The ribosomal exit tunnel is the primary structure affecting the release of nascent proteins at the ribosome. The ribosomal exit tunnels from different species have elements of conservation and differentiation in structural and physico-chemical properties. In this study, by simulating the elongation and escape processes of nascent proteins at the ribosomal exit tunnels of four different organisms, we show that the escape process has conserved mechanisms across the domains of life. Specifically, it is found that the escape process of proteins follows the diffusion mechanism given by a simple diffusion model and the median escape time positively correlates with the number of hydrophobic residues and the net charge of a protein for all the exit tunnels considered. These properties hold for twelve distinct proteins considered in two slightly different and improved Gō-like models. It is also found that the differences in physico-chemical properties of the tunnels lead to quantitative differences in the protein escape times. In particular, the relatively strong hydrophobicity of the E. coli's tunnel and the unusually high number of negatively charged amino acids on the tunnel's surface of H. marismortui lead to substantially slower escapes of proteins at these tunnels than at those of S. cerevisiae and H. sapiens.

## I. INTRODUCTION

The ribosomal exit tunnel is a narrow structure connecting the peptidyl transferase center (PTC), where the polypeptide polymerization takes place during translation, to the surface of the ribosome. It is the first structure encountered by the nascent polypeptides and is the only passage for nascent proteins to be released from the ribosome. The ribosomal exit tunnel is believed to play important roles in translation regulation<sup>1-3</sup> as well as cotranslational protein folding $^{4-6}$ . The tunnel dimensions, 10-20 Å in width and 80-100 Å in length, allow it to accommodate up to  $\sim 40$  amino acids<sup>7</sup> but limit the size of the folded peptide inside the tunnel<sup>8</sup>. In general, the protein and RNA composition of the ribosome can vary in different domains and different species, leading to different structural details of the exit tunnel. A comparison of the tunnel structures from a range of species have shown certain similarities and differences<sup>9</sup>. For example, it has been shown that the upper part of the tunnel, near the PTC, is relatively conserved across the species. On the other hand, the lower part of the tunnel is substantially narrower in eukaryotes than in bacteria, which may have implications for antibiotic resistance<sup>10</sup>.

The post-translational escape of nascent proteins at the ribosomal exit tunnel is the final release of a protein from the ribosome when the protein's N-terminus is no longer attached to the PTC. This process is a necessary step of a nascent protein to empty the ribosomal exit tunnel for the next translation process and to complete its own folding to the native state. Only very few studies have addressed this process until recently. In earlier works<sup>11,12</sup>, by coarse-grained simulations in the Gō-like models, we have shown that the escape process is assisted by the folding of the nascent protein and is akin to the diffusion of a Brownian particle in a linear potential field. In more recent works, by using the atomistic tunnel of H. marismortui, it was shown that the roughness of the exit tunnel can increase the difficulty of nascent proteins to escape<sup>13</sup> and that the escape time is modulated by energetic interactions of the protein with the exit tunnel, such as hydrophobic and electrostatic interactions<sup>14</sup>. Another study with the E. coli's tunnel suggests that electrostatic interaction can extremely delay the protein escape<sup>15</sup>.

The present study is aimed to extend our understanding of the protein escape process at the ribosomal exit tunnels of different species. In particular, we consider the exit tunnels from four organisms, namely E. coli, H. marismortui, S. cerevisiae and H. sapiens, which are representatives from all three domains of life (bacteria, archaea and eukarya). Their ribosome structures have been experimentally determined at high resolutions allowing us to have atomic details for the tunnel models used in the simulations. The belief is that the differences in the structural and chemical details of the exit tunnels considered will help us to have a more complete picture of the protein escape process at ribosomal exit tunnels.

We used the same simulation approach as in the previous study<sup>14</sup> to study the escape process but with a larger set of proteins and with improved models for the nascent proteins. The Gō-like models in the present study, namely the Gō-MJ and Gō-MJ-nn models, incor-

<sup>&</sup>lt;sup>a)</sup>Corresponding author, E-mail: txhoang@iop.vast.vn

porate the well-known Miyazawa-Jernigan's contact energy matrix in the depths of the Lennard-Jones potentials for native and non-native contacts, thereby to a certain degree take into account the effects of the amino acid sequences in the escape and folding of these proteins. The energy parameters in the Gō-like models are also rescaled such that the melting temperature in the model matches the experimental melting temperature of each protein.

We will show that while there are significant variations in the escape times among the exit tunnels of different organisms, the mechanisms governing the protein escape are remarkably similar at different exit tunnels suggesting that they are conserved across the domains of life.

### II. MODELS AND METHOD

#### A. Improved Gō-like models

Gō-like models have been widely used to study the protein folding dynamics due to their simplicity and effectiveness<sup>16–18</sup>. They are a class of models which emphasizes the importance of native interactions<sup>19</sup> and can be applied to any protein with a known native structure. In this work, we used two variants of improved Gō-like models to simulate nascent proteins: the first one incorporates variable strengths of the potentials for native contacts, and the second one includes also attractive potentials for non-native contacts. These models partially take into account the effects of the amino acid sequence through the use of the Miyazawa-Jernigan matrix for inter-residue contact energies<sup>20</sup>, in a similar manner to other Gō-like models used in the literature<sup>21–24</sup>.

#### Gō-MJ model

The Gō-MJ model is modified from the one of Clementi et al.<sup>25</sup> by adding a variation in the strengths of the potentials for native contacts. Considering only the  $C_{\alpha}$ atoms, the potential energy of a protein in a given conformation is given by

$$V_{G\bar{o}-MJ} = \sum_{\text{bonds}} K_b (r_{i,i+1} - r_{i,i+1}^*)^2 + \sum_{\text{angles}} K_\theta (\theta - \theta^*)^2 + \sum_{\text{dihedrals}} \sum_{n=1,3} K_\phi^{(n)} [1 - \cos(n(\phi - \phi^*))] + \sum_{j>i+3}^{\text{native}} \epsilon_{ij}^{\text{NC}} \left[ 5 \left( \frac{r_{ij}^*}{r_{ij}} \right)^{12} - 6 \left( \frac{r_{ij}^*}{r_{ij}} \right)^{10} \right] + \sum_{j>i+3}^{\text{non-native}} \epsilon \left( \frac{\sigma}{r_{ij}} \right)^{12}, \qquad (1)$$

where the terms on the right side correspond to the potentials on the bond lengths, bond angles, dihedral angles, native contacts and non-native contacts, respectively, as described in detailed elsewhere<sup>13,25</sup>. The native

