Abstract—Zero-shot learning (ZL) is crucial for tasks involving unseen categories, such as natural language processing, image classification, and cross-lingual transfer. Current applications often fail to accurately infer and handle new relations or entities involving unseen categories, severely limiting their scalability and practicality in open-domain scenarios. ZL learning faces the challenge of effectively transferring semantic information of unseen categories in multi-modal knowledge graph (MMKG) embedding representation learning. In this paper, we propose ZSLLM, a framework for zero-shot embedding learning of MMKGs using large language models (LLMs). We leverage textual modality information of unseen categories as prompts to fully utilize the reasoning capabilities of LLMs, enabling semantic information transfer across different modalities for unseen categories. Through model-based learning, the embedding representation of unseen categories in MMKG is enhanced. Extensive experiments conducted on multiple real-world datasets demonstrate the superiority of our approach compared to stateof-the-art methods.

*Index Terms*—zero-shot learning, large language models, multimodal knowledge graph, semantic information transfer

# I. INTRODUCTION

Multi-modal knowledge graph (MMKG) is a kind of knowledge representation structure that integrates multiple modalities, such as text, images, and audio, to provide a more comprehensive description of entities and their relations. MMKG embedding representation learning maps multi-modal information into a low-dimensional vector space, capturing the semantic features of entities and relations to support reasoning and knowledge expansion tasks. MMKGs have been applied in fields such as intelligent search and recommendation systems [1], question-answering [2], and medical data analysis [3]. However, a large number of unseen categories involving new relations or entities frequently emerge across various domains, severely limiting the development and application of diverse systems in the era of big data. In Figure 1, we provide a set of examples to facilitate the reader's understanding of this issue.

Zero-shot learning (ZL) has been proposed to address this issue, with current methods primarily focusing on establishing a mapping relation from seen classes to unseen classes to enable ZL in multi-modal scenarios. For instance, Zhang et al. [4] developed a zero-shot learning framework that introduced a semantic knowledge graph (KG) to capture correlations between classes. However, in the context of ZL for embedding representations in current MMKGs, the semantic information of unseen categories often fails to be effectively transferred, resulting in significantly insufficient accuracy.

In this paper, we propose ZSLLM, a model for MMKG representation learning in zero-shot learning scenarios, leveraging large language models (LLMs). LLMs possess powerful natural language understanding and generation capabilities, enabling them to capture deep semantic relations through rich context and demonstrate exceptional generalization and reasoning abilities across multiple tasks. We use the known information of unseen classes as prompts, leveraging LLMs to assist in generating similar auxiliary features for unknown information, thereby enhancing semantic information transfer among unseen categories. By leveraging their strong natural language capabilities, LLMs can utilize textual information of unseen categories as prompts to achieve cross-modal semantic alignment. Their outstanding reasoning ability and generalization further enable the effective capture of semantic features for unseen categories, addressing the challenges of zero-shot learning (ZL) in MMKGs.

Our main contributions are as follows:

- To the best of our knowledge, this is the first work to apply LLMs to the zero-shot embedding representation learning scenario in MMKGs, demonstrating the superiority of LLMs in addressing this problem.
- Based on the proposed ZSLLM model, we achieved effective semantic information transfer for unseen categories in multi-modal knowledge graph scenarios, enabling zeroshot embedding representation learning.
- Extensive experiments demonstrate that our proposed framework outperforms all existing baseline methods.

# II. RELATED WORKS

Three aspects of research are related to our work: knowledge graph embeddings, zero-shot learning, and large language models. The details are as follows.

## A. Knowledge Graph embeddings

KG embeddings are vector representations of entities and relations in KGs, enabling them to be processed by machine learning models. Currently, KG embeddings are classified into three main categories: translation-based models, semantic matching models, and neural network-based models.

