ABSTRACT

Context. The formation of first stars and galaxies at the Cosmic Dawn had been preceded by the chain of primordial chemistry reactions during Dark Ages which generated first molecules, mostly H₂, HD, and HeH⁺, so crucial for first stars to emerge. These molecules absorbed and scattered CMB quanta this way distorting CMB spectrum.

Aims. Estimate how much bound-bound transitions between the rovibrational levels of H₂, HD, and HeH⁺ molecules contribute to the distortion of CMB spectrum in the standard ACDM cosmology.

Methods. We describe the kinetics of the formation of the first molecules with system of 166 chemical reactions involving 20 reagents. The system of differential equations is solved to describe the processes of spontaneous and collisional transitions between rovibrational levels of H₂, HD, and HeH⁺ molecules. The populations of rovibrational levels and optical thickness of the gas in transition lines between these levels were used to estimate the differential brightness produced by the first molecules on the cosmic microwave

Results. It is shown that the signal from the first molecules in the standard ACDM cosmology takes the form of an absorption profile in the CMB spectrum and originates from the Dark Ages. The absorption profile of H_2 molecule: features multiple peaks; reaches maximum of $\sim 10^{-3}$ Jy/sr within the frequency range from ~ 50 GHz to ~ 120 GHz; and major contribution in absorption comes from redshifts 300 > z > 200. The absorption profile of HD molecule: features double peaks; reaches maximum of $\sim 10^{-5}$ Jy/sr within the frequency range from ~ 40 GHz to ~ 70 GHz; and largest part of absorption comes from redshifts 300 > z > 30. The absorption profile of HeH⁺ ion-molecule: has no features and reaches maximum of $\sim 10^{-7}$ Jy/sr within the frequency range from ~ 200 GHz to ~ 800 GHz; and absorption comes mainly from redshifts range 100 > z > 4.

 1. Introduction 1. huroduction 1. huroduction 1. huroduction

 well galaxies come to being at z ~ 20 - 30. During this time period, the Universe was filled with: CMB photons, dark matter (DM), dark energy (DE), and a weakly ionised gas, almost entirely made up of hydrogen (≈92.4 % of total number density), helium-4 (≈7.6 % (Aver et al. 2015)), along with trace amounts of deuterium (≈2.45·10⁻³ % (Cooke et al. 2014)), as well as lithium-7 (as predicted by (Coc & Vangioni 2017) to amount to ~5.61·10⁻⁸ % while observed (Sbordone et al. 2014)), to amount to ~5. to be $\approx 1.58 \cdot 10^{-8}$ %). Also DM halos were formed from the initial over-density perturbations at the time, and primordial chemical reactions synthesized first molecules, with H₂ hydrogen molecules as most abundant (Latter & Black 1991; Lepp et al. 2002; Coppola et al. 2011; Longo et al. 2011), deuterium hydride molecules HD (Lepp et al. 2002; Glover & Abel 2008; Gay et al. 2011), helium hydride ion-molecule HeH⁺ (Schleicher et al. 2008; Bovino et al. 2011b), and lithium hydride molecules LiH (Dalgarno et al. 1996; Stancil et al. 1996; Bougleux & Galli 1997; Schleicher et al. 2008; Stancil et al. 1996).

The estimation of fractions of the molecules is determined by the primordial chemistry model used, namely the set of chemical reactions and their rates as functions of gas, electron or radiation temperatures. The system of primordial chemistry equations can include as much as 300 reactions for about 30 reagents (Gay et al. 2011). However, besides the completeness of reaction set, the accuracy of molecular number predictions also depends on the accuracy of reactions' rates. Since any updates to the reaction chains and rates can affect the estimation of abundances, numerous attempts to trace chemical evolution during the Dark Ages have yielded quite different results, sometimes by orders of magnitude (Signore & Puy 2009; Bovino et al. 2009; Galli & Palla 1998; Galli & Palla 2002; Black 2006; Sethi et al. 2008; Puy & Signore 2007; Puy et al. 1993; Schleicher et al. 2008; Lepp et al. 2002; Lepp & Shull 1984). According to papers above, the absence of dust and heavy elements in the early Universe leads to extremely low molecular abundances. The fraction of molecules in the baryonic gas in relation the cosmological background reaches ~ $10^{-5} - 10^{-6}$ for hydrogen molecules, ~ $10^{-9} - 10^{-10}$ for HD molecules, ~ $10^{-11} - 10^{-14}$ for HeH⁺ ionmolecules, and the fraction of LiH molecules reaches $\sim 10^{-20}$ at the end of the Dark Ages. In the Dark Matter halos chemical processes are expected to be more intense due to the denser and hotter environment. The number densities of H₂ and HD molecules at the moment of halo virialization are estimated as respectively $\sim 10^3$, it's ~ 400 times larger than that of uniformly expanding background, while the number density of HeH⁺ ion molecules on the contrary appears to be of orders of magnitude

lower (Novosyadlyj et al. 2018, 2022). Despite quite low abundances of primordial molecules in early Universe they are a crucial ingredient for the formation of the first stars. Therefore, their detection will provide an important insight into the processes in early Universe that led to the emergence of the first stars, galaxies, and supermassive black holes.