contacts are determined from an all-atom consideration<sup>26</sup> of the protein structure from the Protein Data Bank (PDB) and the atomic van der Waals radii<sup>27</sup>.  $r_{ij}$  is the distance between residue *i* and residue *j*, the \* symbol denotes the native state's value,  $\sigma$  is an effective diameter of amino acids, and  $\epsilon$  is an energy parameter. The value of  $\epsilon_{ij}^{\rm NC}$ , which sets the potential depth for a native contact, is calculated as

$$\epsilon_{ij}^{\rm NC} = \frac{n_{ij}e_{\rm HB} + e_{\rm MJ}(s_i, s_j)}{u} \,\epsilon,\tag{2}$$

where  $n_{ij}$  is the number of hydrogen bonds between residue *i* and residue *j* in the native state,  $e_{\rm HB} =$ 1.5 kcal/mol is a hydrogen bond's energy,  $e_{\rm MJ}(s_i, s_j)$  is the inter-residue contact energy for the pair of amino acids of the types  $s_i$  and  $s_j$  given by the Miyazawa-Jernigan matrix<sup>20</sup> with the energy converted to kcal/mol and given in the absolute value; *u* is a normalizing factor, such that the average energy of all the native contacts is  $\epsilon$ . Other parameters in the model are  $\sigma = 5$  Å,  $K_b =$  $100 \ \epsilon \ {\rm A}^{-2}$ ,  $K_{\theta} = 20 \ \epsilon \ ({\rm rad})^{-2}$ ,  $K_{\phi}^{(1)} = \epsilon$ ,  $K_{\phi}^{(3)} = 0.5\epsilon$ .

### Gō-MJ-nn model

In the Gō-MJ-nn model, the last term in Eq. (1) is replaced by

$$\sum_{j>i+3}^{\text{non-native}} \epsilon_{ij}^{\text{NN}} \left[ 5 \left( \frac{\sigma_1}{r_{ij}} \right)^{12} - 6 \left( \frac{\sigma_1}{r_{ij}} \right)^{10} \right], \qquad (3)$$

which provides attraction to the non-native contacts. The potential depth for a non-native contact is calculated as

$$\epsilon_{ij}^{\rm NN} = f \, \frac{e_{\rm MJ}(s_i, s_j)}{u} \, \epsilon, \tag{4}$$

where f is a factor that sets the relative strengths of nonnative contacts. In the present study, we used  $\sigma_1 = 5.5$  Å and f = 0.4.

In both the Gō-MJ and Gō-MJ-nn models,  $\epsilon$  is the single parameter that sets the energy scale of the whole protein. Because temperature effects are important for the dynamics of proteins, especially for their diffusion in the ribosomal tunnel, it is important to have the correct energy scale for each protein. Following the previous work<sup>14</sup>, we determined  $\epsilon$  individually for each protein by fitting the melting temperature in the model to the experimental melting temperature,  $T_m$ . The melting temperature of the specific heat's maximum of a protein obtained by simulations. The parameter  $\epsilon$  is calculated as  $\epsilon = \frac{(273+T_m)}{503.2195 \times T_{max}}$  (kcal/mol), where  $T_{max}$  is given in units of  $\epsilon/k_B$  and  $T_m$  is given in °C. The values of  $T_{max}$  and  $\epsilon$  in both Gō-MJ and Gō-MJ-nn models for a list of 12 proteins considered are given in Table S1.

### B. Tunnel model

Models of the exit tunnels are constructed based on the PDB structures of the large ribosomal subunits of the organisms. The structures of the PDB IDs  $7k00^{28}$ ,  $1jj2^{29}$ , 5gak<sup>30</sup> and 4ug0<sup>31</sup> and considered for the ribosomes of E. coli, H. marismortui, S. cerevisiae and H. sapiens, respectively. The model considers all the heavy atoms for ribosomal RNA but only  $C_{\alpha}$ 's for ribosomal proteins. To reduce computational time, we kept only atoms within a cylinder of radius R centered around an approximate chosen tunnel axis for the tunnel model. The value of R must be sufficiently large to enclose the atoms of the tunnel's wall. We have chosen R = 30 Å for the ribosome tunnels of H. marismortui, S. cerevisiae and H. sapiens and R = 45 Å for that of E. coli. The model also ignores the motion of the ribosome, thus all the tunnel atoms are kept fixed during the simulations.

For interactions of the tunnel with nascent proteins, the model used in this study is the T3 model described in Ref.<sup>14</sup>, which contains three types of interactions: excluded volume, hydrophobic and electrostatic. Details of the interaction potentials are given in Ref.<sup>14</sup>. In short, the exclude volume interaction provides a short-range repulsion between the tunnel's atoms and the nascent chain's residues. The hydrophobic interaction gives an attraction between hydrophobic residues (Ile, Leu, Phe, Met, Val, Pro, Trp) of a nascent protein and those of the same type in ribosomal proteins via a 10-12 Lennard-Jones potential. The depth of this potential is constant for all pairs of hydrophobic residues and is equal to  $\epsilon_{\rm hvdr} = 1.2$  kcal/mol. The electrostatic interaction is given by a screened Coulomb potential from the Debye-Hückel theory with the Debye's screening length  $\lambda_D = 10$  Å. The electrostatic interaction is considered between all charged residues of a nascent protein and all charged centers of rRNA and ribosomal proteins. In rRNA, each phosphorus atom is assigned with the charge q = -1e. In nascent and ribosomal proteins, lysine and arginine are given with the charge q = +1e, whereas aspartic acid and glutamic acid are given with q = -1e. The charges of amino acids are assumed to be concentrated on the  $C_{\alpha}$  atoms.

### C. Simulation method

A molecular dynamics (MD) method based on the Langevin equation of motion is used to simulate the motions of nascent chains. Details of the method are given in Ref.<sup>11</sup>. We adopt a reduced unit system such that the mass unit is the average mass m of amino acids, the length unit is the effective diameter  $\sigma$  of amino acids, and the energy unit is kcal/mol. The friction coefficient of amino acids used in the simulations is  $\zeta = 1 \sqrt{m\sigma^{-2}(\text{kcal/mol})}$ . Given that m = 120 g/mol and  $\sigma = 5 \text{ Å}$ , the simulation time is measured in the units of  $\tau = \sqrt{m\sigma^2/(\text{kcal/mol})} \approx 3 \text{ ps}$ . This value of

the time unit, suitable for the low-friction regime<sup>32</sup>, results in a much shorter timescale of the simulation folding times than the real folding times. It has been shown that the correct timescale can be reached by simulations by increasing  $\zeta$  to its realistic value and using the high-friction estimate,  $\tau_H = 3$  ns, of the time unit<sup>14,32,33</sup>.

