# Ideas in Inference-time Scaling can Benefit Generative Pre-training Algorithms

Jiaming Song, Linqi Zhou

Luma AI

#### Abstract

Recent years have seen significant advancements in foundation models through generative pre-training, yet algorithmic innovation in this space has largely stagnated around autoregressive models for discrete signals and diffusion models for continuous signals. This stagnation creates a bottleneck that prevents us from fully unlocking the potential of rich multi-modal data, which in turn limits the progress on multimodal intelligence. We argue that an inference-first perspective, which prioritizes scaling efficiency during inference time across sequence length and refinement steps, can inspire novel generative pre-training algorithms. Using Inductive Moment Matching (IMM) as a concrete example, we demonstrate how addressing limitations in diffusion models' inference process through targeted modifications yields a stable, single-stage algorithm that achieves superior sample quality with over an order of magnitude greater inference efficiency.

## 1 Introduction

Despite the significant advances in applications from generative pre-training of foundation models, algorithmic developments in this area have stagnated. The generative pre-training field is currently dominated by two paradigms, both popularized around 2020 — autore-gressive models for discrete signals [BMR<sup>+</sup>20] and diffusion models [HJA20] for continuous signals. This stagnation has created a bottleneck over generative pre-training and led to more explorations in inference-time scaling [SLXK24, BJE<sup>+</sup>24, MTJ<sup>+</sup>25].

In this position paper, we argue that ideas in inference-time scaling can benefit generative pre-training algorithms. We consider two axes of inference-time scaling, sequence length and refinement steps, which apply to autoregressive models and diffusion models respectively. Based on this unified perspective, we believe that in order to develop novel and practical generative pre-training algorithms, one should (1) develop algorithms that scale *efficiently* in the two axes during inference, and (2) design the inference algorithm before the training algorithm to optimally utilize the model capacity at inference time.

We show that Inductive Moment Matching (IMM, [ZES25]) is a concrete example supporting these beliefs in the continuous space. In particular, we examine the one-step iterative process of DDIM [SME20, LCBH<sup>+</sup>22, LGL22] and show that it has limited capacity with respect to the target timestep under the current denoising network design. This can be addressed by adding the target timestep to the inputs of the denoising network [KLL<sup>+</sup>23].

Interestingly, this one fix, plus a proper moment matching objective [GBR<sup>+</sup>12] leads to a stable, single-stage algorithm that surpasses diffusion models in sample quality while being over an order of magnitude more efficient at inference [ZES25]. Notably, these ideas do not rely on denoising score matching [Vin11] or the score-based stochastic differential equations [SSDK<sup>+</sup>20] on which the foundations of diffusion models are built. We hope that these ideas can bring us out of the existing paradigms, inspire further research on effective pre-training algorithms on high-dimensional mixed-modality data, and ultimately breaking the current barriers around pre-training.

## 2 Two axes of inference-time scaling

- **Sequence length** defines the number of tokens. This is seen in standard autoregressive large language models (LLMs), which have recently demonstrated strong chain-of-thought and reasoning capabilities from inference-time scaling.
- **Refinement steps** defines the number of iterative steps that improve existing tokens without changing the sequence length. This is seen in standard score-based diffusion models, where more steps indicate fewer discretization errors in the numerical solver. We note that the refinement process is not restricted to denoising alone; it is considered valid as long as the sequence length does not increase.

Under this definition, autoregressive models scale over sequence length and diffusion models scale over refinement steps. We list a few notable examples that cover most of the techniques surrounding discrete and continuous signals.

Methods that are not scalable in either sequence length or refinement steps:

• VAE [KW13], GAN [GPAM+14], Normalizing Flows [RM15].

Methods that are scalable in sequence length but not refinement steps:

• GPT [BMR<sup>+</sup>20], PixelCNN [vdOKK16], MaskGiT [CZJ<sup>+</sup>22], VAR [TJY<sup>+</sup>25].

Methods that are scalable in refinement steps but not in sequence length:

- Diffusion models [HJA20], Energy-based models [DM19], Consistency models [SDCS23].
- Parallel non-linear equation solving for autoregressive models [SMLE21]; note that this uses an iterative approach to sample from all the tokens in parallel, despite being trained with autoregressive objectives.

Methods that are scalable in both, with sequence length in the outer loop:

- AR-Diffusion [WFL<sup>+</sup>23], Rolling diffusion [RHSH24], MAR [LTL<sup>+</sup>25].
- Blockwise parallel decoding [SSU18], which applies "predict, verify, accept" as part of the refinement process.

Methods that are scalable in both, with refinement steps in the outer loop:

• Autoregressive distribution smoothing [MSS<sup>+</sup>21], which performs an iterative denoising process with an autoregressive model as the inner loop.

