Orbital magnetization, a key property arising from the orbital motion of electrons, plays a crucial role in determining the magnetic behavior of molecules and solids. Despite its straightforward calculation in finite systems, the computation in periodic systems poses challenges due to the ill-defined position operator and surface current contributions. The modern theory of orbital magnetization, formulated in the Wannier representation and implemented within the Density Functional Theory (DFT) framework, offers an accurate solution through the “converse approach.” In this paper, we introduce QE-CONVERSE, a refactored and modular implementation of the converse method, designed to replace the outdated routines from Quantum ESPRESSO (version 3.2). QE-CONVERSE integrates recent advancements in computational libraries, including `scalLAPACK` and `ELPA`, to enhance scalability and computational efficiency, particularly for large supercell calculations. While QE-CONVERSE incorporates these improvements for scalability, the main focus of this work is provide the community with a performing and accurate first principles orbital magnetization package to compute properties such as Electron Paramagnetic Resonance (EPR) g -tensors and Nuclear Magnetic Resonance (NMR) chemical shifts, specially in systems where perturbative methods fail. We demonstrate the effectiveness of QE-CONVERSE through several benchmark cases, including the NMR chemical shift of ^{27}Al in alumina and ^{17}O and ^{29}Si in α -quartz, as well as the EPR g -tensor of $^n\Sigma(n \geq 2)$ radicals and substitutional nitrogen defects in silicon. In all cases, the results show excellent agreement with theoretical and experimental data, with significant improvements in accuracy for EPR calculations over the linear response approach. The QE-CONVERSE package, fully compatible with the latest Quantum ESPRESSO versions, opens new possibilities for studying complex materials with enhanced precision.

INTRODUCTION

Orbital magnetization, a fundamental property arising from the orbital motion of electrons, plays a crucial role in determining the magnetic behavior of molecules and solids. Orbital magnetization arises from the breaking of time-reversal (TR) symmetry by spin-orbit (SO) coupling. This phenomenon can occur spontaneously in ferromagnetic materials or can be triggered in nonmagnetic materials by external perturbations, such as magnetic fields. While the calculation of the orbital magnetization in finite systems is straightforward, it becomes challenging in periodic systems due to the ill-defined position operator and the contribution of itinerant surface current [1, 2]. Over the past two decades, this challenge has been tackled through the formulation of the modern theory of orbital magnetization [3, 4] in the Wannier representation (similarly to the modern theory of polarization using the Berry Phase approach [5, 6]). This formulation [2], enables the calculation of orbital magnetization in the thermodynamic limit within the framework of Density Functional Theory (DFT) in the so-called “the converse approach” [7, 8].

Through first-principles orbital magnetization, several

derived macroscopic properties can also be computed, such as the Electron Paramagnetic Resonance (EPR) g -tensor parameter and Nuclear Magnetic Resonance (NMR) chemical shifts [7, 8]. In systems where spin-orbit coupling cannot be described as a perturbation or the g -tensor exhibits a large deviation from the free electron value [7, 9], the “converse” approach is known to be more accurate than the widely exploited linear response (LR) approach [7]. An example is given by the PbF family of molecules, which due to the degenerate e level occupied by unpaired electrons and the absence of SO coupling along the bond direction, a failure of the LR approach is observed in contrast to the converse approach (see Table III of ref. [7]).

The converse approach was originally implemented [7] in the `PWscf` code of the, now, obsolete Quantum Espresso (QE) version 3.2. In this paper, we present a deep refactoring and revised implementation of the former converse routines gathered in a stand-alone module called QE-CONVERSE package. QE-CONVERSE is fully compatible with latest Quantum ESPRESSO versions [10] (from version 7.2 onward). It fully exploits recent advances and improvements in QE libraries (`mpi` scalability including additional parallelization levels and use

of optimized linear algebra libraries such as scaLAPACK [11] or ELPA [12]) that enhance computational performance in larger systems, compared to the former version (see Supplementary Materials). However, the main goal of the present work is not focused on computational efficiency, but rather on ensuring the high accuracy of the calculated properties, such as EPR g -tensors and NMR chemical shifts, which are often crucial in the study of complex systems. With respect to the original version, few bugs have been solved, in particular, the calculation of orbital magnetization, NMR chemical shifts and EPR g -tensor parameters for any cell symmetry.

This paper is organized as follows. In Section 2, we briefly review the theoretical background of the converse method. Sections 3 and 4 cover the implementation, installation, and usage of the QE-CONVERSE package. Finally, Section 5 and 6 showcase the new QE-CONVERSE version on selected benchmark systems going from molecules to extended systems.

THEORETICAL BACKGROUND

In the following, we only outline the theoretical background of quantities derived from the calculation of orbital magnetization, i.e EPR g -tensor and NMR shielding tensor. For a detailed derivation of the orbital magnetization within the modern theory, we refer the reader to Refs. [1–4].