Dark Ages are studied by detecting spectral distortions of the CMB caused by primordial chemistry and the 21 cm transition in neutral hydrogen. The idea that resonant scattering of CMB photons in the rovibrational lines of some primordial molecules of Dark Ages halos could lead to an observable signature in the CMB thermal spectrum was first proposed by Dubrovich (1977) in the late 1970s. Since then, a number of papers have analysed the possibility of detecting the resonant lines (e.g. Maoli et al. (1994, 1996); Basu (2007); Dubrovich et al. (2008)) and there have been three attempts to observe the effect, without success so far (Persson, C. M. et al. 2010; Gosachinskij et al. 2002; de Bernardis et al. 1993). Paper Schleicher et al. (2008) considers the distortion of CMB spectrum due to absorption, photoionization, and photo-dissociation processes during freefree and bound-free transitions involving atomic and molecular ions on the cosmological background of Dark Ages. There, most promising results were obtained for the negative hydrogen ion H⁻ and the HeH⁺ ion-molecules. In this paper we have calculated the contribution to the distortion of the CMB spectrum by bound-bound transitions between rovibrational levels of the first molecules H₂, HD, and HeH⁺. LiH molecules are not considered due to their low abundance.

2. Primordial chemistry

Primordial chemical reactions start at the epoch of recombination when neutral atoms emerged and continue in the postrecombination Universe due to the presence of residuals of free electrons and ions. The presence of such ingredients in almost neutral post-recombination gas triggers a chain of chemical reactions, thus leading to the synthesis of the first diatomic compounds, among which the most common are molecules H_2 and HD, as well as the helium hydride ion HeH⁺. They are expected to have played a crucial role in forming the first stars by allowing protostellar gas clouds to cool and collapse. However, as mentioned above the primordial gas was chemically depleted from atoms in various ionized and excited states. In our calculations, we took into account twenty most common reactants, namely photons of cosmic relic radiation (γ), e⁻, H, H⁺, H⁻, H₂, H₂⁺, H₃⁺, He, He⁺, He⁺⁺, HeH⁺, D, D⁻, D⁺, D₂, D₂⁺, HD, HD⁺, and H_2D^+ . For these reagents, we consider 166 reactions listed in Table B.1 subdivided into three groups: reactions not involving He and D nuclei are labelled with the prefix "H_", reactions involving He nuclei and not involving D nuclei are labelled with the prefix "He_", reactions involving D nuclei are labelled with the prefix "D_". The Table shows the rates of the reactions as a function of gas temperature, electron temperature, or radiation temperature. The description in the Table lists the publications where corresponding approximate expressions were obtained.

In the Table B.1 we present new approximate expressions for the reaction rates of H_{21} and He_{19} . The first one is calculated based on the cross-section from the online database¹. The second is our approximation to the combined data from Schauer et al. (1989) and Johnsen et al. (1980). Some reactions involving molecules are sensitive to their quantum state. For them, the Table B.1 contains reaction rates for two cases: v = 0 corresponds to the case when the molecule is in the ground vibrational state, LTE corresponds to condition of local thermodynamic equilibrium for the population of rovibrational levels. Under conditions of early Universe the population of rotational and vibrational levels of molecules is mainly determined by the temperature of CMB radiation. At the same time, the frequency of collisions depends on the temperature of the gas. At redshifts z > 200, the gas and background radiation temperatures are equal, so it is correct to use LTE approximation. At lower redshifts, the gas temperature is slightly below the temperature of the background radiation, so the LTE approximation is less accurate though we continue to use it.

