In cancer therapeutics, protein-metal binding mechanisms critically govern drug pharmacokinetics and targeting efficacy, thereby fundamentally shaping the rational design of anticancer metallodrugs. While conventional laboratory methods used to study such mechanisms are often costly, low throughput, and limited in capturing dynamic biological processes, machine learning (ML) has emerged as a promising alternative. Despite increasing efforts to develop protein-metal binding datasets and ML algorithms, the application of ML in tumor protein-metal binding remains limited. Key challenges include a shortage of high-quality, tumor-specific datasets, insufficient consideration of multiple data modalities, and the complexity of interpreting results due to the "black box" nature of complex ML models. This paper summarizes recent progress and ongoing challenges in using ML to predict tumor protein-metal binding, focusing on data, modeling, and interpretability. We present multimodal protein-metal binding datasets and outline strategies for acquiring, curating, and preprocessing them for training ML models. Moreover, we explore the complementary value provided by different data modalities and examine methods for their integration. We also review approaches for improving model interpretability to support more trustworthy decisions in cancer research. Finally, we offer our perspective on research opportunities and propose strategies to address the scarcity of tumor protein data and the limited number of predictive models for tumor protein-metal binding. We also highlight two promising directions for effective metal-based drug design: integrating protein-protein interaction data to provide structural insights into metal-binding events and predicting structural changes in tumor proteins after metal binding.

Highlights

- Tumor protein-metal binding is key to designing metal-based anticancer therapies.
- Multimodal data can enable accurate binding prediction and deep biological insights.
- Cross-referencing datasets can help address the scarcity of tumor protein metal-binding data.
- Existing protein-metal binding models can be adapted for tumor-specific prediction.
- Improving interpretability can support cross-disciplinary research and collaboration.

1. Introduction

Cancer remains one of the leading causes of death worldwide, accounting for approximately 25% of all fatalities. Each year, about 0.5% of the global population is newly diagnosed with the disease [1]. In 2022 alone, nearly 20 million new cases were reported, resulting in an estimated 9.7 million cancer-related deaths [2]. While chemotherapy has long been a primary treatment option, its use is often limited by severe side effects, such as nausea and systemic complications [1]. Therefore, there is a need to improve chemotherapy by reducing toxicity and enhancing efficacy. Metal-based drugs, owing to their diverse chemical compositions, have emerged as a promising class of chemotherapeutic agents. By changing the metal center, ligands, and metal-ligand interactions, researchers can optimize metal-based compounds to match the biological characteristics of different cancer cells. This adaptability supports the development of more personalized treatment strategies. Widely used examples, such as cisplatin and carboplatin, have demonstrated success in overcoming chemoresistance [3]. Metal-based drugs can also be integrated with nanotechnology and immunotherapy to improve their therapeutic effectiveness. For example, metal-intermetallic compounds have shown potential not only in eliminating cancer cells but also in stimulating memory immune cells, thereby reducing the risk of tumor relapse [4].

The design and characterization of metal-based compounds mainly rely on conventional wet-lab methods, such as mass spectrometry, X-ray crystallography and nuclear magnetic resonance [5–8], as shown in Fig. 1A. These methods provide valuable insights into the properties of metal-based compounds and the structural basis of their interactions with tumor proteins. However, they are often expensive, time-consuming, and low throughput, and they struggle to capture dynamic biological processes. The emergence of machine learning (ML) presents new opportunities, as ML techniques can efficiently analyze large amounts of complex biological data and build predictive models for protein-metal binding, thereby accelerating metal-based drug discovery. Figure 1D shows three key ML application tasks in tumor protein-metal binding: tumor metalloprotein identification, metal type classification, and binding site prediction. Despite this potential, the application of ML remains limited due to challenges including the scarcity of high-quality datasets, insufficient integration of multimodal information, and lack of interpretability in existing models.