Converse EPR

The converse method for calculating the EPR g -tensor, introduced in Ref [7], can be summarized as follows. The starting point is an independent particles Kohn-Sham Hamiltonian that preserves the translation symmetry of the crystal but breaks Time-Reversal (TR) symmetry. In the all-electron (AE) formalism, the Hamiltonian in atomic units is given by:

$$H_{\text{AE}} = \frac{1}{2} [\mathbf{p} + \alpha A(\mathbf{r})]^2 + V(\mathbf{r}) + \frac{\alpha^2 g'}{8} \sigma \cdot [\nabla V(\mathbf{r}) \times \mathbf{p} + \alpha A(\mathbf{r})] \quad (1)$$

where $A(\mathbf{r})$ is the symmetric gauge vector potential equal to $\frac{1}{2} \mathbf{B} \times \mathbf{r}$, $\alpha = \frac{1}{c}$ is the fine structure constant, $g' = 2(g_e - 1)$ and σ are the Pauli matrices. In contrast to the linear response approach, the converse method bypasses the perturbation of the Hamiltonian: the spin-orbit coupling (SO) term is explicitly incorporated into the self-consistent field calculations, while the spin other orbit (SOO) term, that in general gives a small contribution to the g -tensor, is neglected. The orbital magnetization

is formally given by the Hellmann-Feynman equations as:

$$\mathbf{M} = f_n \sum_n \langle \psi_n | - \frac{\partial H_{\text{AE}}}{\partial \mathbf{B}} | \psi_n \rangle \quad (2)$$

where f_n is the occupation of the eigenstate n where the expectation values is taken on ground-state spinor ψ_n . Equation (2) provides a direct evaluation of orbital magnetization in finite systems. However, extending this to periodic systems is challenging due to the undefined nature of the position operator. To overcome this limitation, the equation has been reformulated in the Wannier representation, which allows for the computation of orbital magnetization in the thermodynamic limit using the Berry-phase formula:

$$\mathbf{M} = - \frac{\alpha N_c}{2N_k} \text{Im} \sum_{n, \mathbf{k}} f_{n, \mathbf{k}} \langle \partial_{\mathbf{k}} u_{n, \mathbf{k}} | \times (H_{\mathbf{k}} + \epsilon_{n, \mathbf{k}} - 2\epsilon_F) | \partial_{\mathbf{k}} u_{n, \mathbf{k}} \rangle \quad (3)$$

where $H_{\mathbf{k}}$ is the crystal Hamiltonian with $\mathbf{B} = 0$, $\epsilon_{n, \mathbf{k}}$ and $u_{n, \mathbf{k}}$ are its eigenvalues and eigenvectors, ϵ_F is the Fermi level, N_c is the number of cells and N_k is the number of \mathbf{k} points. The $|\partial_{\mathbf{k}} u_{n, \mathbf{k}}\rangle$ is \mathbf{k} the derivative of the Bloch wave function for n occupied states. In the context of an AE method, Equation (3) is valid for both normal periodic insulators and metals, as well as Chern insulators with a non-null Chern invariant. In the norm-conserving pseudopotential framework, instead, where the core regions of AE wave functions are replaced by smoother pseudo waves (PS), the gauge including projection augmented wave (GIPAW) reconstruction is needed, as shown by Pickard and Mauri's theory [13]. The GIPAW approach transforms the Hamiltonian of Equation (1) into pseudo GIPAW Hamiltonian, that at zero order of the magnetic field yields to the following terms:

$$H_{\text{GIPAW}}^{(0,0)} = \frac{1}{2} \mathbf{p}^2 + V_{\text{loc}}(\mathbf{r}) + \sum_{\mathbf{R}} V_{\mathbf{R}}^{NL} \quad (4)$$

$$H_{\text{GIPAW}}^{(1,0)} = \frac{g'}{8} \alpha^2 \left[\sigma \cdot (\nabla V_{\text{loc}}(\mathbf{r}) \times \mathbf{p}) + \sum_{\mathbf{R}} F_{\mathbf{R}}^{NL} \right] \quad (5)$$

where $V_{\text{loc}}(\mathbf{r})$ is the local Kohn-Sham potential and $V_{\mathbf{R}}^{NL}$ is the nonlocal pseudopotential in the separable Kleinmann-Bylander (KB) form:

$$V_{\mathbf{R}}^{NL} = \sum_{nm} |\beta_{\mathbf{R}, n}\rangle v_{\mathbf{R}, nm} \langle \beta_{\mathbf{R}, m} | \quad (6)$$

while $F_{\mathbf{R}}^{NL}$ is the separable nonlocal operator accounting the so-called paramagnetic contribution of the atomic site \mathbf{R} , that given the set of GIPAW projectors $|\tilde{\rho}_{\mathbf{R}, n}\rangle$ can be written as:

$$F_{\mathbf{R}}^{NL} = \sum_{\mathbf{R}, nm} |\tilde{\rho}_{\mathbf{R}, n}\rangle \sigma \cdot f_{\mathbf{R}, nm} \langle \tilde{\rho}_{\mathbf{R}, m} | \quad (7)$$