Since the density of the *i*-th reactant, n_i , changes not only due to chemical reactions but also due to the expansion of the Universe, it is convenient to represent the amount of the reactant in the form of a fraction, that is, relative to the total number of hydrogen nuclei as $x_i \equiv n_i/n_H$. The evolution of the fraction of the *i*-th reactant, x_i , is determined only by chemical reactions and is described by a kinetic equation that has the following general form (Puy et al. 1993; Galli & Palla 1998; Vonlanthen et al. 2009; Novosyadlyj et al. 2018):

$$\left(\frac{dx_i}{dt}\right)_{\text{chem}} = \sum_{mn} k_{mn}^{(i)} n_{\text{H}} x_m x_n + \sum_m k_{m\gamma}^{(i)} x_m - \sum_j k_{ij} n_{\text{H}} x_i x_j - k_{i\gamma} x_i, \quad (1)$$

where $k_{mn}^{(i)}$ is the reaction rate of reactants *m* and *n* with the formation of reactant *i*. The number of differential equations can be reduced by applying four equalities $1 = x_{HI} + x_{HII} + x_{H-} + x_{HD} + x_{HD^+} + x_{HeH^+} + 2x_{H_2^+} + 2x_{H_2} + 2x_{H_2D^+} + 3x_{H_3^+}, x_D = x_{DI} + x_{DII} + x_{HD} + x_{HD^+} + x_{H_2D^+}, x_{He} = x_{HeI} + x_{HeII} + x_{HeII} + x_{HeH^+}, and <math>x_e = x_{HII} + x_{DII} + x_{HeII} + 2x_{HeII} + x_{H_2^+} + x_{D_2^+} + x_{HeH^+} + x_{H_3^+} + x_{HD^+} + x_{H_2D^+} - x_{H^-}.$

In practice, we used the last equality to calculate the fraction of free electrons, while the others allowed us to control the accuracy of the integration of the differential equations. We did not calculate the change in the number of photons since, as noted above, the number of relic photons exceeds the number of photons arising from recombination by nine orders of magnitude. All calculations were performed for the period from the cosmological recombination up to hydrogen reionization at $z_{rei} \approx 6$ and for corresponding values of main parameters of the cosmological model as determined by final data release of the Planck Space Observatory (Planck Collaboration et al. 2020), listed in the previous section.

Main results of our calculations are shown in Fig. 1, where the relative abundances of representative species involved in the formation of H2 (top left panel), HD (top right), and HeH+ (bottom left panel) are given in units of hydrogen nucleus number density, deuterium nucleus number density, and helium nucleus number density, respectively. The relative abundances of first molecules in units of hydrogen nucleus number density are presented in the bottom right panel. Our results qualitatively reproduce the results of other authors, since the core of the most important reactions is common.

We have analysed chemical reactions for their influence on the chemistry of the early Universe from the moment of recombination to the moment of reionization. In the Table B.1, we have highlighted in bold those reactions that, in the indicated redshift range, give a maximum contribution to the synthesis or destruction of any of the reactants of more than 0.1 percent. Such an analysis shows which of the reactions played a noticeable role in the early Universe (within the framework of the standard cosmological model). It is assumed that in halos and cosmological

Fig. 1. Abundances of atoms, molecules, and ions across redshifts. Panels show relative abundances of key species for H_2 (top left), HD (top right), and HeH⁺ (bottom left) in units of the density of hydrogen, deuterium, and helium nuclei, respectively. The bottom right panel displays the first molecules' abundances in hydrogen nucleus number density across redshifts.

models with additional sources of ionization and heating (primordial magnetic fields, decaying or annihilating dark matter particles, primordial black holes) this set will be somewhat different. The interactive chemical reaction map we propose (i.e. Table B.2) is a new way of visualizing a network of chemical reactions, allowing us to visually track which reactions are already included in the model of primordial chemistry, and which ones can or should still be included.

2.1. The Chemistry of H₂

Direct radiative association of two neutral hydrogen atoms in the ground states to form a hydrogen molecule is very unlikely (rate $\ll 10^{-25}$ cm³s⁻¹ (Gould & Salpeter 1963)) since the emitted photon in this process must be a result of forbidden transition between the two Hitler-London states of the molecule. Direct radiative association of two neutral hydrogen atoms is possible if one of the two colliding atoms is in an excited state (say, in the 2p state), then the emission of photon will occur through an allowed transition between the two states of the molecule. However, the fraction of H atoms in the 2p and other excited states in the post-recombination Universe is so small that this process can be neglected. Therefore, in the conditions of the early Universe, two indirect channels of formation of hydrogen molecules dominate – one through the mediation of ion H⁻:

$$H^- + H \to H_2 + e^-, \tag{2}$$

and other through the mediation of ion-molecule H_2^+ :

$$\mathrm{H}_{2}^{+} + \mathrm{H} \to \mathrm{H}_{2} + \mathrm{H}^{+}. \tag{3}$$

Fig. 2. Kinetics of formation and destruction of H_2 molecules. The dependencies of the rates of the main reactions involved in the formation and destruction of H_2 molecules are provided.