For an isolated protein, the temperature of the specific heat's maximum  $T_{\text{max}}$  is determined from the temperature dependence of the specific heat by using replicaexchange molecular dynamics (REMD) simulations<sup>34</sup> and the weighted histogram analysis method  $^{35,36}$ . For studying the protein escape at a ribosome tunnel, both the translation process and the escape process are simulated. In the translation process, a nascent chain is elongated at the position of the PTC at a constant rate corresponding to a growth time  $t_q$  per residue.  $t_q$  must be chosen sufficiently large such that the escape properties are converged given that the growth times in cells are orders of magnitude larger than in simulations. We used  $t_g = 400\tau$  for most proteins, and  $t_g = 2000\tau$  for proteins that are kinetically trapped at the tunnel. The escape time is measured from the moment of complete elongation (the C-terminal residue is released from the PTC) until the nascent protein has fully escaped the tunnel. All simulations of the translation and escape processes of proteins are carried out at the room temperature T = 300 K. Typically, the escape time distribution and the escape probability are calculated from 1000 independent trajectories for each protein.

### D. Diffusion model

The diffusion model<sup>12</sup> considers the protein escape process as the diffusion of a Brownian particle in a onedimensional potential field U(x) with x the position of the particle. Such process is governed by the Smoluchowski equation. Given the linear form U(x) = -kx of the external potential, where k is a constant force acting on the particle, the distribution of the escape time can be obtained from an exact solution of the Smoluchowski equation and is given by<sup>12</sup>

$$g(t) = \frac{L}{\sqrt{4\pi Dt^3}} \exp\left[-\frac{(L - D\beta kt)^2}{4Dt}\right],$$
 (5)

where L is diffusion distance equal to the tunnel length, D is the diffusion constant assumed to be position independent,  $\beta = (k_B T)^{-1}$  is the inverse temperature where  $k_B$  is the Boltzmann constant. Interestingly, the escape time distribution in Eq. (5) can fit the data from various simulations of protein escape in the Gō-like model<sup>12–14</sup>. It has been shown that the free energy of a protein at the ribosome tunnel is approximately linear along an escape coordinate<sup>11,14</sup>, which justifies the linear form of U(x) in the diffusion model.

The distribution in Eq. (5) gives the mean value  $\mu_t = L/(D\beta k)$  and the standard deviation  $\sigma_t = \frac{\sqrt{2L}}{D(\beta k)^{3/2}}$  for

the escape time<sup>12</sup>. Note that both  $\mu_t$  and  $\sigma_t$  diverges when k = 0, for which g(t) becomes a heavy-tailed Lévy distribution.

#### III. RESULTS

# A. Differences in physico-chemical properties of nascent proteins and the ribosomal exit tunnels

This study considered twelve small globular proteins with known melting temperatures  $T_m$ . They consist of the B1 domain of protein G  $(1pga)^{37}$ , Rop protein  $(1rop)^{38}$ , the SH3 domain  $(1shg)^{39}$ , the Z domain of Staphylococcal protein A (2spz)<sup>40</sup>, Cro repressor  $(1 \text{ or } c)^{41}$ , chymotrypsin inhibitor 2  $(2 \text{ ci } 2)^{42}$ , antifreeze protein  $(1 \text{ msi})^{43}$ , cold-shock protein  $(1 \text{ csp})^{44}$ , ubiqui- $(1ubq)^{45}$ , histidine-containing phosphocarrier protein HPr (1poh)<sup>46</sup>, hyperthermophilic archaeal DNA-binding protein Sso10b2  $(1udv)^{47}$ , and barnase  $(1a2p)^{48}$  with the PDB IDs of their native structures enclosed in the parentheses. The references associated with the proteins correspond to the experimental studies in which  $T_m$  has been reported (see Table S1 for the values of  $T_m$  and other properties of the proteins). For convenience, we will call the proteins by their PDB IDs. These proteins have lengths between 56 and 108 amino acids and distinct native structures with two all- $\alpha$ , two all- $\beta$  and eight  $\alpha/\beta$  proteins. Their  $T_m$  values range from 43.8°C (for 1csp) to 157.5°C (for 1udv). Our analyses show that the fraction of hydrophobic residues in their amino acid sequences varies from  $\sim 21\%$  to  $\sim 47\%$ , the fraction of positively charged amino acids varies between  $\sim 6\%$  and  $\sim 18\%$ , and the fraction of negatively charged amino acids ranges from  $\sim 6\%$  and  $\sim 19.6\%$ . The protein net charges are from -6e to +3e. These properties indicate that the proteins considered have a wide range of specificities leading to diverse interactions with the exit tunnel.

All proteins in our considerations are small-sized and cannot compare to any protein length distribution in proteomes (Fig. S1). However, it can be expected that the chain length does not impact the escape time, as shown in one of our previous studies<sup>12</sup>. The structural class, on the other hand, can have a minor effect on the protein escape with  $\alpha$ -proteins escaping somewhat more slowly than  $\beta$ -proteins<sup>12</sup>. We have checked that the structural class composition of our set of proteins is not too different from that of Richardson's Top2018 high-quality protein structures<sup>49</sup> with a strong dominance of  $\alpha/\beta$ proteins (see Table S2). Even though our protein set is quite small with only 12 proteins, its protein sequences have similar ranges of hydrophobicity and fractions of positively and negatively charged amino acids as found in various proteomes, whose sequences are taken from the UniProt database<sup>50</sup> (Figs. S2 and S3). For example, the range of fraction of hydrophobic amino acids in our 12 proteins is shared by 97% of the protein population in the human proteome, whereas the corresponding numbers for

Organism	$N_h^{(t)}$	$N_{+}^{(t)}$	$N_{-}^{(t)}$
E. coli	46	30	4
H. marismortui	35	26	19
S. cerevisiae	33	32	4
H. sapiens	37	26	1

TABLE I. Hydrophobic and charged properties of ribosomal exit tunnels' surfaces of the organisms. For each organism, the listed properties are the number of hydrophobic residues  $(N_h^{(t)})$ , the numbers of positively  $(N_+^{(t)})$  and negatively  $(N_-^{(t)})$  charges of ribosomal amino acid residues that are found at the tunnel's surface. Note that these properties do not refer to the ribosomal RNA.

the ranges of fractions of positively and negative charged amino acids are 92% and 88% (Fig. S2 (a-c)). In the proteomes of S. cerevisiae (Fig. S2 (d-f)) and E. coli (Fig. S3 (a-c)), these percentages are also very high ranging from 84% to 98%. The proteins in the H. marismortui's proteome (Fig. S3 (d-f)) tend to have a lower fraction of positively charged amino acids and a higher fraction of negatively charged amino acids than in the other organisms, resulting in only 78% and 68% of the proteome sharing the ranges of these two fractions, respectively, with the 12 proteins considered. These statistics suggest that the chosen proteins to a good extent reflect the variabilities of hydrophobic and charge compositions of the proteins in the organisms considered, though they do slightly worse for H. marismortui. They can be considered as representative of typical globular proteins in terms of hydrophobic and charge fractions in the amino acid sequences.