The expression $f_{\mathbf{R},nm}$ refer to the paramagnetic GIPAW integral and is given by Eq. 10 of Ref. [14]. At the first order in the magnetic field, the GIPAW transformation yields the two terms:

$$H_{\text{GIPAW}}^{(0,1)} = \frac{\alpha}{2} \mathbf{B} \cdot \left(\mathbf{L} + \sum_{\mathbf{R}} \mathbf{R} \times \frac{1}{i} [\mathbf{r}, V_{\mathbf{R}}^{NL}] \right) \quad (8)$$

$$H_{\text{GIPAW}}^{(1,1)} = \frac{g'}{16} \alpha^3 \mathbf{B} \cdot \left(\mathbf{r} \times (\boldsymbol{\sigma} \times \nabla V_{loc}) + \sum_{\mathbf{R}} E_{\mathbf{R}}^{NL} + \sum_{\mathbf{R}} \mathbf{R} \times \frac{1}{i} [\mathbf{r}, F_{\mathbf{R}}^{NL}] \right) \quad (9)$$

where $E_{\mathbf{R}}^{NL}$ similar to $F_{\mathbf{R}}^{NL}$, is the separable nonlocal operator accounting for the diamagnetic contribution which uses the GIPAW integral $e_{\mathbf{R},nm}$ given by Eq. 11 of Ref.[14]:

$$E_{\mathbf{R}}^{NL} = \sum_{\mathbf{R},nm} |\tilde{\rho}_{\mathbf{R},n}\rangle \cdot e_{\mathbf{R},nm} \langle \tilde{\rho}_{\mathbf{R},m}| \quad (10)$$

Inserting the Hamiltonian first order terms, $H_{\text{GIPAW}}^{(0,1)} + H_{\text{GIPAW}}^{(1,1)}$, into Eq. (2) we obtain the final expression of orbital magnetization in the presence of nonlocal pseudopotential:

$$\mathbf{M} = \mathbf{M}_{bare} + \Delta \mathbf{M}_{NL} + \Delta \mathbf{M}_{para} + \Delta \mathbf{M}_{dia} \quad (11)$$

$$\mathbf{M}_{bare} = \frac{\alpha}{2} \sum_{\mathbf{R}} \langle \mathbf{r} \times \frac{1}{i} [\mathbf{r}, H_{\text{GIPAW}}^{(0,0)} + H_{\text{GIPAW}}^{(1,0)}] \rangle \quad (12)$$

$$\Delta \mathbf{M}_{NL} = \frac{\alpha}{2} \sum_{\mathbf{R}} \langle (\mathbf{R} - \mathbf{r}) \times \frac{1}{i} [\mathbf{r} - \mathbf{R}, V_{\mathbf{R}}^{NL}] \rangle \quad (13)$$

$$\Delta \mathbf{M}_{para} = \frac{g' \alpha^3}{16} \sum_{\mathbf{R}} \langle (\mathbf{R} - \mathbf{r}) \times \frac{1}{i} [\mathbf{r} - \mathbf{R}, F_{\mathbf{R}}^{NL}] \rangle \quad (14)$$

$$\Delta \mathbf{M}_{dia} = \frac{g' \alpha^3}{16} \sum_{\mathbf{R}} \langle E_{\mathbf{R}}^{NL} \rangle \quad (15)$$

where $\langle \dots \rangle$ stands for $\sum_{n,\mathbf{k}} f_{n,\mathbf{k}} \langle \psi_n | \dots | \psi_n \rangle$. The \mathbf{M}_{bare} can be easily computed by the modern theory of orbital magnetization of Eq. (3) where $H_{\mathbf{k}}$ is the is the GIPAW Hamiltonian, and $\epsilon_{n,\mathbf{k}}$ and $u_{n,\mathbf{k}}$ are its eigenvalues and eigenvectors. The $\Delta \mathbf{M}_{NL}$, $\Delta \mathbf{M}_{para}$ and $\Delta \mathbf{M}_{dia}$ are respectively the nonlocal, paramagnetic and diamagnetic correction and their expression in the framework of Bloch functions can be found in Appendix B of Ref. [15]. In the converse approach, for the sake of simplicity, the orbital magnetization is computed using

a collinear approach where the total spin is aligned along an "easy axis" denoted as \mathbf{e} , which is typically one of three magnetic directions. The choice of \mathbf{e} affects the spin-orbit coupling within the system. Since the spin-orbit coupling is dependent on the orientation of the spin axis \mathbf{e} , the computed orbital magnetization is a function of \mathbf{e} . Therefore, to obtain a comprehensive understanding of the orbital magnetization within the system, it is necessary to compute the orbital magnetization as a function of the three different orientations of \mathbf{e} . Finally, from the orbital magnetization the deviation of the g -tensor $\Delta g_{\mu\nu}$ from the free electron values ($g_e = 2.002319$) is obtained by the variation in \mathbf{M} with a spin flip:

$$\Delta g_{\mu\nu} = -\frac{2}{\alpha} \mathbf{e}_{\mu} \cdot \frac{\mathbf{M}(\mathbf{e}_{\nu}) - \mathbf{M}(-\mathbf{e}_{\nu})}{S - (-S)} = -\frac{2}{\alpha S} \mathbf{e}_{\mu} \cdot \mathbf{M}(\mathbf{e}_{\nu}) \quad (16)$$

where $\mu\nu$ are Cartesian directions of the magnetic field, and S is the total spin.