As shown in Fig.2, the former process dominates at $z \le 127$ and reaches the maximum rates at the two peaks located at $z \approx 1270$ and $z \approx 98$. The second process dominates at $129 \le z \le 1400$, reaching peak efficiency at $z \approx 1220$ and $z \approx 320$. The gray and yellow lines in Fig.2 show the overall rates of synthesis and destruction of H₂ molecules, respectively, which takes into account all the involved reactions listed in Table B.1. The total formation rate is the difference between the

synthesis and destruction rates as shown in Fig. 2 by the solid cyan line. As can be seen from the figure, the formation of H_2 molecules at $z \ge 1050$ is an equilibrium process, while at lower redshifts, the rate of synthesis of H_2 molecules begins to prevail over their destruction.

The main channel for creating H⁻ ions is the process

$$H + e^- \to H^- + \gamma. \tag{4}$$

The main channel for destruction H⁻ ions at $z \ge 100$ is process

$$H^- + \gamma \to H + e^-, \tag{5}$$

while at $z \le 100$, H⁻ ions are mainly spent on the formation of the H₂ molecule during the process (2). Since the formation of H⁻ ions is an equilibrium process in the early Universe, their number density can be easily estimated by the equality $k_{(4)}n_{\rm H}n_{e^-} = n_{\rm H^-}(k_{(5)} + k_{(2)}n_{\rm H})$, where $k_{(4)}$, $k_{(2)}$, and $k_{(3)}$ mark rates of processes (4), (2), and (5), respectively.

There are two main processes for formation of H_2^+ , the first of which

$$H + H^+ \to H_2^+ + \gamma, \tag{6}$$

dominates at $z \leq 140$, while the second

$$\text{HeH}^+ + \text{H} \to \text{H}_2^+ + \text{He},\tag{7}$$

dominates at $z \ge 140$. There are also two main processes for destruction of H₂⁺, the first of which

$$\mathrm{H}_{2}^{+} + \gamma \to \mathrm{H} + \mathrm{H}^{+}, \tag{8}$$

dominates at $z \leq 325$, while the second

$$\mathrm{H}_{2}^{+} + \mathrm{H} \to \mathrm{H}_{2} + \mathrm{H}^{+}, \tag{9}$$

dominates at $z \ge 325$. The formation of H₂⁺ is an equilibrium process in the early Universe, and their number density can be easily estimated by the equality $k_{(6)}n_{\rm H}n_{\rm H^+} + k_{(7)}n_{\rm HeH^+}n_{\rm H} = n_{\rm H_2^+}(k_{(8)} + k_{(9)}n_{\rm H})$, where $k_{(6)}, k_{(7)}, k_{(8)}$, and $k_{(9)}$ mark rates of processes (6), (7), (8), and (9), respectively.

2.2. The Chemistry of HD

Unlike H_2 , molecule of HD can be formed by direct radiative association of two neutral atoms in the process

$$H + D \rightarrow HD + \gamma,$$
 (10)

which reaches its maximum efficiency in the epoch of recombination ($z \approx 1100$). However, two processes of formation of HD molecules from H₂ molecules are more effective in the conditions of the early Universe, namely charge transfer

$$H_2 + D^+ \to HD + H^+, \tag{11}$$

and deuteron exchange

$$H_2 + D \to HD + H. \tag{12}$$

These processes have two peaks in efficiency at $z \approx 1180$ and $z \approx 307$ and dominate at $z \ge 20$. At a later time, as well as in the recombination epoch, processes involving H⁻ and D⁻ ions should also be considered, namely

$$H + D^{-} \rightarrow HD + e^{-}, \tag{13}$$

and

$$H^- + D \to HD + e^-.$$
(14)

Article number, page 4 of 15

Fig. 3. Kinetics of formation and destruction of HD molecules. The dependencies of the rates of the main reactions involved in the formation and destruction of HD molecules are given.

Fig. 4. Kinetics of formation and destruction of HeH⁺ ion-molecules. The dependencies of the rates of the main reactions involved in the formation and destruction of HeH⁺ ion-molecules are given.

The cyan and blue lines in Fig.3 show the overall rates of synthesis and destruction of HD molecules when all reactions from Table B.1 are involved. The total formation rate is the difference between the synthesis and destruction rates and is shown in Fig. 3 by the solid orange line. As it follows from Fig. 3, the formation of HD molecule is an equilibrium process in early Universe at $z \ge 120$. At later stages of evolution ($z \le 120$), the synthesis of HD molecules dominates over their destruction.