The ribosomal exit tunnels of the four organisms considered have notable differences and similarities. The differences in the shape of these tunnels can be visualized through the graphs representing their effective diameter d along the tunnel axis x shown in Fig. 1(a). For each position x, d is calculated as  $d = 2\sqrt{(S/\pi)}$ , where S is the tunnel's cross-sectional area accessible by a probe sphere of radius 3 Å. Although the effective diameter does not reflect all information about the shape of a tunnel, it already shows that the detailed shapes are different for different species. The diameter of the H. marismortui's tunnel appears to be the most uniform while the other tunnels show stronger variations of d. The tunnel of E. coli is somewhat wider than the other tunnels<sup>9</sup>. The diameter profiles in Fig. 1(a) also show some similarities, such as the average widths of the tunnels are more or less the same, the tunnels become wider near the exit, and the position at which the tunnel is narrowest appears to be about half-way from the opening of the tunnel for all tunnels. The d profile of S. cerevisiae looks the most similar to that of H. sapiens.

We have inspected the tunnel surfaces to get information about the hydrophobic and charged amino-acid residues exposed on the surface from ribosomal proteins. The numbers of these residues for each tunnel are listed in

FIG. 1. (a) Dependence of the effective diameter, d, on the coordinate x along an approximate tunnel axis for the ribosomal exit tunnels of 4 organisms considered. The lines shown are for E. coli (dashed), H. marismortui (dash-dotted), S. cerevisiae (dotted) and H. sapiens (solid) as indicated. The effective diameter d is calculated as  $d = 2\sqrt{(S/\pi)}$ , where S is the tunnel cross-sectional area accessible for a probe sphere of radius 3 Å. (b) Distribution of hydrophobic residues at the tunnel surface along the tunnel axis for the considered species as indicated. For a given data point at position x,  $n_h^{(t)}$  is the number of surface's hydrophobic residues within 5 Å from xalong the tunnel axis.

Table I. The distribution of hydrophobic residues along the tunnel axis is shown in Fig. 1(b). It is found that E. coli has the highest number of hydrophobic residues on the tunnel surface, about 30% higher than the other organisms. The hydrophobic residues are the most abundant near the tunnel exit for E. coli, S. cerevisiae and H. sapiens (Fig. 1(b)). It is interesting to note that almost all the charges of amino acids on the tunnel surface are positive charges for E. coli, S. cerevisiae and H. sapiens (Table I), suggesting that the charged amino acids play an important role for the function of the exit tunnel. Note that the ribosomal RNA is negatively charged so only positively charged amino acids can significantly change the electrostatic potential inside the tunnel. An exception is found for H. marismortui, for which the number of negatively charged amino acids on the tunnel surface is much higher than in the other organisms, even

though it is still significantly smaller than the number of positively charged ones (19 vs. 26). The distinction of the electrostatics of H. marismortui's tunnel may be related to the fact that this species can survive in extreme environmental conditions, such as at high temperatures, with high salt concentration, or at high or low pH.

# B. Conservation of the diffusion mechanism of the escape process

We have carried out simulations of the nascent chain's growth and the escape processes of all proteins considered in the Gō-MJ model at the four ribosomal tunnels and in the Gō-MJ-nn model at the human ribosomal tunnel only. In most cases, the protein can escape easily at the exit tunnel, but for several proteins at some of the tunnels, kinetic trapping can delay the escape. A kinetic trap is found in a simulation if the protein get stuck in some state at the tunnel leading to a much longer escape time, more than 10 times longer than in an average trajectory. Kinetic trapping can be due to the roughness in the shape of the exit tunnel as well as the interactions between nascent proteins and the tunnel wall<sup>13,14</sup>. Interestingly, it has been shown that the probability of trapping of a protein decreases with the growth time per residue  $t_g$ , and can become negligibly small at realistic translation rates<sup>14</sup>. In our study, we have simulated the easily escaped proteins with  $t_g = 400\tau$ , whereas those with kinetic trapping with the increased  $t_g = 2000\tau$ . The latter value of  $t_q$  reduces the trapping probability to below 5% and makes the statistics reliable. We have checked that further increase of  $t_q$  produces very little changes to the escape time distribution and the median escape time.

Figure 2 shows that the escape probability,  $P_{\rm escape}$ , increases sigmoidally with time and asymptotically approaches the value of 1 for all proteins in both Gō-MJ and Gō-MJ-nn models at the human ribosomal exit tunnel. The proteins also escape efficiently at all other ribosomal exit tunnels. The proteins that are more likely to get kinetically trapped are 1pga, 1rop, 1orc and 1udv with 1udv being the slowest escaper. The median escape time,  $t_{\rm esc}$ , the time at which  $P_{\rm escape} = 0.5$ , varies among the proteins from a few hundred to a few thousand  $\tau$  (see Table III).

We inspected the diffusion mechanism of the escape process by examining the escape time distributions of the proteins. The model mechanism is that of the diffusion model described in Section II. B, which corresponds to the diffusion of a one-dimensional Brownian particle in a linear potential field. Interestingly, for all proteins and all the tunnels considered, the escape time distribution follows relatively well that of the diffusion model. For example, Figure 3 shows that the histogram of the escape times of the 2ci2 protein obtained by the simulations can be fitted to the distribution function in Eq. (5) for all the exit tunnels considered. Thus, the diffusion mechanism is conserved among the proteins and

TABLE II. Diffusional properties of the protein escape process at ribosomal exit tunnels. The proteins are identified by their PDB ID (first column) and the chain length, N. For each protein, the properties given are the diffusion constant D and the pulling force k of the diffusion model, whose values, in units of  $Å^2 \tau^{-1}$  and pN, respectively, are obtained by fitting the histograms of escape times from simulations to the diffusion model (see text). The names of the organisms and the model for nascent proteins considered are given on tops of the D and k columns.