Converse NMR

The formulation of the converse method for the calculation of NMR chemical shielding is very similar to the formulation used for EPR calculations, with the main difference being the inclusion of an additional vector potential term. This term corresponds to a magnetic dipole \mathbf{m}_s centered at the atom \mathbf{s} and coordinates \mathbf{r}_s :

$$A_s(\mathbf{r}) = \frac{\mathbf{m}_s \times (\mathbf{r} - \mathbf{r}_s)}{|\mathbf{r} - \mathbf{r}_s|^3} \quad (17)$$

The inclusion of this vector potential modifies the AE Hamiltonian to:

$$H_{\text{AE}} = \frac{1}{2} \left\{ \mathbf{p} + \alpha [A(\mathbf{r}) + A_s(\mathbf{r})] \right\}^2 + V(\mathbf{r}) \quad (18)$$

When applying the GIPAW transformation—similar to the method used for EPR calculations—and considering the zeroth order in the external magnetic field, $H_{\text{GIPAW}}^{(0,0)}$ matches Equation (4). At the first order, the term $H_{\text{GIPAW}}^{(1,0)}$ is expressed as follows:

$$H_{\text{GIPAW}}^{(1,0)} = \frac{\alpha}{2} \left[\mathbf{p} \cdot A_s(\mathbf{r}) + A_s(\mathbf{r}) \cdot \mathbf{p} \right] + \sum_{\mathbf{R}} K_{\mathbf{R}}^{NL} \quad (19)$$

where $K_{\mathbf{R}}^{NL}$ addressing the paramagnetic contribution of the magnetic dipole and takes the form of a nonlocal operator:

$$K_{\mathbf{R}}^{NL} = \frac{\alpha}{2} \sum_{\mathbf{R},nm} |\tilde{\rho}_{\mathbf{R},n}\rangle \mathbf{k}_{\mathbf{R},nm} \langle \tilde{\rho}_{\mathbf{R},m}| \quad (20)$$

where $k_{\mathbf{R},nm}$ refers to the GIPAW paramagnetic integrals that take into account the effect of the additional vector potential. These integrals, obtained from a set of AE partial waves $|\phi_{\mathbf{R},n}\rangle$ and pseudopotential partial waves $|\tilde{\phi}_{\mathbf{R},n}\rangle$, can be expressed as:

$$k_{\mathbf{R},nm} = \langle \phi_{\mathbf{R},n} | \mathbf{p} \cdot A_s(\mathbf{r}) + A_s(\mathbf{r}) \cdot \mathbf{p} | \phi_{\mathbf{R},n} \rangle - \langle \tilde{\phi}_{\mathbf{R},n} | \mathbf{p} \cdot A_s(\mathbf{r}) + A_s(\mathbf{r}) \cdot \mathbf{p} | \tilde{\phi}_{\mathbf{R},n} \rangle \quad (21)$$

At first order in the external magnetic field, we obtain a term $H_{\text{GIPAW}}^{(0,1)}$ that is equal to Eq. (8), while the term $H_{\text{GIPAW}}^{(1,1)}$ becomes:

$$H_{\text{GIPAW}}^{(1,1)} = \frac{\alpha}{2} \mathbf{B} \cdot \left(\mathbf{r} \times A_s(\mathbf{r}) + \sum_{\mathbf{R}} J_{\mathbf{R}}^{\text{NL}} + \sum_{\mathbf{R}} \mathbf{R} \times \frac{1}{i} [\mathbf{r}, K_{\mathbf{R}}^{\text{NL}}] \right) \quad (22)$$

where $J_{\mathbf{R}}^{\text{NL}}$ is the nonlocal operator:

$$J_{\mathbf{R}}^{\text{NL}} = \sum_{\mathbf{R},nm} |\tilde{\rho}_{\mathbf{R},n}\rangle \mathbf{j}_{\mathbf{R},nm} \langle \tilde{\rho}_{\mathbf{R},m}| \quad (23)$$

and the $\mathbf{j}_{\mathbf{R},nm}$ its GIPAW integrals addressing the diamagnetic contribution:

$$\mathbf{j}_{\mathbf{R},nm} = \langle \phi_{\mathbf{R},n} | (\mathbf{r} - \mathbf{R}) \times A_s(\mathbf{r}) | \phi_{\mathbf{R},n} \rangle - \langle \tilde{\phi}_{\mathbf{R},n} | (\mathbf{r} - \mathbf{R}) \times A_s(\mathbf{r}) | \tilde{\phi}_{\mathbf{R},n} \rangle \quad (24)$$

As in the case of EPR, solving the Hellmann-Feynman equation using the first-order in magnetic field Hamiltonian terms, yields the orbital magnetization as the sum of \mathbf{M}_{bare} , $\Delta \mathbf{M}_{\text{NL}}$, $\Delta \mathbf{M}_{\text{para}}$ and $\Delta \mathbf{M}_{\text{dia}}$ terms like the Eq. (11). However, in the calculation of NMR, the $\Delta \mathbf{M}_{\text{para}}$ and $\Delta \mathbf{M}_{\text{dia}}$ terms are defined by replacing the nonlocal operators $E_{\mathbf{R}}^{\text{NL}}$ and $F_{\mathbf{R}}^{\text{NL}}$, respectively, with $K_{\mathbf{R}}^{\text{NL}}$ and $J_{\mathbf{R}}^{\text{NL}}$:

$$\Delta \mathbf{M}_{\text{para}} = \frac{\alpha}{2} \sum_{\mathbf{R}} \langle (\mathbf{R} - \mathbf{r}) \times \frac{1}{i} [\mathbf{r} - \mathbf{R}, K_{\mathbf{R}}^{\text{NL}}] \rangle \quad (25)$$

$$\Delta \mathbf{M}_{\text{dia}} = \frac{\alpha}{2} \sum_{\mathbf{R}} \langle J_{\mathbf{R}}^{\text{NL}} \rangle \quad (26)$$