2.3. The Chemistry of HeH⁺

As can be seen from Fig. 1 (see lower right panel), the helium hydride ion (HeH⁺) was the first molecular ion that began to form in the early Universe during the recombination of He nuclei during the recombination epoch due to three processes

4)
$$\text{He} + \text{H}^+ \rightarrow \text{HeH}^+ + \gamma$$
, (15)

and

$$\text{He}^+ + \text{H} \rightarrow \text{HeH}^+ + \gamma,$$
 (16)

and

$$\mathrm{He}^{+} + \mathrm{H} + \gamma \to \mathrm{HeH}^{+} + 2\gamma. \tag{17}$$

The main channel for destruction HeH⁺ ion-molecules at $z \ge$ 300 is process

$$\mathrm{HeH}^{+} + \gamma \to \mathrm{He} + \mathrm{H}^{+}, \tag{18}$$

while at $z \le 300$, HeH⁺ molecular ions were destroyed in collisions with neutral atoms of hydrogen due to process

$$\mathrm{HeH}^{+} + \mathrm{H} \to \mathrm{He} + \mathrm{H}_{2}^{+}.$$
 (19)

The brown and pink lines in Fig.4 show the overall rates of synthesis and destruction of HeH⁺ molecules, taking into account all reactions listed in Table B.1. The fact that these lines merge in Fig. 4 means that the formation of HeH⁺ molecules is an equilibrium process at all redshifts, and their number density can be estimated by the equality $k_{(15)}n_{\text{He}}n_{\text{H}^+} + (k_{(16)} + k_{(17)})n_{\text{He}^+}n_{\text{H}} = n_{\text{HeH}^+}(k_{(18)} + k_{(19)}n_{\text{H}})$, where $k_{(15)}$, $k_{(16)}$, $k_{(17)}$, $k_{(18)}$, and $k_{(19)}$ mark rates of processes (15), (16), (17), (18), and (19), respectively.

3. Rovibrational levels occupation

The kinetic equations for the population of rotational and vibrational levels are as follows

$$\frac{dX_{\nu,j}^{m}}{dt} = \sum_{s} n_{s} \sum_{\nu',j'} \left[k_{\nu',j'\to\nu,j}^{s} X_{\nu',j'}^{m} - X_{\nu,j}^{m} k_{\nu,j\to\nu',j'}^{s} \right] \\
+ \left[\alpha_{\nu,j}^{m} \frac{d_{+}}{dt} - X_{\nu,j}^{m} \frac{d_{-}}{dt} \right] \ln(n_{m}a^{3}),$$
(20)

where $X_{v,j}^m = n_{m,\{v,j\}} / \sum_{v',j'} n_{m,\{v',j'\}}$ is the fraction of molecules $m \in \{H_2, HD, HeH^+\}$ that is in the quantum state $\{v, j\}$, and the index $s \in \{\gamma, H, p, e\}$ indicates the collision partner of molecule *m* that caused the transitions. Here, we assume that the transitions between the rovibrational levels of Dark Age and Cosmic Down molecules are mainly due to the emission/absorption of photons, collisions with neutral hydrogen atoms, protons (responsible for ortho \Longrightarrow para transitions in H₂) and electrons (considered only for HeH⁺). The last term of Eq. 20 describes the trend that population of rovibrational levels of newly synthesized molecules, $\alpha_{v,j}^m$, differs from the population of levels of molecules that have already been exposed to the environment, $X_{v,j}^m$. The former is obviously determined by the gas temperature,

$$\alpha_{\nu,j}^m \approx g_j \exp\left\{-E_{\nu,j}/k_bT\right\} / \sum_{\nu',j'} g_{j'} \exp\left\{-E_{\nu',j'}/k_BT\right\},\,$$

while the other is preferably determined by the CMB temperature. The derivative² $d_{+} \ln(n_m a^3)/dt$ specifies the rate of molecule synthesis, while derivative $d_{-} \ln(n_m a^3)/dt$ determines the rate of their destruction.

The main process to define the population of the rovibrational levels of the first molecules in the early Universe was collisions with quanta of cosmic microwave background radiation. **Table 1.** Values of spontaneous rovibrational transitions allowed by quantum selection rules, along with frequencies and energy for the lowest rovibrational energy levels of para- and ortho-hydrogen molecules H_2 , hydrogen deuteride molecules HD, and helium hydride ion HeH⁺.