To summarize recent advances, highlight key challenges, and explore promising directions, this paper is organized around three key areas: data resources, multimodal learning approaches, and interpretability techniques. First, we reviewed existing data resources and observed that, while high-quality general protein-metal binding datasets are abundant, those specific to tumor proteins are scarce. Since tumor proteins are not structurally different from general proteins, the learning mechanisms in ML models remain applicable across both types. Therefore, we collected datasets on both general protein-metal binding and tumor proteins. We then proposed a strategy to construct tumor-specific datasets by integrating these complementary sources. For example, although the Protein Data Bank (PDB) [9] does not explicitly annotate tumor protein-metal binding interactions, it includes cancer-associated proteins with experimentally resolved metal-binding structures. Identifying and using these entries to extract key biological features can help mitigate current data scarcity.

Next, different data modalities can provide complementary biological insights to enhance feature learning when effectively integrated. To capture this diversity, we identified four key data modalities relevant to tumor protein: sequence, structure, protein pocket, and text, as shown in Fig. 1B. For each modality, we introduced its unique characteristics and outlined an ML-oriented data processing workflow, including data acquisition, data preprocessing and feature extraction. This workflow can support researchers in locating, preparing, and adopting raw data for ML model development.

Integrating these heterogeneous modalities into a model is nontrivial and can significantly influence

Figure 1 | Interpretable multimodal learning for tumor protein-metal binding. A) The process of transferring bioinformatics data to ML-oriented datasets. Created with BioRender.

model performance. To better understand the current landscape, we examined existing ML models developed for tumor protein-metal binding. To the best of our knowledge, only three such models have been developed to date - multichannel convolutional neural network (MCCNN) [10], MetalPrognosis [11], and MetalTrans [12] - but they all have limited success in multimodal integration. Therefore, we studied multimodal ML methods from broader bioinformatics applications, including 14 recent protein–metal binding models and four protein foundation models, and proposed strategies for adapting them to tumor-specific tasks. Building on these insights, we highlighted the important value of multimodality for tumor protein-metal binding, suggested promising combinations of data

modalities, and provided an overview of general multimodal learning methods, as shown in Fig. 1B.

Finally, in medical and biological applications, predictive accuracy alone is insufficient. ML models should also be interpretable and trustworthy to support scientific and clinical understanding. However, the "black box" nature of popular complex ML models limits transparency into their internal decision-making processes. In practice, interpretability is often restricted to indirect evaluations, such as performance comparisons with benchmark models, without clarifying how specific inputs contribute to predictions. This lack of transparency poses challenges for researchers, particularly those from clinical and biological backgrounds, in assessing model reliability and extracting clinically or biologically relevant insights. To address this issue, we examined interpretability in the context of tumor protein-metal binding from two perspectives: designing models with inherent interpretability and applying post-hoc analysis techniques.

Building on these findings, we summarized key challenges and discussed the perspectives on potential solutions. Moreover, we identified two emerging directions that can advance tumor protein–metal binding prediction. The first involves integrating protein-protein interaction data to provide a structural context for metal-binding events. The second focuses on predicting the structural changes in tumor proteins after metal binding, which can inform the design of more effective metal-based therapeutics. To our knowledge, this is the first comprehensive study of interpretable multimodal ML for tumor protein-metal binding. Our work synthesized research advances, identified ongoing challenges, and offered a forward-looking perspective into future research opportunities. By integrating knowledge from protein structure datasets, multimodal ML, and interpretability analysis, we aim to support the development of biologically grounded, accurate, and clinically applicable ML models for tumor protein-metal binding prediction.

The main contributions of this paper can be summarized as follows:

- We presented and summarized potential data resources for tumor protein-metal binding, outlined a systematic data processing workflow, and proposed a strategy to construct tumor-specific datasets by integrating protein-metal binding and cancer-related datasets.
- We identified key protein data modalities, explored their combinations, and reviewed multimodal learning methods focusing on their applicability to tumor protein-metal binding. We also emphasized the importance of interpretability and summarized current approaches that support biological and clinical insight.
- We offered a forward-looking perspective by proposing two promising research directions, i.e., exploring protein-protein interaction and predicting tumor protein structural changes upon metal binding, to inform drug design and discovery.