1) Translation-based models: These models aim to minimize the distance between the head entity plus the relation vector and the tail entity vector. Fan et al. (2024) achieve knowledge graph embedding of full hyperplane through Lorentz transformation. Concept2Box (Huang et al., 2023) uses dual geometric representations to jointly embed the two views of a KG.

2) Semantic matching models: These models focus on measuring the similarity between entities and relations in the embedding space, optimizing based on the compatibility of their semantic representations. Xu et al. (2023) proposed the GeomE method that uses multivector representations and the geometric product to model entities and relations and score them. Cao et al. (2021) introduces dual quaternions to score similarity.

*3) Neural network-based models:* These models use neural networks to learn complex and non-linear embeddings of entities and relations, often leveraging deep architectures for richer representations. Cheng et al. (2024) use FT-KGE and PT-KGE to perform the knowledge graph embeddings as the pre-step of the editing task. Zhao et al. (2023) uses a Multiplex Relational Graph Attention Network (MRGAT) to learn on Heterogeneous Relational Graph (HRG) and generate embeddings.

Translation-based models are efficient and interpretable but struggle with complex relations, while semantic matching models excel at compatibility but face scalability issues. Neural network-based models are powerful for capturing nonlinear patterns but require high computational resources and large datasets. Unlike traditional KG embeddings, this paper explores embedding representation learning for MMKG under unseen class data samples.

# B. Zero-shot Learning

Zero-shot learning is a machine learning paradigm where a model is trained to recognize and predict categories it has never seen during training by leveraging auxiliary information such as semantic attributes or embeddings. Current approaches to ZL are generally categorized into two types: inductive ZL and transductive ZL.

1) Inductive ZL: These models rely solely on the training data without access to unseen class information. Liu et al. (2024) propose POPRNet that incorporates discriminative part semantics and object-centric semantics guided by semantic intensity to improve cross-domain transferability. Chen et al. (2024) improve the ability to recognize unseen classes by building explanatory graphs and partial aggregations to

reduce virtual connections. PSVMA+ (Liu et al., 2024) handles attribute diversity and instance diversity through crossgranularity learning and fusion of multi-granularity features.

2) Transductive ZL: These models incorporate information from the distribution of unseen class data during inference. Wu et al. (2024) propose a Prototype-augmented Selfsupervised Generative Network that separates the generated unseen features and the generated seen features to solve bias problems. Chen et al. (2023) propose a DSP method to align the empirically predefined semantic prototypes and the real prototypes for class-related feature synthesis. Wang et al. (2023) propose Bi-VAEGAN that strengthens the distribution alignment between the visual space and an auxiliary space to reduce the domain shift.

Inductive ZL generalizes to unseen classes based on learned features, offering flexibility but struggling with limited or dissimilar training data. Transductive ZL adapts to specific test sets for higher accuracy but sacrifices generalization and depends on test data distribution. The model proposed in this paper belongs to transductive ZL, where the training process leverages textual modality information of unseen classes to infer the image distribution of unseen class data for training.

# C. Large Language Models

LLMs are a kind of advanced AI systems trained on massive amounts of text data to understand and generate human-like language. Currently, LLMs can be categorized into two types: general-purpose models and specialized models.

1) General-purpose models: These models are designed for a wide range of tasks. Touvron et al. (2023) train LLaMA using publicly available datasets and the scaling laws. Bi et al. (2024) propose DeepSeek by delving into the scaling law. Adler et al. (2024) proposed Nemotron by combining LLM and SFT and fine-tuning preferences.

2) Specialized models: These models are fine-tuned for specific applications or domains. Shen et al. (2024) propose a model-agnostic framework for learning custom input tags, which are parameterized as continuous vectors attached to the embedding layer of LLM to fine-tune them. Dai et al. (2024) proposed the DeepSeekMo architecture, which improves specialization by finely partitioning experts and isolating shared experts. Lee et al. (2024) proposed the OWQ method to achieve LLM fine-tuning with minimal memory overhead.