Since this radiation is a blackbody, the population of rovibrational levels can be considered to be in equilibrium with great accuracy, i.e., described by a Boltzmann distribution with temperature $T_{\rm R}$. The contributions of spontaneous and radiative rovibrational transitions to the right-hand side of the equation (20) have the following form

$$n_{\gamma} \cdot k_{ul}^{\gamma} = A_{ul} + B_{ul} \cdot U(v_{ul}), \quad n_{\gamma} \cdot k_{lu}^{\gamma} = B_{lu} \cdot U(v_{ul}),$$

where index '*ul*' means up to low levels transition whereas index '*lu*' means low to up levels transition, A_{ul} is the rate of spontaneous emission, $B_{ul} = (c^3/4hv_{ul}^3)A_{ul}$ is the rate of radiative emission, $B_{lu} = B_{ul}$ is the rate of radiative absorption, and

$$U(\nu) = \frac{4h\nu^3}{c^3} \frac{1}{\exp\left(\frac{h\nu}{kT_R}\right) - 1}$$

is the blackbody energy density. The values of transition frequencies and energies for allowed spontaneous rovibrational transitions are listed in Table 1, for low rovibrational energy levels. Data for para- and ortho- hydrogen molecules H_2 are taken from Roueff et al. (2019), data for hydrogen deuteride molecules HD and helium hydride ion HeH⁺ are taken from Amaral et al. (2019).

Spontaneous emission and radiative rovibrational transitions for diatomic molecules with non-zero electric dipole moments

² The complete differential $d = d_+ - d_-$, where d_+ indicates an increase in the number of molecules due to their synthesis, and d_- means the destruction of molecules due to their destruction.

(case for HD and HeH⁺) obey quantum selection rules $\Delta j = \pm 1$ and $\Delta v = \pm 1$. Hydrogen molecules are homonuclear diatomic molecules with a zero electric dipole moment. For this reason, it is two types of them depending on the relative orientation of the nuclear spins: ortho- and para-. Ortho-hydrogen molecules are those in which the spins of both nuclei (protons) point in the same direction, so their total spin is $I_n + I_n = 1$, where $I_n = 1/2$ is the spin of one nucleus (proton). Molecules of hydrogen in which spins of both nuclei are directing in opposite directions are called para-hydrogen, and their total spin is $I_n + I_n = 0$. Spontaneous emission and radiative rovibrational transitions do not lead to the mixing of these spin isomers of hydrogen molecules because they obey the quantum selection rules $\Delta i = \pm 2$ and $\Delta v = \pm 1$. Spin isomers of homonuclear diatomic molecules have distinct sequences of statistical weights of rotational levels, $g_j = g_n(2j + 1)$, which differ in nuclear statistical weights – $g_n = I_n(2I_n+1)$ or $g_n = (I_n+1)(2I_n+1)$ depending on the parity of j and symmetries of the binding wave functions. Ortho-hydrogen corresponds to odd values of *j*, and its nuclear statistical weight is $g_n = 3$, while for para-hydrogen, with even values of j, nuclear statistical weight is $g_n = 1$. The statistical weight of any vibrational level *v* of a diatomic harmonic oscillator is $g_v = 1$.

The next factor affecting the population of the rovibrational levels of molecules is their collisions with the components of the baryon gas. As seen from Fig. 1, neutral hydrogen atoms used to be most abundant. In this paper, we used the collisional deexcitation rates, k_{ul} , of rovibrational levels of H₂ molecules by H given in Lique (2015), where *u* and *l* mean upper and lower rovibrational energy levels. The reverse transition rate (excitation) coefficients can be obtained as follows

$$k_{lu}(T) = \frac{g_u}{g_l} \exp\left\{-\frac{E_u - E_l}{k_{\rm B}T}\right\} k_{ul}(T),\tag{21}$$

where E_u and E_l are the energies of the levels, g_u and g_l are statistical weights of the levels, and T is the baryon gas temperature. We used the rates from Desrousseaux et al. (2022) for collisional de-excitation of HD molecules by H. For collisional deexcitation of HeH⁺ molecules by H we used rates from Kulinich et al. (2020), which are somewhat higher than those obtained in Desrousseaux & Lique (2020). Although collisions of molecules H₂ with protons in the early Universe are much rarer, they nevertheless make a significant contribution to ortho-para transitions: $p + H_2(j) \leftrightarrow p + H_2(j')$, where $\Delta j = j' - j = \pm 1, \pm 2, \pm 3, \dots$ For collisional de-excitation of H_2 molecules by p, we used the rates from paper Gerlich (1990). Free electrons are faster than free protons, so their impact on the excitation and deactivation of the rotational levels of ion molecules HeH⁺ is more significant. To describe the rotational transitions in the helium hydride ion, HeH⁺, caused by collisions with free electrons, we used the transition rates from Khamesian et al. (2018), which unfortunately are only given for $j \leq 5$.