The remainder of this paper is organized as follows. Section 2 introduces the role of metal ions in tumor proteins. Section 3 outlines a workflow for processing multimodal data. Section 4 introduces strategies for combining data modalities and reviews existing multimodal learning methods. Section 5 introduces current efforts to improve model interpretability. Section 6 highlights two key considerations for advancing future research in tumor protein-metal binding. Finally, Section 7 presents our conclusions.

2. Biological significance of tumor protein-metal binding

The tumor microenvironment is a dynamic and essential foundation for tumor survival, composed of diverse cells, vasculature, secreted factors, and extracellular matrix components that tumors actively shape and induce. Driven by their intense metabolic demands, tumors generate unique conditions,

such as hypoxia, acidity, and elevated reactive oxygen species (ROS) that impair the function of pro-inflammatory immune cells, resulting in evasion of the immune system [13]. Within the tumor microenvironment, metal ions engage with proteins to establish a sophisticated and multi-tiered regulatory network that precisely modulates cellular signaling pathways, metabolic activities, and immune cell functionalities. This elaborate network plays a pivotal role in governing tumor initiation and progression.

Calcium ions (Ca²⁺) bind to the EF-hand domains of calmodulin [14], inducing a conformational change that enables the Ca²⁺-calmodulin complex to activate calcineurin. This, in turn, dephosphorylates the nuclear factor of activated T cells (NFAT), promoting its translocation to the nucleus and subsequent transcription of cytokine genes such as IL-2 [15]. In tumor cells, Ca²⁺ signaling regulates key pathways such as PI3K/AKT and MAPK, which are critical for cell survival and proliferation. Zinc ions (Zn²⁺) interact with zinc finger proteins such as MTF-1, binding to conserved cysteine and histidine residues within their zinc finger domains. This interaction regulates the expression of metallothioneins (MT1/2), which protect tumor cells from oxidative stress. In T cells, Zn²⁺ modulates the activity of transcription factors like GATA-3 and T-bet, thus influencing Th1/Th2 differentiation and antitumor immunity [15].

Iron ions (Fe²⁺/Fe³⁺) bind to iron-sulfur clusters in proteins such as aconitase [16] and SDHB [17], regulating mitochondrial metabolism and ROS production. Dysregulated iron metabolism can induce ferroptosis in tumor cells through the accumulation of lipid peroxides [18]. In TAMs, Fe^{2+}/Fe^{3+} modulates polarization by regulating HIF-1 α and NF- κ B signaling, thereby influencing tumor progression [19]. Copper ions (Cu⁺/Cu²⁺) bind to copper-dependent enzymes such as superoxide dismutase 1 (SOD1) and LOX, modulating intracellular redox reactions and extracellular matrix remodeling. Manganese ions (Mn²⁺) activate manganese superoxide dismutase (Mn-SOD) by binding to its active site, which is composed of conserved histidine and aspartate residues. This binding induces a conformational change that enables Mn-SOD to catalyze the dismutation of superoxide radicals (O_2^-) into hydrogen peroxide (H_2O_2) and oxygen (O_2) [20, 21], thereby reducing oxidative stress and protecting tumor cells from apoptosis. Magnesium ions (Mg²⁺) bind to phosphate groups of ATP, forming a Mg-ATP complex that stabilizes ATP and enhances its biological availability for energy transfer and hydrolysis. In tumor cells, Mg²⁺ acts as a cofactor for kinases such as mitogen-activated protein kinase (MAPK), including ERK, p38, and JNK, facilitating their phosphorylation and activation. This regulation of MAPK signaling pathways influences critical cellular processes, including proliferation, differentiation, and apoptosis.

These protein-metal interactions form a highly coordinated regulatory system that influences tumor progression, immune response, and cellular metabolism. The biological significance underscores the potential for developing targeted cancer therapies and motivates this work.