General-purpose models are versatile and adaptable across tasks but may lack optimal performance on specific domains, while specialized models excel in targeted tasks with higher accuracy but are less flexible and require retraining for broader applications. The model proposed in this paper is based on a general-purpose large model.

# III. THE PROPOSED FRAMEWORK

In this chapter, we first describe the basic process of proposing the overall framework ZSLLM, and then we will introduce the specific details of each module of the proposed framework separately. The overall framework diagram we proposed is shown in Figure 1.

Fig. 1. Overall framework of ZSLLM

#### A. Framework outline

As shown in Figure 1, the input consists of two parts, the first part is the text features of visible and invisible classes, and the second part is the visual features of visible classes. We use the chatGPT interface to obtain word embeddings for the text features of visible classes. For visible class image features, we use CNN [5] convert them into embedded features for input. In the model, we first input the image and text features of the visible class into the visible class learning module to learn the recognition experience within the visible class. At the same time, we import the text features of invisible classes into the invisible class recognition module to fully capture the available information of invisible classes. Finally, based on the learning experience of the first two modules, we use the invisible class classification module to classify images of invisible classes. The ultimate goal of the proposed model is to classify images of invisible classes, such as the classification of images of horses and cats shown in Figure 1.

# B. Visible Class Learning Module

In order to fully solve the problem of difficult knowledge generalization caused by the lack of target samples in zero sample learning, a knowledge distillation model is introduced in ZSLLM. We train the teacher model in the knowledge distillation model based on visible class text features and visual features to facilitate the generalization of knowledge to classification problems of invisible classes.

Generate word features based on chatGPT interface for visible class text labels, and generate visual features based

on CNN for visible class image features:

$$x = concat (Ws, Vs)$$

$$x = reshape(x,[batch_size,1, 28, 28])$$

$$x1 = ReLU(Conv(x, W1) + b1)$$

$$x2 = Pool(x1)$$

$$x3 = flatten(x2)$$

$$x4 = ReLU(W4 \cdot x3 + b4)$$
output = W5 \cdot x4 + b5

Then, we train the teacher model based on and:

$$x = \text{concat}(Ws, Vs)$$
  

$$x_1 = \text{ReLU}(\text{Dropout}(W_1 \cdot x + b_1))$$
  

$$x_2 = \text{ReLU}(\text{Dropout}(W_2 \cdot x_1 + b_2))$$
  

$$x_3 = W_3 \cdot x_2 + b_3$$
(2)

Then, based on knowledge distillation, we transfer the knowledge from the teacher model to the student model:

Here we optimize based on the following formula:

student\_loss = CrossEntropyLoss(student\_preds,target)

distillation loss\_ = KLDivLoss 
$$\left(\frac{\log(\text{softmax}(student preds/temp))}{temp}\right)_{-}$$
,  
 $\frac{\text{softmax}(teacher preds/temp)}{temp}$  (4)  
loss =  $\alpha$  · student loss + (1 -  $\alpha$ ) · distillation loss

#### C. Invisible class recognition module

In order to obtain auxiliary recognition information for invisible classes, we generate word features for invisible classes based on the chatGPT interface. Then, based on the knowledge graph embedding model [4], we import the structural information of the multimodal knowledge graph into:

$$\bar{F}_{s+u} = \sigma(D^{-1}A\sigma(D^{-1}AF_{s+u}\theta)\theta)$$

$$F_{s+u} = GDAN(w_u \cdot c_c \cdot)$$
(5)

Fully tapping into the massive pre training knowledge of LLMs in ZSLLM provides a broad knowledge foundation for zero sample learning. Using Dall-e to generate similar invisible class image features for student models to train and learn, we will generate reference feature vectors based on CNN for the generated images:

$$L = \alpha \cdot \text{Hard}_{\text{Loss}} + (1 - \alpha) \cdot \text{Soft}_{\text{Loss}}$$
$$= \alpha \cdot \text{CE}(V_g, V_c) + (1 - \alpha) \cdot \text{CE}(V_g'', V_c) \qquad (6)$$
$$V_g'' = \text{softmax}(V_g/T)$$