FIG. 2. The escape probability,  $P_{escape}$ , as a function of time at T = 300 K for proteins in the Gō-MJ (a, b) and the Gō-MJnn (c, d) model at the human ribosomal exit tunnel. The 8 proteins in panels (a) and (c) were simulated with  $t_g = 400\tau$ whereas the 4 proteins in (b) and (d) were simulated with  $t_g = 2000\tau$ . An increased value of  $t_g$  was used because the latter proteins have higher probabilities of kinetic trapping.

among the species although the individual distributions can be different from each other. From the fits to the diffusion model we can get the values of the parameters Dand k, which can be considered as an effective diffusion constant of a protein at a tunnel and an effective mean force acting on the protein along the escape coordinate, respectively. These are highly collective quantities which reflect the complex dynamics of nascent proteins at the

FIG. 3. Distributions of the escape time for the 2ci2 protein in the Gō-MJ model at the ribosomal tunnels of E. coli (a), H. marismortui (b), S. cerevisiae (c), H. sapiens (d) and in the Gō-MJ-nn model at the H. sapiens ribosomal tunnel (e). The normalized histograms obtained by simulations (boxes) are fitted to the diffusion model (solid line) by using Eq. (5). The simulations were carried out at the temperature T = 300 K and with the growth time per residue  $t_g = 400\tau$ .

exit tunnels. The values of D and k are listed in Table II for all the proteins in each tunnel. They strongly vary with the protein and with the tunnel (Fig. S4). D is in the range from 0.4 to 1.2 Å<sup>2</sup>  $\tau^{-1}$ . With  $\tau = 3$  ps, the

obtained values of D are of the order of  $10^{-8}$  m<sup>2</sup> s<sup>-1</sup>, i.e. about two orders of magnitude larger than diffusion constants of isolated proteins in water  $(\sim 10^{-10} \text{ m}^2 \text{ s}^{-1})^{51}$ . Note that D depends on the friction coefficient  $\zeta$  and the value of  $\zeta$  used in the simulations is 100 times smaller than that of amino acids in water<sup>14</sup>. It is expected that at realistic friction, D is smaller but of the same order of magnitude to that of isolated proteins. The force k varies more strongly than D. It is interesting that the obtained values of k are in the range from a sub-piconewton to few tens of piconewtons, which is within the scale of molecular forces in proteins<sup>52</sup>.

# C. Conservation of the effects of hydrophobic and electrostatic interactions on the protein escape time

To evaluate the effects of the tunnel's interactions on the protein escape, we investigated the dependence of the median escape time,  $t_{esc}$ , on the number of hydrophobic residues,  $N_h$ , and the net charge, Q, of a protein (Table III). Figure 4 shows that  $t_{esc}$  positively correlates with both  $N_h$  and Q for all the species considered indicating that both the hydrophobic and electrostatic interactions modulate the escape time. The Pearson's correlation coefficient R varies from about 0.42 to about 0.84 for different tunnels and protein models. The *p*-values for these correlations, calculated using the one-tailed Student's ttest, are given in the panels of Fig. 4. Except the one case shown in Fig. 4 (b) for the H. marismortui's tunnel, which shows a weak correlation between  $t_{esc}$  and  $N_h$ (R = 0.418 and p = 0.088), all other correlations have medium to high R-values and are statistically significant (p < 0.05). The correlation of  $t_{esc}$  with Q is higher than the correlation with  $N_h$  for all the tunnels except for E. coli. Thus, the effect of electrostatic interaction on the protein escape tend to be stronger than that of the hydrophobic interaction, though this still depends on the tunnel.

It is expected that the C-terminal segment of a protein is most relevant to its escape  $process^{15}$ . We have checked that by calculating  $N_h$  and Q only for the C-terminal 50 residues, as shown in Fig. S9, the correlation of  $t_{esc}$  with  $N_h$  becomes very poor or almost disappears for all the tunnels, while the correlation with Q remains statistically significant and even slightly improves for some tunnels compared to the cases without the C-terminal cut-off. This result indicates that the impact of electrostatic interaction on the protein escape time is dominating over hydrophobic interaction for residues near the protein Cterminus. The impact of hydrophobic interaction on the protein escape seems to appear with a longer protein segment (the longest protein in our study is barnase with 108 residues), as indicated by the correlations in Fig. 4. However, in longer proteins, it is unlikely that residues too distant from the C-terminus can influence the escape time.

Following the previous  $work^{14}$ , we tested the depen-

dence of  $t_{esc}$  on a linear function of both  $N_h$  and Q. The form of the function chosen is  $(1-s)N_h + sQ$  where  $s \in (0, 1)$  is a tunable parameter. We find that this function yields a better correlation with  $t_{esc}$  than both  $N_h$ and Q alone at some intermediate value of s (Fig. S6). Figure 5 plots the dependence of  $t_{esc}$  on the function  $(1-s)N_h + sQ$  for the optimal value of s, i.e. the value that maximizes the correlation coefficient R, for all the tunnels and the protein models considered. The values of R in these plots range from 0.668 to 0.885 and all the p-values are < 0.01. The best correlations are found for the tunnels of S. cerevisiae and H. sapiens with R exceeding 0.8. For the H. sapiens tunnel, the Gō-MJ-nn model yields a better correlation than the Gō-MJ model.

The above results show that the effects of hydrophobic and electrostatic interactions on the protein escape time at different exit tunnels are qualitatively similar. Generally, increasing  $N_h$  and Q leads to an increased escape time, though the quantitative effects depends on the protein and the tunnel.

The common mechanism of these effects is that attraction between the protein and the tunnel slows down the protein escape while repulsion speeds it  $up^{14}$ . The slowest escape is found for protein 1udv at the H. marismortui's tunnel with  $t_{esc} \approx 5800\tau$  (Fig. S5) due to a strong electrostatic attraction between the protein and the tunnel. The 1udv protein has the highest net charge among the proteins (Q = +3e) (Table III) while the H. marismortui's tunnel has the highest number of negatively charged amino acid residues on the tunnel's surface  $(N_{-}^{(t)} = 19)$  (Table I). We have checked that switching off the electrostatic interaction of 1udv drastically reduces its median escape time by 10 times to about  $600\tau$ . An example for a strong effect of hydrophobic interaction is of the protein 2ci2 at the E. coli's tunnel with  $t_{esc} \approx 1900\tau$ . The 2ci2 is among the proteins with the highest numbers of hydrophobic residues  $(N_h = 29)$  (Table III) and E. coli has the highest number of hydrophobic residues on the tunnel's surface  $(N_h^{(t)} = 46)$  (Table I).