3. Tumor protein-metal binding data

Given the limited availability of tumor-specific protein-metal binding datasets, applying ML in this domain remains challenging. This section reviewed existing data resources, identified key data modalities, and proposed strategies to mitigate data scarcity. We introduced publicly available cancer-related and protein-metal binding datasets and discussed how integrating these resources can support the construction of tumor-specific datasets. Additionally, we examined four key data modalities in protein research and outlined a data processing workflow to prepare these modalities for ML model development.

3.1. Tumor protein and metal-binding datasets

Several publicly available datasets offer valuable information on cancer biology and protein-metal binding, enabling researchers to investigate the structural and functional roles of metal ions in both tumor and general proteins. As summarized in Table 1 and 2, cancer-related datasets mainly focus on genomic, proteomic, and clinical data relevant to tumor biology, while protein-metal binding datasets contain detailed structural and functional annotations for proteins that coordinate metal ions. Because tumor proteins are not structurally distinct from general proteins, we propose a strategy to integrate tumor protein annotations with metal-binding data, enabling researchers to cross-reference information across specialized datasets. By leveraging multiple data sources, researchers can identify proteins of interest and explore their metal coordination properties and relevance in tumor biology. For example, a protein can be identified through the Cancer Genome Atlas Program (TCGA) [22], and its metal-binding features, such as coordination details, binding motifs, and potential roles, can be explored using UniProt [23]. A case in point is the copper transport protein ATOX1, which exhibits altered RNA transcript levels in various cancers [24]. Researchers can find ATOX1 in TCGA and use its UniProt accession number (O00244) to access its metal-binding information. ATOX1 binds copper and functions as a chaperone, delivering copper to targets such as P-type ATPases. The dataset also links to studies on ATOX1's roles in breast and liver cancer, while structural data is accessible via external resources like PDB.

This strategy highlights how integrating datasets such as TCGA and PDB enables researchers to investigate metal-binding proteins, even when explicit metal annotations are missing in tumor datasets, by leveraging cross-referenced structural and functional insights. Looking ahead, we envision a future where an integrated dataset combines gene expression, metal-binding, and structural data, streamlining protein-level analysis in cancer. Such a resource would allow researchers to readily query proteins like ATOX1 to assess tumor-specific expression, metal-coordination, and structural context, ultimately supporting the discovery of new targets for metal-based cancer therapies.

Figure 2 | Overview of data processing workflow for four data modalities: sequence, structure, protein pocket, and text. This workflow progresses from raw data acquisition and data preprocessing to feature extraction. Created with BioRender.

3.2. Raw data acquisition

Since different data modalities provide complementary biological insights, integrating them can significantly enhance feature learning. In protein research, we identified four key data modalities: sequence, structure, protein pocket, and text. Each modality has distinct characteristics and unique biological information. Below, we introduced the key features of each modality and described the methods used to prepare them for ML applications.

Sequence represents the unique order of amino acids in a protein chain, defining its primary structure. It reveals the specific arrangement of residues that can indicate functional regions, including conserved motifs-such as zinc fingers, H-N-H, and CXXC — that frequently contain key metal-binding residues like cysteine, histidine, aspartic acid, and glutamic acid, which coordinate metal ions critical for structural stability and function [40, 41]. Standard file formats include FASTA, GenBank, and other plain-text formats listing amino acids or nucleotide sequences and can be derived from multiple datasets, including the PDB and UniProt, through their websites or application programming interfaces (APIs). It is also possible to extract protein sequences from a PDB structural data file using tools like Biopython [42].

