R(s, s'). A detailed view on different reward functions used is provided in Section III-B. The state  $s \in S$  cannot be directly observed. Instead, only the high-dimensional sensor output  $O_W(s)$  is given, which is controlled by a conditional probability density function depending on *s*. We explain in Section IV-A how an image  $O_W(s)$  is sampled from the sensor at a given state *s*. For given *W*, an episode ends once a *terminal state*, that is an optimal state from  $\{s \in S : ||O_W(s) - O^*|| \le \theta\}$ , or an upper limit of steps  $T \in \mathbb{N}$  is reached. The goal is to find a *policy*  $\pi$  that maps observations to actions in a way that maximizes the accumulated observed reward. More formally, given the observation  $O_W(s)$  for *s*, the next state is  $s + W_{\text{dist}} \cdot \pi(O_W(s))$ . Starting from an initial state  $s_0$ , this combined dynamics of sampled observations from the sensor and generated actions by the policy  $\pi$  yields a trajectory  $(s_0, \ldots, s_k)$  of subsequent states with  $s_{i+1} =$  $s_i + W_{\text{dist}} \cdot \pi(O_W(s_i))$  where the last state  $s_k$  is either optimal or k = T holds. The goal is to find a policy such that

$$\mathbb{E}_{W \sim \rho, (s_0, \dots, s_k) \sim \pi} \left[ \sum_{i=0}^{k-1} \gamma^i R(s_i, s_{i+1}) \right]$$
(2)

is maximized, where  $\gamma \in (0,1)$  is the *discount factor* given to trade-off rewards in early and late states. Note that in general the reward also depends on the action taken, which is not required in this work and hence omitted.

# B. Rewards

To train effective agents for an alignment task, the reward function R has to be designed in a way that the optimization task from Equation (2) is solved in a minimal number of steps. We consider two distinct reward functions: The first,  $R_{\text{step}}$ , assigns a fixed penalty of -1 for each step taken, independent of the states and their distance to the goal, i.e.,  $R_{\text{step}}(s,s') = -1$ . The second approach involves rewarding each step based on the extent to which the action brings the system closer to the optimal state. More formally, we define

$$R_{\text{pot}}(s,s') = \|O_W(s) - O^*\| - \|O_W(s') - O^*\|.$$

That is, a larger reward is obtained if s' is closer to the optimal state than s. Note that  $R_{pot}$  is a *potential-based* reward [25], that means that if  $\gamma = 1$ , the reward of a trajectory  $(s_0, \ldots, s_k)$  satisfies  $\sum_{i=0}^{k-1} R_{pot}(s_i, s_{i+1}) = R_{pot}(s_0, s_k)$ .

#### **IV. SIMULATING ALIGNMENTS**

One main challenge in simulating realistic optical alignments is to accurately model how a sensor measures light emitted from a source and propagated through optical lenses. Here, we use Mitsuba3, a physically based rendering engine for forward and inverse light-transport simulation. This not only allows calculating light intensities  $O_W(s)$  measured at the sensor (see Section IV-A) for a concrete position *s*, but also changing *s* dynamically (see Section IV-B). All Mitsuba scenes consist of a sensor, *k* many identical biconvex single lenses, and a light source.

#### A. Sensor Outputs

The Mitsuba scene emulates collimated light using a binary environment map with a centered rectangular light source. Starting at the sensor, Mitsuba traces light rays backwards that pass through the lenses. We use an irradiance meter as sensor, which measures the incident power per unit area over a predefined shape. In our setup, the sensor shape is  $0.5 \times 0.5$  in Mitsuba space coordinates. To solve the high-dimensional problem of rendering  $O_W(s)$  numerically, Mitsuba employs Monte Carlo integration, drawing  $s_c$  many samples from a uniform distribution. As a consequence, the sensor output  $O_W(s)$  is different when rendering the same position *s* with different seeds. This leads to the probability density function of the POMDP as described in Section III-A. An example of the resulting sensor output is shown in Figure 1. The measurements are interpreted as a grayscale image and stored without any post-processing.