Finally, the chemical shielding tensor $\sigma_{s,\alpha\beta}$ is obtained from the derivative of the orbital magnetization \mathbf{M} with respect to a magnetic point dipole \mathbf{m}_s , located at the site of atom s :

$$\sigma_{s,\alpha\beta} = \delta_{\alpha\beta} - \Omega \frac{\partial \mathbf{M}_{\beta}}{\partial \mathbf{m}_s} \quad (27)$$

where $\delta_{\alpha\beta}$ is the Kronecker delta and Ω is the volume of the simulation cell.

IMPLEMENTATION

The initial stage of the QE-CONVERSE code involves the application of specialized norm-conserving pseudopotentials with GIPAW reconstruction. These pseudopotentials, apart from the standard norm-conserving pseudopotentials, integrate a complete set of AE core wavefunctions as well as AE ($\phi_{\mathbf{R},n}$) and PS ($\tilde{\phi}_{\mathbf{R},n}$) partial waves. During this initial phase, the code uses these pseudopotentials to calculate the necessary GIPAW integrals—namely, ($f_{\mathbf{R},nm}$, $e_{\mathbf{R},nm}$, $k_{\mathbf{R},nm}$ and $j_{\mathbf{R},nm}$) and to determine the GIPAW projectors ($\tilde{\rho}_{\mathbf{R},n}$). Details on constructing these pseudopotentials are provided in Ref.[15], and a non-exhaustive library of GIPAW pseudopotentials is available in Ref.[16]. (Figure 1 illustrates the overall workflow of the QE-CONVERSE code.)

The first step in the process involves solving the Kohn-Sham equation self-consistently, where the Hamiltonian is the sum of GIPAW Hamiltonian terms at zero order magnetic field ($H_{\text{GIPAW}}^{(0,0)} + H_{\text{GIPAW}}^{(1,0)}$). In the QE-CONVERSE code, these terms are constructed by the `h_psi_gipaw` routine, which, similar to `h_psi` of the PWscf code, computes the product of the kinetic energy, the local part of the potential, and its non-local part in KB form of the Hamiltonian matrix with wavefunctions. The input flag, `lambda_so` $\neq 0$ (see Appendix B), activates the EPR g -tensor calculations, adding the SO term and its paramagnetic contribution $F_{\mathbf{R}}^{\text{NL}}$ to the Hamiltonian. While in the NMR chemical shift calculation, if `m_0` $\neq 0$, the vector potential and its paramagnetic term $K_{\mathbf{R}}^{\text{NL}}$ are added. A schematic representation of `h_psi_gipaw` routine is presented in Figure 2. Once a new ground state is reached, the next step is the calculation of the \mathbf{k} derivative of the Bloch wave functions implementing the covariant finite difference formula. This formula calculates the finite difference between gauge-invariant "dual" states in the mesh direction i according to:

$$|\tilde{\partial}_i u_{n\mathbf{k}}\rangle = \frac{1}{2} (|\tilde{u}_{n,\mathbf{k}+\mathbf{q}}\rangle - |\tilde{u}_{n,\mathbf{k}-\mathbf{q}}\rangle) \quad (28)$$

Here, $|\tilde{u}_{n,\mathbf{k}+\mathbf{q}}\rangle$ is constructed as a linear combination of the occupied state $|u_{n,\mathbf{k}+\mathbf{q}}\rangle$ at neighboring mesh point \mathbf{q} :

$$|\tilde{u}_{n,\mathbf{k}+\mathbf{q}}\rangle = \sum_{n'} (S_{\mathbf{k}+\mathbf{q}}^{-1})_{n'n} |u_{n',\mathbf{k}+\mathbf{q}}\rangle \quad (29)$$

where $(S_{\mathbf{k}+\mathbf{q}})_{nn'}$ is the overlap matrix defined as:

$$(S_{\mathbf{k}+\mathbf{q}})_{nn'} = \langle u_{n,\mathbf{k}} | u_{n',\mathbf{k}+\mathbf{q}} \rangle \quad (30)$$

The QE-CONVERSE code runs the covariant finite procedure as follow:

1. Loop over \mathbf{k} -points.
 1. Read $|u_{n,\mathbf{k}}\rangle$ from the disk, all bands.

2. Loop over \mathbf{q} -points: $\pm q\hat{x}$, $\pm q\hat{y}$, $\pm q\hat{z}$.
 1. Loop over bands
 1. Diagonalize the KS Hamiltonian at $\mathbf{k}+\mathbf{q}$
 2. Compute the overlap matrix: $(S_{\mathbf{k}+\mathbf{q}})_{nn'}$
 3. Invert the matrix: $(S_{\mathbf{k}+\mathbf{q}}^{-1})_{n'n}$
 4. Compute the dual state: $|\tilde{u}_{n,\mathbf{k}+\mathbf{q}}\rangle$
 5. Compute the finite difference: $\frac{1}{2}(|\tilde{u}_{n,\mathbf{k}+\mathbf{q}}\rangle - |\tilde{u}_{n,\mathbf{k}-\mathbf{q}}\rangle)$
2. Save the derivative on disk.