# D. Effects of non-native interactions on the escape process

The effects of non-native interactions on the protein escape time can be seen by comparing the results of the Gō-MJ and the Gō-MJ-nn models at the human ribosomal exit tunnel. It is shown that the two models yield qualitatively and quantitatively similar results, in the escape time distribution (Fig. 3) as well as in the dependence of of  $t_{esc}$  on  $N_h$  and Q (Figs. 4 and 5). A more careful examination shows that non-native interactions reduce the escape time by 4% to 28% depending on the protein (Table III). This reduction effect is consistent with a result for homopolymer models, which shows that selfattractive polymers escape faster than self-repulsive polymers for polymer lengths larger than about 60 residues (Fig. S7). Non-native interactions that are governed by

TABLE III. Median escape times of proteins at the ribosomal exit tunnels of different organisms. The proteins are listed with the number of hydrophobic residues,  $N_h$ , the net charge, Q, and the median escape times,  $t_{esc}$ , given in units of  $\tau$  obtained by simulations. The names of the organism and the protein model used in the simulations are given on top of each  $t_{esc}$  column.

FIG. 4. Dependence of the median escape time,  $t_{esc}$ , on the number of hydrophobic residues,  $N_h$ , (a–e) and the total charge, Q, (f–k) of nascent proteins at the ribosomal exit tunnels of different species. The names of the species and the protein model are given on top of each panel. Dashed line represents a linear fit. The Pearson's correlation coefficient R and the corresponding p-value calculated using the one-tailed Student's t-test are given in each figure.

attractive potentials energetically drive the protein escape because the chain can form more non-native contacts if it is found outside the tunnel. Even though the native contacts can be more competitive in energy compared to the non-native contacts as assumed in the  $G\bar{o}$ -MJ-nn model, they are fewer in numbers and some of the native contacts cannot be formed once the protein has not been fully escaped. This effect can be seen for protein 2ci2 by looking at the distributions of native and non-native contacts, and radius of gyration of the protein conformations at the moment of complete translation at the human ribosomal tunnel (Fig. S8). These distributions show that, on average, the  $G\bar{o}$ -MJ-nn model yields more compact conformations with smaller numbers of native contacts and larger numbers of non-native contacts than the Gō-MJ model.

# IV. DISCUSSION

It is suggested that the driving forces for the protein escape come from different sources, including (i) an enthalpic preference associated with the folding of a nascent protein near the tunnel<sup>11,53</sup>, (ii) an entropy gain of a chain emerging from the tunnel<sup>54</sup>, and (iii) the stochastic motion of a partially folded chain leading to a kind

FIG. 5. Dependence of the median escape time,  $t_{esc}$ , on the function  $(1-s)N_h+sQ$  of the number of hydrophobic residues,  $N_h$ , and the total charge, Q, of nascent proteins at the ribosomal exit tunnels of E. coli (a), H. marismortui (b), S. cerevisiae (c), and H. sapiens (d, e). The proteins are considered in the Go-MJ model (a-d) and in the Go-MJ-nn model (e). The names of the species and the protein model are given on top of each panel. The dependence is shown for the value of s that maximizes the correlation coefficient R. The values of s, R, and p are given in each panel. Dashed line shows a linear fit of the data.

of diffusion process<sup>11,12</sup>. The mechanical forces of the first two types, in ribosome stalling and ribosome bound systems, have been quantified experimentally<sup>53,54</sup> and also computationally<sup>54,55</sup>, giving values from several to about 12 piconewtons. Apart from these sources, the force governing the protein escape may also come from interactions of nascent chains with the ribosomal tunnel. Electrostatic repulsion and attraction as well as hydrophobic attraction can speed up or slow down the escape process<sup>14,15</sup>.

The mean force from all the above sources acting on a nascent protein at the ribosome may be well represented by the force k in the diffusion model, which can be obtained by non-equilibrium methods via the escape time distribution. Interestingly, the magnitude of k found in the present study for different proteins and ribosomes (Table II) is similar to the mechanical forces reported in other studies<sup>53–55</sup>. For a tunnel that has energetic interactions with nascent proteins, the force acting on a

protein by the tunnel may contribute or counter balance the other forces depending on whether it is attractive or repulsive. If the attraction to the tunnel is sufficiently strong, the protein may have very long escape times and may not follow the diffusion model. The slowest escaping protein in our consideration is 1udv at the H. marismortui's model, having a very small force k = 0.396 pN. The escape time distribution of this protein has a long tail but still follows the diffusion model (Fig. S5). Note that the diffusion model predicts that for k = 0 both the mean escape time and the dispersion diverge (see Methods). It is possible that some proteins can have  $k \leq 0$  resulting in infinite escape times.

In a recent work<sup>15</sup>, Nissley et al. have reported very long ejection times of some proteins at the E. coli's tunnel, including the ones with PDB IDs 2jo6, 1u0b and 4dcm, using similar coarse-grained simulations. We have checked that the fractions of hydrophobic amino acids as well as the fractions of positively and negatively charged amino acids of these three proteins are within the ranges given by the 12 proteins considered. Furthermore, 2jo6 and 4u0b have negative net charges for the whole chain (for the C-terminal 50 residues, the net charge is zero for 2jo6 and -1e for 1u0b), suggesting that they are not slow escapers due to overall electrostatic repulsion with the tunnel. Indeed, our simulations of 2io6 and 1u0b at the E. coli's tunnel, using an averaged value of  $\epsilon$  from the 12 proteins studied, show that they escape efficiently with the median escape time  $t_{esc} \approx 666\tau$  for 2jo6 and  $t_{esc} \approx 1270\tau$  for 1u0b (Fig. S10), i.e. within the same range of escape times as for other proteins. It is also found that their escape time distributions are consistent with the conserved mechanism given by the diffusion model (Fig. S10). Including these two proteins into the initial set of 12 proteins, however, slightly deteriorates the correlations of  $t_{esc}$  with  $N_h$  and Q (Fig. S11). It would be interesting to check what specific detail causes the extreme delay of the escape process in Nissley et al.'s approach. We did not simulate 4dcm because the PDB structure of this protein is not contiguous containing missing residues. This protein, however, is expected to escape very slowly because it has a positive net charge of Q = +8e in the C-terminal 50 residues, compared to +5e in 1udv, the slowest escaping protein in the 12 proteins considered.