## B. Position Changes

Without loss of generality, we assume that the set of all possible states is the unit interval  $[0,1]^6$ . We place k many lenses in the lens system L in a way that  $s^* := (0.5, ..., 0.5) \in \mathbb{R}^6$  is the optimal position. Upon initialization, we sample  $W_L$  from a normal distribution and reposition the single lenses within L accordingly. Afterward, a starting vector  $W_{\text{off}} \in [0,1]^6$  is sampled uniformly which defines the initial state  $s_0 := W_{\text{off}}$ . The movement distortion matrix is constructed as  $W_{\text{dist}} = I_6 + \varepsilon \in \mathbb{R}^{6\times 6}$  where each coordinate in  $\varepsilon \in \mathbb{R}^{6\times 6}$  is sampled from a normal distribution. The positioning of the lens system can be varied by setting an action  $a \in \mathbb{R}^6$  leading to an update  $s' = s + W_{\text{dist}} \cdot a$ . To ensure that s' stays within  $[0,1]^6$ , each coordinate of  $s + W_{\text{dist}} \cdot a$  is clipped into [0,1] before updating the Mitsuba scene. Subsequently, the sensor output  $O_W(s')$  is generated as described in Section IV-A.

## C. Generating the Reference Pattern

To decide whether a state *s* is in the optimality condition, the observation  $O_w(s)$  has to be compared to a reference pattern  $O^*$ . This reference pattern only depends on the number of lenses *k* in the lens system, not on the noise level of *W*. To generate *W* in our synthetic setting, we use a perfectly aligned lens system where each of the *k* many lenses are perfectly aligned as well, i.e.,  $W^* := 0$ . We then sample 1.000 observations from  $O_{W^*}(s^*)$  and compute the pixel-wise mean image as an approximation for  $O^* = \mathbb{E}[O_{W^*}(s^*)]$ .

#### V. EXPERIMENTS

#### A. Benchmark Environments

When rendering images, one typically faces a trade-off between computational efficiency and image quality. To reduce overall RL training time, we prioritize fast image generation at the cost of lower pixel resolution and increased sensor variance. Because of that, we only use  $50 \times 50$  pixels and 512 samples per pixel for rendering. This also motivates the decision to use a simple rectangle as reference pattern, as more detailed patterns are not recognizable at this resolution.

For the evaluation, we focus on six distinct benchmark setups. Each setup considers a set of  $k \in \{2,3\}$  single lenses with radii of curvature of -1.0 and 3.8 and thickness of 0.2. Each single lens can have none, low or high individual variances  $W_L$ . The first three components of  $W_L$  represent translation offsets along the *x*, *y* and *z* axes and are sampled from a normal distribution  $(W_L)_i \sim N_{0,6.25}$  for low and  $(W_L)_i \sim N_{0,12.5}$  for high variances with  $i \in \{1,2,3\}$ . The remaining two represent rotation offsets along the *x* and *y* axes, sampled as  $(W_L)_j \sim N_{0,0.00625}$  for low and  $(W_L)_j \sim N_{0,0.0125}$  for high variances with  $j \in \{4,5\}$ . These variances account for potential manufacturing imperfections within a certain tolerance bound. To create a challenging alignment situation, they are intentionally set very high (see Figure 2 for an extreme case). Furthermore, rotation around *z* is considered redundant, as in a perfectly aligned scenario, rotation around the *z* axis has no effect. Note that  $O^*$  does not change for setups including object variances.

#### B. Algorithms

Expert-designed alignment algorithms typically rely on hand-crafted features extracted from  $O_W(s)$  that need to be optimized simultaneously. These features as well as their optimality region highly depend on the exact use case. To have a fair and generic comparison of our RL approach with conventional learning methods, we decided to benchmark against state-of-the art black-box optimizers to solve Equation (1) actively. For our study, we focused on three different models to solve the task of optical alignments:

1) Proximal Policy Optimization: Proximal policy optimization (PPO) is a policy-based RL algorithm that trains a stochastic policy in an on-policy way [26]. To process the images, a CNN is used as policy network. While PPO is a versatile learning algorithm, many learning tasks are too complex to solve from scratch via RL. Instead of training an agent on a hard task from the start, curriculum learning structures the training by introducing simpler subtasks first, enabling the agent to build foundational skills before tackling more challenging scenarios. This typically leads to faster convergence, better generalization, and improved sample efficiency, especially in environments with sparse rewards or long-horizon decision-making problems [27]. The same holds true when training an RL agent for a too low optimality threshold  $\theta$ : The agent fails to reach the optimality region, even when allowing long trajectory lengths before truncation. Thus, we apply a curriculum strategy where  $\theta$  is decreased gradually in an exponential fashion, that is, starting from an initial threshold  $\theta_0$ , the threshold of the *i*-th task is  $\theta_i = C \cdot \theta_{i-1}$  with C < 1 (in our experiments, we set C = 0.9). We denote the task as solved when the agent manages to reach the optimality region defined by  $\theta_i$  within 20 steps in five subsequent online evaluations. The maximal length of an episode T is set to 100. All models have been trained for  $1.5 \cdot 10^6$  global steps with an initial learning rate of  $1e^{-4}$ which is decreased by a factor of 0.8 if the reward stagnates and which is reset to the initial value if the task of the curriculum is solved. Figure 4 shows the evolution of the reward along the curriculum for k = 3 lenses. All trainings are executed on NVIDIA H100 GPUs requiring roughly 0.32 seconds per global step resulting in a total train time of approximately five days.