The diagonalization of the Hamiltonian, undertaken by both the routines dedicated to SCF calculations and those executing the \mathbf{k} derivative of the Bloch functions, employs the Davidson method, addressed by the `cegterg` routine of Quantum ESPRESSO (Fig.1).

In the outline of the code, the third step is the orbital magnetization calculation implementing the Eq. (3). \mathbf{M}_{bare} is computed using a nested loop over \mathbf{k} -points, magnetic directions, and electronic bands. This step involves calculating the expectation value of the Hamiltonian operator within the $|\partial_i u_{n\mathbf{k}}\rangle$ state (Fig.3). In order to speed up the calculation of this part and improve the scalability when running the calculation at high parallel cores, in the `QE-CONVERSE` code, with respect to the former version of converse code, we add a new level of parallelization which is based on band group bands and electronic bands MPI communicator, by slitting the `ibnd` index across processors (Fig.3). The nonlocal, paramagnetic, and diamagnetic correction terms are then computed starting from the converged ground state and using the nonlocal operators $E_{\mathbf{R}}^{NL}$, $F_{\mathbf{R}}^{NL}$, and $K_{\mathbf{R}}^{NL}$, $J_{\mathbf{R}}^{NL}$ respectively for the EPR g -tensor and for the NMR chemical shielding. All the magnetization terms are summed as specified by Eq. (11) to yield the total orbital magnetization. At the end, once \mathbf{M} is obtained, the deviation $\Delta g_{\mu\nu}$ is calculated according to Eq. (16). Alternatively, in the case of NMR, it is derived with respect to the magnetic dipole according to Eq. (27).

Appendix A (Table V) shows the comparisons between PbF radicals g -tensors in Ref. [7] and the present converse implementation.

INSTALLATION AND USAGE

The repository of our code is released at GitHub (<https://github.com/mammasmias/QE-CONVERSE.git>). A Fortran 90 compiler and the Quantum ESPRESSO package must be previously installed. To take advantage of the enhancements in linear algebra operations, the `scaLAPACK` package or the `ELPA` library are required. To install the code, the program files must

be copied or cloned from the repository. Then, the code must be configured with the desired version of QE by typing `./configure --with-qe-source="QE folder containing make.inc"` replacing "QE folder containing make.inc" with the path to the main directory of QE. Finally, by typing `$` make the executable binary `qe-converse.x` is compiled in `/bin/` directory. To execute a converse calculation with the `QE-CONVERSE`, the first step is to perform a SCF calculation using the `PWscf` code of Quantum ESPRESSO on a physically meaningful (e.g. a geometrically optimized) structure. For an EPR g -tensor calculation, the SCF calculation must be spin-polarized; this is can be archived by including the flag `nspin=2` in the input for `PWscf` code. The \mathbf{k} -points grid mesh should be set up without applying symmetry operations to the crystal, and given that the Kohn-Sham Hamiltonian breaks time-reversal symmetry, it is necessary to assume that the k points and $-k$ points are not equivalent. This grid construction can be easily implemented including the flags `nosym=.true.` and `noinv=.true.` in the input for the SCF calculation. In the same directory where the calculation with the `PW` program is executed, the `QE-CONVERSE` code is launched with `./qe-converse.x` using an input file (an example for EPR and NMR calculation is provided in Appendix B). It is essential that the `prefix` and `outdir` flags match those used in the SCF calculation with the `PWscf` program. This is because the `QE-CONVERSE` code reads essential data such as atomic coordinates, ground state function, pseudopotentials, and the \mathbf{k} -points grid from the XML file in the `outdir` directory of a preceding spin-polarized SCF calculation. The flag `q` in the input file refers to the small vector used into covariant derivative finite difference formula. Since its value influences the accuracy of the derivative, it is suggested to keep its default value of 0.01. To compute the EPR g -tensor, the flag `lambda_so(1, . . . , 3)` must be included in the input file to incorporate the SO term into the Hamiltonian. The integer value within the parentheses indicates the direction in which the orbital magnetization is calculated. When calculating the NMR chemical shift instead, it is necessary to introduce into input file the nuclear dipole moment flag, `m_0(1, . . . , 3)` and the index of the atom carrying the dipole moment using the designated flag `m_0_atom`. Appendix B describes briefly the most relevant textual inputs and outputs.

EPR g -TENSOR BENCHMARKS

The input and textual output files can be found in the `/examples/` directory of the official code repository.