4. Global signals of the first molecules

During the Dark Ages, the temperature of baryonic matter is mainly determined by the competition between adiabatic cooling and heating due to the Compton scattering of CMBRs on free electrons. Other factors affecting the energy balance of the gas are collisional activations and de-activations of molecular rovibrational levels and primordial chemistry. However, as it shown in Puy et al. (1993); Novosyadlyj et al. (2023), these processes make a small contribution to the total energy balance of the gas in the cosmological background. Thus, energy balance for the

Fig. 5. Thermal history of the early Universe.

baryonic component on the cosmic background can be expressed by the equation of the evolution of its temperature with time

$$\frac{dT_m}{dt} = -2HT_m + \frac{8\sigma_T a T_{\rm R}^4 (T_{\rm R} - T_m) x_e}{3m_e c},\tag{22}$$

where σ_T is the Thomson cross-section, *a* is the radiation constant, m_e is the electron mass, and x_e is the ionization fraction, n_b – is baryonic gas number density. Energy exchange between free electrons and the radiation field played a leading role in the early Universe, causing the equalization of baryon gas and radiation temperatures at redshifts z > 300 (see Fig. 5). At lower redshifts, the transfer of energy from radiation to the baryonic gas slows down significantly due to the reduced frequency of collisions between electrons and quanta of CMB radiation in the expanding Universe. From this moment on, adiabatic cooling begins to dominate, therefore baryon gas cooled faster than radiation.

Population of the rovibrational levels starts to deviate from the equilibrium at redshifts z < 300 due to collisions between molecules and other components of the baryon gas, where the temperature of the baryon gas is slightly lower than the temperature of the CMB radiation. These deviations can be represented as a deviation of the excitation temperature,

$$T_{ex}^{ul} \equiv \frac{E_u - E_l}{k_B} \ln^{-1} \left(\frac{g_u n_l}{g_l n_u} \right),\tag{23}$$

from the radiation temperature T_R . The differential brightness of the first molecules on the background of CMB can be expressed as

$$\delta I_{ul} = \frac{2hv_{ul}^3}{c^2} \left[\frac{1}{e^{\frac{hv_{ul}}{k_B T_{ex}}} - 1} - \frac{1}{e^{\frac{hv_{ul}}{k_B T_r}} - 1} \right] \tau_{ul},$$

where the optical depth in the transition lines $u \rightarrow l$ in the approximation of narrow line looks as follows

$$\tau_{ul} = \frac{1}{8\pi} \frac{\lambda_{ul}^3 A_{ul}}{H(z)} n_{\text{mol}} \left(X_l \frac{g_u}{g_l} - X_u \right),$$

where $\lambda_{ul} = c/\nu_{ul}$ is wavelength, H(z) is expansion rate that depend on redshift, n_{mol} is number density of molecules. Note, we can not observe individual lines but their superposition

$$\delta I_{\rm tot} = \sum_{\rm transitions} \delta I_{ul}.$$

Fig. 6. Left panel: superposition of absorption profiles of the first molecules H_2 and HD, and ion-molecule HeH⁺. Right panel: redshifts at which absorption occurred.

Differential brightness of the molecules in the rovibrational lines, as well as their superposition, are shown in Fig. A.1, where the left panels show absorption profiles in the rotational lines of molecules H₂ (upper panel) and HD (middle panel), and ionmolecule HeH⁺ (bottom panel). The dotted coloured lines show contributions from separate transitions, whereas the black line shows their superposition. The right panels on Fig. A.1 show the redshifts at which absorption occurred for corresponding transitions for H₂ (upper panel) and HD (middle panel) molecules and for ion-molecule HeH⁺ (bottom panel). As you can see, absorption begins at $z \simeq 300$ when the gas temperature T starts to deviate from the CMB temperature T_R . The absorption profile of H₂ molecule has a multi-peak feature and reaches a maximum amplitude of ~ 10^{-3} Jy/sr within the frequency range from about 50 GHz to about 120 GHz. The maximum absorption in rovibrational lines of H_2 molecules comes from redshifts 300 > z > 200. The absorption profile of the HD molecule has a double peak feature and reaches a maximum amplitude of ~ 10^{-5} Jy/sr within the frequency range of 40 GHz to 70 GHz. Maximal absorption in rovibrational lines of HD molecules comes from redshifts 300 > z > 30. The absorption profile of HeH⁺ ionmolecule has no features and reaches a maximum amplitude of $\sim 10^{-7}$ Jy/sr within the frequency range of 200 GHz to 800 GHz. The maximal contribution to absorption in rovibrational lines of HeH⁺ ion-molecule comes from redshifts 100 > z > 4.