The previous work<sup>14</sup> has estimated the timescale of the protein escape times to be of the order of 0.1–1 ms by rescaling the simulation times to the values at the realistic friction and simultaneously using the high-friction value of the time unit,  $\tau_H = 3 \text{ ns}^{32,33}$ . In accordance to this estimation, the longest median escape times of the proteins in the present study are of the order of 10 ms, which is still shorter than the times needed by the ribosome to translate one codon. Given that the 12 proteins considered can be representative for most proteins in the proteomes in terms of hydrophobic and charge fractions as discussed in Section III.A, this result suggests that typical proteins escape efficiently at the ribosome tunnel

and do not delay the ribosome's new translation cycle.

# V. CONCLUSION

The ribosomal exit tunnel has many structural and chemical elements that could affect the post-translational escape of nascent proteins. These elements include the irregular shape of the tunnel, the exposed hydrophobic side-chains of the ribosomal proteins and the charged amino acids on tunnel's surface. The exit tunnels from different organisms of different domains of life, as the ones considered in our study, show significant differences in structural and physico-chemical properties beside certain similarities. The present study shows that despite all these differences of the exit tunnels, the protein escape process has conserved mechanisms across the domains of life. First, it is shown that the escape process follows the simple diffusion mechanism described by the diffusion model. This property holds true for twelve proteins of distinct native structures and diverse physico-chemical properties within two different protein models that are given with and without non-native interactions. Second, the median escape time,  $t_{esc}$ , positively correlates with both the number of hydrophobic residues,  $N_h$ , and the net charge, Q, of protein, with a sufficient statistical significance in most cases. This property underlines the simple mechanism that attraction between the protein and the tunnel slows down the protein escape while repulsion speeds it up. The effects of hydrophobic and electrostatic interactions on the escape time are additive to each other as indicated by improved correlations when considering the dependence of  $t_{esc}$  on a linear function of  $N_h$  and Q. These results reinforce our understanding of the protein escape process as the one that is simple and predictable. The results also suggest that the impact of electrostatic interaction on the escape time is stronger than that of hydrophobic interaction and becomes dominant towards the C-terminal residues of nascent proteins. It is expected that proteins with a high positive net charge in the Cterminal segment may have unusually long escape times.

Our study also shows significant variations among the organisms when considering the quantitative effects of the exit tunnels on the escape process. The exit tunnels of E. coli and H. marismortui generally yield longer protein escape times than that of S. cerevisiae and H. sapiens. These observations are related to the facts that E. coli has  $\sim 30\%$  higher number of hydrophobic residues exposed inside the exit tunnel than the other organisms, and H. marismortui has the number of negatively charged amino acids on the tunnel's surface that is substantially larger than the other organisms (19 vs. 1 to 4). From an evolutionary perspective, it could be that the exit tunnels of S. cerevisiae and H. sapiens have evolved to deal with a larger number of proteins in their genomes in suppressing the escape time. The argument for this hypothesis is that a too slow escape of a nascent protein from the exit tunnel could hamper the ribosome productivity, thus it is

beneficial to have an exit tunnel that allows all proteins in the genome to escape efficiently.

## SUPPLEMENTARY MATERIAL

See supplementary material for the list of 12 proteins considered with selected properties, for the structural class compositions of Richardson's Top2018 dataset and our protein set, for the distributions of protein length in various proteomes, for the histograms of hydrophobicity and charges in protein sequences of various proteomes, for the dependences of the diffusion constant D and the force k from the diffusion model on the chain length, N, of proteins, for the escape properties of protein 1udv, for the dependence of the correlation coefficient R between the median escape time and the function  $(1-s)N_h + sQ$ on the parameter s for the tunnels and protein models considered, for the escape properties of self-repulsive and self-attractive homopolymers, for an analysis of the effects of non-native interactions on the escaping conformations, for the correlations of  $t_{esc}$  with  $N_h$  and Q calculated for the C-terminal 50 residues, for the histograms of escape times and the escape probabilities of 2jo6 and 100b proteins, and for the correlations of  $t_{esc}$  with  $N_h$ and Q by adding 2jo6 and 1u0b to the initial protein set.

## ACKNOWLEDGEMENTS

This research is funded by Graduate University of Science and Technology under grant number GUST.STS.DT2020-VL03 for the postdoctoral fellowship of Phuong Thuy Bui. We also acknowledge the supports of the Institute of Physics and the Centre for Informatics and Computing of VAST for the use of their computer clusters.

TABLE S1. List of 12 proteins considered with selected properties. Each protein is given with the PDB ID of its native structure (ID), the structure classification (Class), the experimental melting temperature  $(T_m)$ , the protein length in the number of amino acid residues (N), the number of hydrophobic residues  $(N_h)$ , the numbers of positively  $(N_+)$  and negatively  $(N_-)$  charged residues, and the total charge (Q). Also shown are the temperature of the specific heat maximum  $(T_{\text{max}})$  and the energy parameter  $(\epsilon)$  obtained for each protein in the Gō-MJ and Gō-MJ-nn models.

	Richardson's Top201	8 dataset	Present study's prot	ein set
Structural Class	Number of proteins	%	Number of proteins	%
$\alpha$	1,164	8.6%	2	16.7%
$\beta$	261	1.9%	2	16.7%
lpha / eta	$12,\!257$	89.6%	8	66.6%
Total	$13,\!677$	100%	12	100%

TABLE S2. Number and percentage of proteins from different structural classes in the Richardson's Top2018 dataset of highquality protein structures [C. J. Williams, D. C. Richardson, & J. S. Richardson, Prot. Sci. 31, 290–300 (2022)] at a 70% structural homology level and in the protein set of the present study.

FIG. S1. Distributions of protein length (in number of amino acids) in the proteomes of E. coli (dot-dashed), H. marismortui (dotted), S. cerevisiae (dashed) and H. sapiens (solid). The protein sequences of the proteomes are taken from the UniProt database [The UniProt Consortium, Nucl. Acid. Res. 49, D480 (2021)] with one sequence per gene.