2) Bayesian Optimization: Bayesian Optimization (BO) is a strategy for minimizing functions f that are expensive

Fig. 4: Achieved reward  $R_{\text{pot}}$  during an online evaluation for k = 3 lenses and different noise levels while optimality threshold  $\theta$  is adjusted according to the curriculum.

to evaluate by building a probabilistic model of the objective function [28], [29]. It selects new evaluation points by balancing exploration and exploitation using an acquisition function, which predicts where the function is likely to improve. This approach is particularly useful when function evaluations are costly, as it finds optimal solutions with relatively few evaluations. Setting  $f_W(s) := ||O_W(s) - O^*||$ , an alignment problem can be interpreted as a black-box optimization problem. We evaluated BO algorithms using a different probabilistic model than implemented in scikitoptimize [30]: Gaussian Processes (BO-GP) [31] and Random Forests (BO-RF) [32]. As vanilla BO algorithms explore  $f_W$  for each W and without a priori information, the state space has to be explored first randomly costing unnecessary steps. Thus, we also tested the method proposed in [33] (TransferGP) that allows pre-training a Gaussian process on samples from problem instances  $f_{W_1}, \ldots, f_{W_m}$ .

3) *Random:* As a baseline, we implemented an algorithm that samples uniformly at random from the alignment space.

# C. Results

For evaluation, each algorithm was executed on 100 different environments for each of the six benchmark situations as described in Section V-A. We compared approaches that operate without any a priori information and require no domain knowledge. Except for the RL algorithms, the algorithms used do not involve a training phase. To address this imbalance, we reduced the search space for baseline algorithms to approximately eight percent of the search space used for RL. Figure 5 shows the RL-based method trained with  $R_{\rm pot}$ surpases in all scenarios all other algorithms in terms of convergence speed. Moreover, independent of the number of lenses and the noise level, RL-PPO reaches the optimality region in under ten steps. As expected, the benchmarks with larger noise levels converge at a higher error, because due to the lens variances, even the best alignment cannot reach the minimal render variance error. In a direct comparison, the potential-based reward  $R_{pot}$  converges slighly faster than  $R_{\text{step}}$  to the optimal region (see Figure 6).

Only considering the computation time, RL-PPO requires a constant 25 ms and BO-RF 95 ms per alignment step. In

Fig. 5: Comparison of alignment algorithms.

Fig. 6: Evaluation of RMSE for the best PPO models. The upper plot compares two reward functions for a fixed number of single lenses (three). The lower plot compares two different lens systems using the best reward function.

contrast, BO-GP becomes increasingly time consuming as the number of steps increases. For 20 steps, each step takes an average of 100 ms, while for 50 steps the time per step increases to 178 ms. For the pre-trained Gaussian processes of TransferGP, the processing time for each step increases with the number of instances it has been pre-trained on. Already when trained on m = 10 instances with 100 samples each, their processing time per step takes several minutes while their performance equals almost the performance of vanilla BO-GP. Due to their impractical computation time, we have not included pretrained GP models in our benchmark.

#### VI. CONCLUSION

This work introduced an RL approach for active alignments of optical components. Unlike traditional alignment methods that rely on expert-designed alignment concepts involving the computation of hand-crafted features, our approach learns optimal alignment strategies directly from high-dimensional sensor observations. By leveraging RL, we demonstrated that alignment tasks can be solved more efficiently, even in the presence of noise and manufacturing tolerances. However, the low inference time of RL-algorithms at runtime comes at the price of many training iterations. Our experiments show that RL-based alignment not only outperforms conventional machine learning approaches in terms of efficiency but also eliminates the need for manually designed features. This work opens the door for further exploration of RL in high-precision optical assembly, with potential applications in automated manufacturing, adaptive optics, and real-time calibration of complex optical systems. Future research could focus on improving sample efficiency, integrating domain adaptation techniques, and extending RLbased alignment to real-world hardware implementations.

# ACKNOWLEDGMENT

We thank Marco F. Huber and our colleagues from the Institute of Machine Vision for their careful proofreading and constructive feedback on the manuscript.