$n\Sigma(n \geq 2)$ molecules

In this first example, we illustrate the EPR g -tensor of $^2\Sigma$ and high-spin $^3\Sigma$ (O_2 and SO) radicals. We performed the calculations in a cubic cell with a large volume of 8000 \AA^3 and the Brillouin zone sampled at Γ point with an energy cutoff of 100 Ry where the Kohn-Sham equation is solved using the PBE functional. The following Table I compares the Δg components in ppm from the QE-CONVERSE code with available experimental data and other computational approaches, such as Gauge-Independent Atomic Orbital-Density Functional Theory (DFT-GIAO) [17, 18] and coupled-cluster singles and doubles level of theory (CCSD) [19]. Table I demonstrates that the results from QE-CONVERSE are well aligned with the other computational models and are in good agreement with experimental observations. It is important to note that for some of the radicals, a direct comparison with experimental g -value is not fully suitable due the use of the noble-gas matrix isolation technique, which can affect the value of EPR parameters [20].

Substitutional Nitrogen in Silicon

The following section presents the EPR g -tensor calculation for the substitutional Nitrogen defect in Silicon (N_{Si}). This defect has recently garnered significant theoretical and experimental attention due to its potential role as a spin donor in silicon-based quantum devices [26, 27]. It is characterized by the presence of two minima, so that the Nitrogen atom transitions from the tetra-coordinated on-center (T_d) configuration site to a tri-coordinated off-center configuration (with C_{3v} symmetry) along one of the $\langle 111 \rangle$ crystal directions, through a pseudo Jahn-Teller mechanism [28]. In this example, we focus solely on the off-center configuration (4), corresponding to the SL5 experimental EPR signals. Regarding the g -tensor in SL5, g_1 corresponds to the component aligned with the principal axis parallel to the $\langle 111 \rangle$ crystal direction (or g_{\parallel}), while g_2 and g_3 represent the isotropic perpendicular components to the $\langle 111 \rangle$ crystal direction (or g_{\perp}). All ab-initio calculations were performed using the PBE exchange-correlation functional, together with norm-conserving Trouiller-Martins pseudopotentials with GIPAW reconstruction and employing a plane wave basis set with a kinetic energy cutoff of 84 Ry. To model the (N_{Si}) off-center point defect we used a 512 atoms supercell in which a substitutional Nitrogen atom is embedded within a silicon cell. Geometry optimization was conducted by sampling at the Γ point and setting the ionic convergence threshold to 0.026 eV/\AA [28]. In the subsequent SCF and EPR g -tensor calculation, we ensured convergence of the parameters by sampling \mathbf{k} -points on a $3 \times 3 \times 3$ mesh grid without consider-

ing symmetry, resulting in the integration of the Brillouin zone over a total of 54 \mathbf{k} -points. The SCF convergence threshold was set to $1 \cdot 10^{-8}$ Ry.

The Table II presents the values of the g -tensor calculated using the QE-CONVERSE code, compared with experimental results [26] and the g -tensor calculated by Simha et al. [27] where the linear response method was implemented [14]. Our results demonstrate good agree-

ment with the experimental data. Moreover, our calculations yield a g -tensor that is fully consistent with the axial symmetry along the $\langle 111 \rangle$ crystal directions, as shown by experiments, thus improving upon the results previously computed by the linear response method of Ref. [27].

NMR CHEMICAL SHIFTS BENCHMARKS

^{17}O and ^{29}Si NMR chemical shifts in α -quartz

In the first example, we predicted the ^{17}O and ^{29}Si NMR chemical shifts in α -quartz using the converse method through the QE-CONVERSE code. We first computed the isotropic shielding tensor, σ_{iso} , for both isotopes and then extrapolated their chemical shifts using the relationship $\delta_{iso} = \sigma_{ref} - \sigma_{iso}$, where we used reference values, σ_{ref} , of 324.51 ppm and 253.34 ppm for the ^{29}Si and ^{17}O nuclei, respectively [15]. We performed the DFT calculations with the PBE functional, using a 70 Ry kinetic energy cut-off and integrating the Brillouin zone on a $2 \times 2 \times 2$ mesh grid. We present the results of our calculations in the following Table III, where the results are compared with experimental observations. Notably, the calculations demonstrate convergence and alignment with experimental findings.

^{27}Al NMR chemical shifts in alumina

Corundum (α - Al_2O_3) represents the most thermodynamically stable crystalline form of alumina and it can be synthesized through the calcination process starting from unactivated gibbsite ($\text{Al}(\text{OH})_3$), which transforms into corundum via γ and θ - Al_2O_3 transitions at temperatures exceeding 400°C. Determining the structure and the temperature at which transitions phase occur is crucial and it has applications in various industrial fields. For example, γ - Al_2O_3 is used as a catalyst in the petrochemical industry. The most useful technique for this purpose is solid-state NMR of ^{27}Al of which the detailed interpretation of the experimental spectra can be enhanced by first-principle calculations. In this study, we apply the QE-CONVERSE code to perform ab-initio calculations of

the NMR chemical shift of ^{27}Al in θ phase of alumina (Figure 5). In this phase, the experimental spectra of ^{27}Al exhibit two distinct signals: one corresponding to the aluminum atoms octahedrally coordinated (Al_{oct}), and the other to those tetrahedrally coordinated (Al_{tet}) by oxygen atoms [30]. Implementing the Eq. (27) we computed the absolute chemical shift tensors of ^{27}Al nuclei that we converted into isotropic chemical shieldings using $\sigma_{iso} = \text{Tr}[\sigma_s/3]$. Finally, we compared this last one with experimental isotropic chemical shifts by using the expression: $\delta_{iso} = \sigma_{ref} - \sigma_{iso}$, where σ_{ref} in this work is the isotropic shielding of ^{27}Al in α phase, used as reference.