## **3** Designing algorithms that can scale efficiently

The paper takes the following positions.

- 1. Pre-training algorithms for generative AI should have inference-time scalability in sequence length and refinement steps.
- 2. These algorithms should also scale efficiently, *e.g.*, with as few number of model steps as possible.
- 3. Before developing the training method, it should be verified whether the model has enough capacity to represent the target distribution during inference.

For our first position, we note that in the visual generative domain, even very recently, various efforts have been made to "revive" traditional ideas such as GANs [KZZ<sup>+</sup>23, ZYZ<sup>+</sup>23, HGKT25] and Normalizing Flows [KPT24, ZZN<sup>+</sup>24], despite the overwhelming popularity of diffusion models in visual generation. We do not dismiss or promote the training designs (such as the advesarial training procedure, the transformer-based normalizing flow, or the denoising autoencoder objective), but rather attributes the popularity of diffusion models to its ability to leverage inference-time scaling. In the case of LLMs, scaling over sequence length may already be self-evident for practitioners in the field, but methods scaling over refinement steps [LME23, SHW<sup>+</sup>24, SAS<sup>+</sup>25, GRS<sup>+</sup>24] have not received widespread adoption. This is not to say that scaling over refinement steps is a wrong path to take, but rather, as discussed in the third position, there lacks attention to proper inference algorithms that optimally utilize model capacity. If these limitations are resolved, scaling over refinement steps can potentially provide additional performance boost over the current autoregressive paradigms on text.

The second position considers the practical scenario where fewer inference steps in either dimension are desired. Motivated by this, many works have explored diffusion distillation in the continous domain to reduce the number of refinement steps [SH22], as well as diffusion langauge models [LME23, SHW<sup>+</sup>24, ONX<sup>+</sup>24, SAS<sup>+</sup>25] in the discrete space that have a chance to reduce the number of steps needed to represent the same sequence length. Advancing in these directions can lower the latency at inference time.

The third position provides a "necessary condition" to analyze whether a particular training approach is sound based on its potential behavior at inference. In particular, we need to make sure that the inference process can represent any distribution that we are considering (whether it is the discrete or continuous space), assuming that the universal approximation theorem [HSW89] holds under the model that we are working with. If the model does not have enough capacity to represent the distribution, then no training algorithm can solve the problem perfectly. Unless we are willing to live with these limitations, we need to rethink

Figure 1: Left shows traditional one-step DDIM sampling under Flow Matching construction. Given  $\mathbf{x}_t$  and t,  $\mathbf{x}_s$  is produced by following the prediced velocity field  $v_{\theta}(\mathbf{x}_t, t)$ . However, the model does not have enough capacity to land on the ODE flow result at s in one step because  $v_{\theta}(\mathbf{x}_t, t)$  is unaware of s and thus cannot approximate any function over s. A practical fix, on the right, simply injects s into our network and now the model has enough capacity to approximate a direct jump towards the correct solution.

the design of the pre-training algorithm.

Together, we believe that this inference-first perspective can reveal potential design flaws of current methods and hope that the new generation of pre-training algorithms can place proper attention on resolving such issues during inference.

In the remainder of the section, we illustrate two examples that cover both continuous and discrete distributions, as well as both axes of inference-time scaling. In the continuous case, we show that the DDIM sampler is flawed for efficient few-step sampling because of missing arguments and propose a practical fix. In the discrete case, we show that current multi-token prediction (MTP) models make a naïve Bayes assumption that forces alternative sampling methods to be used.

#### 3.1 A limitation of DDIM and its improvement

We use the DDIM sampler [SME20] under rectified flow formulation [LGL22, GHH<sup>+</sup>24] as an example<sup>1</sup>. In rectified flows, the sampling procedure in each iteration from the current sample  $x_t$  and source timestep t to the target timestep s is defined as:

$$\mathbf{x}_s := \text{DDIM}(\mathbf{x}_t, t, s) = \mathbf{x}_t + (s - t)v_\theta(\mathbf{x}_t, t), \tag{1}$$

which transforms the sample  $\mathbf{x}_t$  to  $\mathbf{x}_s$  via the velocity network  $v_{\theta}$ . Note that in the typical diffusion model formulation,  $v_{\theta}$  takes in only  $\mathbf{x}_t$  and t as arguments.

It is clear that the denoising autoencoder objective [Vin11] will not recover a desirable onestep (or few-step) sampler from DDIM, but how about other training objective functions, especially ones based on diffusion distillation?

<sup>&</sup>lt;sup>1</sup>A similar argument would work for any other first-order Euler ODE solver for diffusion models as well.