The superposition of absorption profiles of the first molecules H₂ and HD, and ion-molecule HeH⁺ is shown on the left panel of Fig. 6. As you can see, despite zero electric dipole moments of molecules H₂, their absorption signal dominates over the HD absorption signal by two orders of magnitude and dominates over the HeH⁺ absorption signal by four orders of magnitude. This happens due to a larger population of hydrogen molecules among all other compounds in the early post-recombination Universe (see Fig. 1). From the right panel of Fig. 6, one can see that molecular absorption occurs in the Dark Ages of the Universe (lie in the redshift range 1000 < z < 30).

5. Discussion and conclusions

The global signal from first molecules is a useful source of information from yet undiscovered parts of the visible Universe. It can provide information about the thermal and ionization history of baryonic matter as well as the kinetics of primordial chemistry in the epoch of the Dark Ages. In standard cosmology, this signal takes a form of an absorption profile on the CMB spectrum. Our estimates of the expected signal from H₂ and HD molecules are of two orders of magnitude lower for the H₂ case and three orders of magnitude lower for the HD case compared to the results of Puy et al. (1993). This discrepancy can be explained by the difference in cosmological models. In the model we used, the baryon abundance is only $\Omega_b = 0.0493$ in contrast to $\Omega_b = 1$ in Puy et al. (1993). The difference in results was also influenced by the difference in the models of primordial chemistry used. What is similar to our results is the position of the H₂ and HD signals in the CMB spectrum.

The effects of primordial chemistry on the CMB spectrum was previously studied also in Schleicher et al. (2008) where free-free and bound-free absorption and emission processes were considered for ions H⁻ and He⁻ as well as for ion-molecules HD⁺ and HeH⁺. There, most promising results were obtained for the negative hydrogen ion H⁻ for which the relative change in the CMB temperature lies in the range $10^{-15} \leq \delta T_R/T_R \leq$ 10^{-6} for the frequency range of $10 \text{ GHz} < \nu < 2000 \text{ GHz}$ (see Fig. 10 in Schleicher et al. (2008)). The authors did not take into account absorption by H₂ and HD molecules, considering it to be relatively small.

To compare molecular absorption obtained here with the ionic absorption from Schleicher et al. (2008), we use the formula that relates small-amplitude intensity fluctuations to small-amplitude temperature fluctuations:

$$\frac{\delta I}{I} \approx f(x) \frac{\delta T_R}{T_R},$$

where $f(x) = x \cdot \exp(x)/(\exp(x) - 1)$, and $x = h\nu/k_BT_R$. At the frequency $\nu \approx 10^2$ GHz, where the absorption amplitude of first molecules is at maximum $\delta I \approx 0.9 \cdot 10^{-3}$ Jy/sr (see Fig. 6), the CMB specific intensity is equal to $I \approx 3 \cdot 10^8$ Jy/sr. For $\nu = 10^2$ GHz and $T_R \approx 2.7$ K we obtain $x \approx 1.7$ and $f(x) \approx 2.0$. Therefore, relative fluctuations of the CMB specific intensity at frequency $\nu = 10^2$ GHz is estimated at the level of $\delta I/I \approx 3 \cdot 10^{-12}$ in correspondence to relative fluctuations of the CMB temperature at the level of $\delta T_R/T_R \approx 1.5 \cdot 10^{-12}$. So the maximum of first molecules signal is located in the minimum of the signal from negative hydrogen ion (see Fig. 10 in Schleicher et al. (2008)), exceeding it by several orders of magnitude. This means that molecular absorption cannot be neglected in comparison to ionic absorption.

To assess the possibility of detecting a signal from the first molecules, other sources of the CMB spectrum distortion in the standard Λ CDM cosmology should be taken into account. These

are μ - and y-distortions, a temperature shift due to a relative error of the measured CMB temperature $|\Delta T_R/T_R| \leq 5 \times 10^{-4}$, and the cosmological recombination radiation (Desjacques et al. 2015). The frequency dependencies of the first three are monotonic and well-determined so that they can be removed from the overall signal. The latter depends on the details of the recombination of H and He at $z \sim 10^3$ and has a non-monotonic character with excess CMB emission at the frequency of $\sim 10^2$ GHz at the level of ~ 10^{-1} Jy/sr. These are two orders of magnitude larger than the signal from the first molecules.

Therefore, we conclude that detecting the signal from the first molecules will require the accuracy of predicting the cosmological recombination radiation up to the third order of magnitude, as well as a radio telescope with a sensitivity of \sim 10^{-4} Jy/sr with spectral resolution of several tens of GHz.

Note: Red and orange labels indicate reactions where reactants are destroyed, while blue and cyan show reactions where reactants are synthesized. Red and blue correspond to reactions with four reactants, and other colours to those with more. Article number, page 15 of 15