We performed DFT calculations with the PBE generalized gradient approximation and using the norm-conserving Trouiller-Martins pseudopotentials with GIPAW reconstruction. We used a cutoff energy of 70 Ry. We first relaxed a 200 atoms θ - Al_2O_3 supercell sampling at the Γ point and setting the ionic convergence threshold to 0.026 eV/Å. We then computed the SCF and NMR calculation setting the \mathbf{k} -points on a $2 \times 2 \times 2$ mesh grid without symmetric constraint. We converged the ground-state to $1 \cdot 10^{-9}$ Ry. In Table IV below, we present the chemical shifts of ^{27}Al obtained in this work, compared to experimental [30] and theoretical data from Ref. [31], where a linear response method was implemented. Our results show very close agreement with both the experimental and previous theoretical results

CONCLUSIONS

In this paper, we present the QE-CONVERSE code, which implements the converse method—a non-perturbative approach to calculating orbital magnetization and related properties, such as the EPR g -tensor and the NMR chemical shift, from first principles. QE-CONVERSE is a standalone package compatible with Quantum ESPRESSO (version 7.2 and onward), replacing the previously implemented, now outdated, PWscf code from QE 3.2. Compared to the former code, QE-CONVERSE integrates modern linear algebra libraries, such as scaLAPACK and ELPA, which enhance the com-

putational performance of NMR and EPR parameter calculations, especially for large supercell. However, the primary focus of QE-CONVERSE is on improving the accuracy of the calculations, especially for EPR and NMR parameters, where it may provide (depending on the system) more reliable results compared to perturbative methods such as the linear response approach. This enhanced accuracy opens new possibilities for studying complex materials with greater precision and for obtaining more accurate insights into their magnetic properties.

ACKNOWLEDGMENTS

This work has received funding from the NextGenerationEU European initiative through the Italian Ministry of University and Research, PNRR Mission 4, Component 2 - ICSC Italian National Center for High Performance Computing, big data and quantum computing - spoke 7, project code HPC (Centro Nazionale 01 CN0000013) CUP B93C22000620006; and by the project SQQS (ab initio control of defects for quantum bits: screening, quantifying, qualifying and selecting) Defi Cle Region Institut Quantique Occitanie (FRANCE). All the calculations were performed using the HPC resources of CALMIP Mesocenter (Toulouse) with grant P1555. APPENDIX A : REF. [7] VS CURRENT IMPLEMENTATION

We benchmarked QE-CONVERSE by comparing the Δg for selected diatomic radicals belonging to the PbF family with those obtained from the converse code integrated in PWscf code of version 3.2. All the results are collected in Table V. The calculations were performed in a cubic repeated cell with a large volume of 8000 \AA^3 and the Brillouin zone sampled at Γ point with an energy cutoff of 100 Ry. The Perdew-Burke-Ernzerhof (PBE)

exchange-correlation functional was [32] employed. The PbF family radicals have only one electron within the p shell and due to the absence of SO coupling, they exhibit a nearly vanishing g -tensor along the bond direction ($\Delta g_{\parallel} \approx -2 \times 10^6$ ppm), as predicted by the converse method [7]. Table V shows that the results here calculated with the QE-CONVERSE code and those previously obtained with the converse method implemented in PWscf 3.2 [7] well match.

TABLE V. The Δg in ppm for the PbF family radicals calculated in this work using the QE-CONVERSE code compared to the values of PWscf 3.2.

APPENDIX B: BRIEF INPUT AND OUTPUT DESCRIPTION

The input consists on a single fortran namelist `&input_qlconverse` which the keywords are summarised in Table VI.

Example of input for EPR g -tensor calculation. `$DIR` is an integer from 1 to 3 that denotes the spin-orbit coupling direction.

```
&input_qlconverse
  prefix = 'example_EPR'
  outdir = './scratch/'
  diagonalization = 'david'
  verbosity = 'high'
  q_gipaw = 0.01
  dudk_method = 'covariant'
  diago_thr_init = 1d-4
  conv_threshold = 1e-8
  mixing_beta = 0.5
  lambda_so($DIR) = 1.0
/
```

Example of input for NMR calculation. `$DIR` is an integer from 1 to 3 that refers to nuclear dipole moment

direction while $\$i$ indicates the atoms that brings the dipole.

```
&input_qeconverse
  prefix = 'example_NMR'
  outdir = './scratch/'
  diagonalization = 'david'
  verbosity = 'high'
  q_gipaw = 0.01
  dudk_method = 'covariant'
  diago_thr_init = 1d-4
  conv_threshold = 1e-8
  mixing_beta = 0.5
  m_0({DIR}) = 1.0
  m_0_atom = ${i}
```

/

The textual output contains the key data are summarised in Table VII.