We believe that the answer is no. To see this, let us take the following partial derivative:

$$\frac{\partial \text{DDIM}(\mathbf{x}_t, t, s)}{\partial s} = v_{\theta}(\mathbf{x}_t, t), \tag{2}$$

which does not depend on *s* at all. This means that even though DDIM has enough capacity to represent any function over  $\mathbf{x}_t$  and *t* (via universal function approximation), the same does not apply to *s*. We show an illustration of this problem in Figure 1.

We further note that this criticism applies to the inference process, not how the model is trained. In fact, even if the model is learned via consistency training [SDCS23] and can generate accurate samples in a single step, it will not necessarily generate accurate samples under multi-step DDIM. This partially explains why consistency models have a restart sampling process [XDC<sup>+</sup>23] that injects additional Gaussian noise at each sampling step.

A natural fix to the above problem is simply to add *s* also to the input of the velocity network [KLL<sup>+</sup>23], so that  $v_{\theta}$  takes three arguments:  $\mathbf{x}_t$ , *t*, and *s*. Now the improved DDIM has enough model capacity to represent any functions over *s* and thus can learn the proper one-step jump to a solution. Recently, Zhou *et al.* [ZES25] demonstrated that a single, stable pre-training procedure is possible with Inductive Moment Matching (IMM). IMM offers a promising single-stage alternative to the current two-stage "diffusion then distillation" paradigm in visual foundational models [LTH<sup>+</sup>23, SBD<sup>+</sup>24, YGZ<sup>+</sup>24, ZLL24, ZZG<sup>+</sup>24, LXR<sup>+</sup>25].

The paper argues that given the simplicity of moment matching and its relative low popularity in the community of visual generative modeling [LSZ15], there can be other promising alternatives to IMM. However, it is imperative to keep the network's dependence over s if one wishes to employ a DDIM-style sampler.

#### 3.2 Multi-token prediction

Multi-token prediction (MTP) is of great interest to the language modeling community because of its potential to achieve faster inference [GIR<sup>+</sup>24], which allows efficient inference-time scaling. However, the current multi-token prediction models often predict the softmax values of multiple tokens in parallel, which is a naïve conditional independence assumption (*i.e.*, naïve Bayes). We argue that this inference design greatly limits the capacity of the model distribution and more efforts should be spent resolving this fundamental issue.

Consider the example of trying to predict the next two words/tokens<sup>2</sup> in the sentence: "The list of poker hands that consist of two English words are: ...". As the list can be arbitrarily ordered, the immediate next two words can be any hand, such as "high card", "two pair", "full house", or "straight flush"; there is a correlation between the two words that makes a valid hand. The multi-token prediction LLM first produce the corresponding softmax weights, and then sample the tokens independently, which may lead to unwanted combinations such as "high house".

Current MTP inference algorithms heuristically bypass this model capacity limitation. For example, Gloeckle *et al.* [GIR<sup>+</sup>24] uses self-speculative decoding whereas Deepseek-

<sup>&</sup>lt;sup>2</sup>For simplicity of the argument, let's assume that a token is a word here.

V3 [LFX<sup>+</sup>24] simply discards the multi-token prediction heads and use regular next-token prediction during inference. Therefore, even though the model is misspecified in representing the joint distribution of the multi-token outcomes, many inference algorithms can be cleverly designed to "correct" this inherent capacity problem.

Notably, MTP is also relevant to diffusion-based language models [LME23, SHW<sup>+</sup>24, SAS<sup>+</sup>25, NZY<sup>+</sup>25] for certain model design choices. To address the model capacity issue while realising latency gains, diffusion language models can adopt a procedure where the initial sampling steps produce a few tokens in parallel, making it closer to an any-order autoregressive model [SSE22], and then sampling more tokens in parallel when conditional independence between the remaining masked tokens is more likely to hold [SHW<sup>+</sup>24].

Despite the current corrections to the inference procedure, it is interesting to see if we can train a well-specified multi-token prediction model without the naïve Bayes assumption, so that we can directly sample from the model and yield multiple tokens during inference without rejection sampling. One challenge here is to optimize through the discrete token sampling processes [JGP16, GCW<sup>+</sup>17]. Resolving this issue can truely unlock the scaling potential over refinement steps for LLMs.

## 4 Conclusions

We believe the future of multi-modal pre-training belongs to algorithms that can scale on both inference axes. By reflecting inference-time scaling behavior before training, we can make proper trade-offs between model tractability and scaling efficiency. In the continuous domain, this has lead to simple, stable, and scalable algorithms with state-of-the-art performance that do not rely on key ideas of denoising diffusion models. We hope that these ideas can mend the Autoregressive-Diffusion Schism in the research community and unlock greater potentials in generative pre-training.