FIG. S2. Histograms of the fraction of hydrophobic amino acids (a, d), the fraction of positively charged amino acids (b, e), and the fraction of negatively charged amino acids (c, f) of proteins in the proteomes of H. sapiens (a–c) and S. cerevisiae (d–f). The human proteome (ID: UP000005640) contains 20,607 protein sequences and the S. cerevisiae's one (ID: UP000470054) contains 5,551 sequences with one protein sequence per gene. The proteome data are obtained from the UniProt database. Horizontal bars (red) indicate the ranges of the above fractions in the 12 proteins considered in the present study, as listed in Table S1. The ranges associated with the horizontal bars correspond to ~97%, ~92% and ~88% of the protein population for the histograms in (a), (b) and (c), respectively, and correspond to ~98%, ~91% and ~90% of the protein population for the histograms in (d), (e) and (f), respectively.

FIG. S3. Histograms of the fraction of hydrophobic amino acids (a, d), the fraction of positively charged amino acids (b, e), and the fraction of negatively charged amino acids (c, f) of proteins in the proteomes of E. coli (a–c) and H. marismortui (d–f). The E. coli's proteome (ID: UP000000625) contains 4,402 protein sequences and the H. marismortui's one (ID: UP000001169) contains 4,234 sequences with one protein sequence per gene. The proteome data are obtained from the UniProt database. Horizontal bars (red) indicate the ranges of the above fractions in the 12 proteins considered in the present study, as listed in Table S1. The ranges associated with the horizontal bars correspond to ~93\%, ~89\% and ~84\% of the protein population for the histograms in (a), (b) and (c), respectively, and correspond to ~96\%, ~78\% and ~68\% of the protein population for the histograms in (d), (e) and (f), respectively.

FIG. S4. Dependence of the diffusion constant D and the pulling force k from the diffusion model on the chain length, N, of proteins. The data are shown for the escape processes of proteins in the Gō-MJ model at the exit tunnels of E. coli (open triangles), H. marismortui (filled circles), S. cerevisiae (open circles) and H. sapiens (filled squares). The data for the Gō-MJ-nm model in the H. sapiens' exit tunnel are not shown because they are very close to that of the Gō-MJ model. The values of D and k are listed in Table 2 of the main text.

FIG. S5. The escape time distribution (a) and the escape probability as a function of time (b) of protein Sso10b2 (1udv) at the H. marismortui's tunnel. (c) A slowly escaping conformation of 1udv at the tunnel. This protein escapes slowly mainly due to electrostatic interactions between the protein and the tunnel.

FIG. S6. Dependence of the correlation coefficient R between the median escape time,  $t_{esc}$ , and the function  $(1-s)N_h + sQ$ , of the proteins considered in the present study (Table S1) on the parameter s for different species and protein models as indicated.

FIG. S7. (a) Dependence of the median escape time,  $t_{esc}$ , on the chain length, N, of the self-repulsive (filled circles) and self-attractive (open circles) homopolymers at the human ribosomal tunnel. A self-repulsive homopolymer is modelled as a chain with a repulsive potential of  $\epsilon(\sigma/r)^{12}$  for the interaction between any pair of non-consecutive beads. A self-attractive one employs the 12-10 LJ potential, as given by Eq. (3) of the main text, but with the potential depth given by  $\epsilon$ , for the attraction between the beads. The value of  $\epsilon = 0.75$  kcal/mol is used for both types of the homopolymers. The polymer chains are grown inside the tunnel with  $t_g = 400\tau$  in the simulations as for nascent proteins. The data were obtained at the temperature T = 300K for the human tunnel. (b and c) The escape time distributions for a N = 88 self-repulsive homopolymer (b) and a N = 88 self-attractive homopolymer (c). The histograms obtained by simulations are fitted to the diffusion model (solid line).

FIG. S8. Normalized histograms of number of native contacts  $N_c$  (a), number of non-native contacts  $N_c^{nn}$  (b), and the radius of gyration  $R_g$  (c) of protein 2ci2 at the moment of complete translation at the human ribosomal tunnel. The statistics are drawn from 1000 conformations obtained by independent trajectories in the Go-MJ model (solid) and the Go-MJ-nn model (dotted). The contacts are defined based on a cut-off distance of  $1.2 r_{ij}^*$  for native contacts and  $1.2 \sigma_1$  for non-native contacts (see Methods).

FIG. S9. Correlations between the median escape time  $t_{esc}$  obtained by simulations and the number of hydrophobic residues  $N_h$  (a–e), and between  $t_{esc}$  and the net charge Q (f–k) of the proteins considered for the organisms and the protein models, as indicated. Here,  $N_h$  and Q are obtained only for the C-terminal 50 residues. The correlation coefficient R and the corresponding p-value are given in each panel.

FIG. S10. Histogram of the escape time (a, c) and the time dependence of the escape probability  $P_{\text{escape}}$  (b, d) of proteins 2jo6 and 1u0b, which are identified by their PDB IDs, at the ribosomal exit tunnels of E. coli. The proteins are considered in the Go-MJ model with  $\epsilon = 0.7417$  kcal/mol, which is the mean value of  $\epsilon$  for the 12 proteins listed in Table S1. The 2jo6 protein has the length of N = 110 residues, in which the number of hydrophobic residues is  $N_h = 40$ , the numbers of positively and negatively charged residues are  $N_+ = 12$  and  $N_- = 17$ , respectively, giving the net charge Q = -5e. The 1u0b protein has the length of N = 461 residues with  $N_h = 148$ ,  $N_+ = 53$ ,  $N_- = 72$ , giving Q = -19e. For C-terminal 50 residues, the net charge is zero for 2jo6 and -1e for 1u0b. The histogram shown are obtained from simulations with 1000 independent trajectories for 2jo6 and 180 independent trajectories for 1u0b with  $t_g = 400\tau$ . The median escape times found are  $t_{esc} \approx 666\tau$  for 2jo6 and  $t_{esc} \approx 1270\tau$  for 1u0b.

FIG. S11. Correlations of the median escape time  $t_{esc}$  with the number of hydrophobic residues  $N_h$  (a, c) and the net charge Q (b, d) of nascent proteins at the E. coli's exit tunnel. The data shown include those of the 12 proteins considered initially (closed circles), as listed in Table S1, and two new proteins, 2jo6 and 1u0b, (open circles). Top panels (a, b) correspond to  $N_h$  and Q obtained for for C-terminal 110 residues if applicable. Bottom panels (c, d) correspond to  $N_h$  and Q obtained for C-terminal 50 residues. *R*-values and *p*-values for the correlations are given in each panel.