# D. Invisible Class Classification Module

In this module, we first aggregate the visible and invisible text and visual feature vectors obtained from the first two modules based on a multimodal knowledge graph

$$\mathbf{M}_{c} = \text{Concat}(\text{MultiModal}_{c}, \mathbf{E}_{c})$$
(7)

Then, we use GCN to determine the specific category to which invisible class images belong:

#### **IV. EXPERIMENTS**

In this section, we will introduce our comparison results with other existing models. In addition, we also validated the effectiveness of various components and partial parameters of the model.

## A. Experimental details

1) data set: Our main experiment was tested on three datasets, namely ImageNet [6], AWA2 [7], and Attribute Pascal and Yahoo (aPY) [8]

ImageNet: This dataset aims to use an average of 500-1000 clean and high-resolution images to form the majority of WordNet [9]'s 80000 synonyms, and to construct a semantic tree of millions of ImageNet images using WordNet. ImageNet currently consists of 12 sub trees, 5247 synonym sets, and 3.2 million images. The ImageNet dataset is larger, more diverse, and more accurate than many existing datasets.

AWA2: This dataset collected 37322 images from 50 categories of the AWA1 dataset [7] from public network resources such as Flickr and Wikipedia. All images of AWA2 can be used for free. In addition, the images in this dataset will not overlap with the images in the AWA1 dataset. The AWA2 dataset contains 50 animal categories. Each class contains an average of 746 images, with the mole class being the least numerous class with 100 images. Horses are the class with the highest number of images, with 1645 images. Attribute Pascal and Yahoo (aPY): This dataset is a smallscale coarse-grained dataset with 64 attributes. Use 20 classes in training and 12 classes in testing, for a total of 32 classes. The dataset of primitive animals with attributes (AWA1) [10] has a coarse granularity and moderate scale.

2) Assessment measures: We use Hits@n As our experimental evaluation metric. Hits@n The average proportion of knowledge in the prediction process is lower than n. In the experiment of this article, Hits@n The higher, the better the experimental effect. Hits@n The calculation method is as follows:

Hits @n = 
$$\frac{1}{|S|} \cdot \sum_{i=1}^{|S|} indicator(\operatorname{rank}_i \leq n)$$

Where the function of indicator is: if the condition is true, the function value is 1; otherwise, it is 0. |S| is the number of quadruple sets, and rank<sub>i</sub> refers to the link prediction ranking of the ith quadruple.

3) Set details: For the GCN used, in order to avoid overfitting, we referred to [4] and used the dropout function [11], with a dropout rate of 0.5 for each layer. The Adam optimizer is trained in 3000 rounds, with a learning rate set to 0.001 and weight decay of 0.0005.

4) Comparison method: ConSE [12]maps images to a semantic embedding space through convex combinations of class label embedding vectors, without the need for additional training. EXEM [13]utilizes clustering structures in the semantic embedding space to enable semantic representations to predict the position of their corresponding visual examples, thereby performing structural constraints. SYNC [14] aligns the semantic space from external information with the model space that focuses on recognizing visual features. Devise [15]proposed using trained word embeddings instead of one hot vectors as the labels to be predicted by the model, and then fine tune based on this. SE-GZSL [16] can generate novel examples from visible/invisible classes, given their respective class attributes, and these examples can then be used to train any ready-made classification model. Gaussian Ort [17] set a simple learning objective inspired by linear discriminant analysis, kernel target alignment, and kernel polarization methods. GCNZ [18] is based on graph convolutional networks and uses both semantic embedding and classification relationships to predict classifiers. SGCN [19] has carefully designed direct links between distant nodes based on a dense graph propagation module. DGP [19] allows the hierarchical graph structure of knowledge graphs to be utilized through additional connections. A zero shot learning method based on a multi modal KG [4]introduces a semantic KG to capture the correlations between classes and learn the visual feature representations of all classes through this correlation. It can be seen that our model outperforms all baseline models and maintains optimal performance on all three datasets.

### B. Main experiments

In Table 1, we present the experimental results of the main experiment. It can be seen that we outperform ex-

isting zero sample learning prediction models in all three datasets, achieving optimal performance in multimodal knowledge graph classification tasks. Unlike traditional prediction models, our proposed model fully utilizes the massive pre training knowledge of LLMs, providing extensive foundational knowledge for zero sample learning and enhancing the model's generalization. In addition, based on the knowledge distillation model, the ability to understand new categories of data has been improved. Thanks to this, our model maintains the most competitive task performance currently available.

# C. Ablation analysis

To verify the effectiveness of the LLMs and knowledge distillation components in our proposed model, we conducted ablation experiments. The experimental results show that removing each component leads to a decrease in performance, proving the importance of each component in the model.

Specifically, after removing the visible class component, the experimental result dropped to 3.24%, a decrease of 1.22% compared to the main experiment result of 4.46%. This fully demonstrates the significant role of the visible class component in improving the model's performance. Similarly, after removing the knowledge distillation component, the experimental result dropped to 3.97%, also lower than the main experiment result of 4.46%, which validates that the knowledge distillation model can effectively leverage pre-trained knowledge, helping the model to perform better inference and prediction in zeroshot learning problems.

# D. Hyper-parameter Analysis

To verify the effectiveness of the parameters in our proposed model, we conducted two sets of parameter variation experiments.

1) Distillation temperature: We present the experimental results of the distillation temperature variation in Figure 2. We will vary the distillation temperature from 2.0 to 5.0, with a magnitude of 0.5 for each change. It can be seen that as the distillation temperature changes from 2.0 to 5.0, the

accuracy of the experiment gradually increases first, reaching its highest value at 3.0, and then decreases. This indicates that as the distillation temperature increases, more inter category relationship information can be provided during the knowledge distillation process. However, after reaching a certain distillation temperature, the effective information that distinguishes the original categories will be lost. Therefore, in the zero sample learning process, richer empirical information can be utilized to match and infer unseen categories, which is beneficial for improving accuracy, but attention should be paid to increasing the range of distillation temperatures.

Fig. 2. Experimental results of distillation temperature variation from 2.0 to 5.0. The accuracy initially increases, peaks at 3.0, and then decreases, indicating the optimal temperature for knowledge distillation.

2) GCN layers: We present the experimental results of GCN layer changes in Figure 3. We will vary the number of GCN layers from 1000 to 5000, with each change being 500. It can be seen that as the number of GCN layers increases, the accuracy of the experiment gradually increases and then decreases, reaching its highest value at 3000 layers. This is because as the number of layers in GCN increases, it can extract more complex features in structures such as KG. However, after reaching a certain number of layers, there will be an issue of over smoothing, causing node features to

become too similar. In the zero sample learning process, based on richer features, it is possible to infer unseen categories, thereby improving the accuracy of prediction. Therefore, it is possible to moderately increase the number of GCN layers while avoiding overfitting.

Fig. 3. Experimental results of GCN layer changes from 1000 to 5000. The accuracy increases with the number of layers, peaking at 3000 layers before decreasing, indicating the optimal number of layers for feature extraction without overfitting.

# V. CONCLUSION

The challenge of ineffective semantic information transfer for unseen categories in MMKG embedding representation learning has not been adequately addressed by previous methods. In this paper, we propose a novel zero-shot learning framework, ZSLLM, which effectively enhances the representation learning of unseen categories in MMKG by establishing semantic connections across different modalities for these unseen categories. To demonstrate the effectiveness of ZSLLM, we conduct extensive experiments on three real-world datasets. The experimental results show that our framework outperforms all baselines.