Structure provides a 3D view of a protein and related metal ions, detailing how its atoms are spatially organized into secondary, tertiary, or quaternary structures, and illustrates the folding pattern and conformational details critical for understanding protein-ligand interactions, including those with metal ions. The secondary structure comprises local folded regions formed by interactions among backbone atoms. The secondary structure of a protein refers to local, repeated arrangements of the amino acid chain, such as alpha-helices and beta-sheets, which are stabilized mainly by hydrogen bonds between the backbone atoms. The tertiary structure represents the overall 3D shape of a single polypeptide chain arising from interactions between the side chains (R groups) of the amino acids. It includes hydrogen bonds, ionic bonds, hydrophobic interactions, and disulfide bridges, which determine the protein's overall functionality. The quaternary structure applies to

proteins composed of multiple polypeptide chains, describing the arrangement and interaction of these subunits. Structural data is typically obtained using X-ray crystallography, NMR spectroscopy, and cryo-electron microscopy (cryo-EM). This information is stored in formats like PDB files or mmCIF, which include 3D coordinates and other structural details. In metal-binding prediction, secondary and tertiary structures are most commonly utilized. Q-BioLip [34] is a recent dataset that provides quaternary structure-based protein-ligand interaction information.

Protein pocket is a 3D cavity within the complex architecture of protein structures which serves as crucial microenvironments for molecular interactions. These indentations can accommodate various ligands, including metal ions, thereby mediating a vast array of protein functions. While pocket data can be extracted from protein structure datasets, several specialized datasets provide detailed pocket data, including PocketDB [38], MetalPDB [31], MetalMine [43], and CavitySpace [39].

Text encompasses the detailed, human-readable information associated with biological entities, such as proteins, found in datasets and scientific literature. Unlike sequences or structures, text provides rich contextual insights, including functional annotations, experimental findings, and disease associations, which complement other data modalities [44]. This modality captures the precise language used to describe protein characteristics, such as metal-binding sites, post-translational modifications, and cellular localization. Resources like UniProt [23], PubMed [45], and PDB present this information in various forms, including free-text entries, abstract summaries, and detailed feature descriptions. Text data is a valuable source for knowledge extraction through natural language processing (NLP) techniques.

3.3. Data preprocessing

Transforming raw biological data into usable features for ML models requires several modality-specific preprocessing steps. Raw data are often unstructured or semi-structured and may contain inconsistencies, noise, or missing values — factors that obscure meaningful biological patterns and degrade model performance. As such, preprocessing is essential for cleaning, normalizing, and extracting relevant signals from biological data. In tumor protein-metal binding, the scarcity of high-quality datasets requires constructing new datasets or augmenting existing ones. In these cases, reproducible and well-defined preprocessing workflows are critical to ensure the resulting data are suitable for feature extraction and downstream ML model development. To support this process, we proposed a data processing workflow for tumor protein-metal binding prediction in Fig. 2B, including the key steps and tools used to transform raw data into high-quality, structured inputs. The methods for each data modality are outlined below.

Sequence data requires three main preprocessing steps to enhance data quality and prepare it for feature extraction. The first step is data filtering and cleaning. Sequences shorter than 45 to 50 residues should be removed, as they may represent incomplete segments that do not accurately reflect full proteins [46]. Then, highly similar sequences are removed to reduce the redundancy. For example, sequences can be clustered according to a certain identity threshold, usually anywhere between 25% or 90% identity, to retain only one representative from each cluster [41, 47–49]. MMseqs2 [50], HH-suite [51], CD-HIT [52], and Clustal Omega [53] can streamline the process. The next step in preprocessing is sequence alignment. This can be performed as a pairwise alignment, where a query protein sequence is compared with another to identify regions of similarity. Such alignments can help determine whether the query protein shares homology with known metal-binding proteins, suggesting a potential metal-binding function. More commonly, multiple sequence alignment (MSA) aligns a set of homologous sequences, highlighting conserved residues across the protein family — often indicative of functional or structural importance. Standard tools for performing sequence alignment include MMseqs2, BLAST [54], and T-Coffee [55]. Once aligned, sequences can be annotated with

metal-binding information using known metal-binding motifs and structural information extracted from datasets. These annotated sequences form high-quality inputs for training ML models.

Structure data preprocessing involves four steps. First, in data filtering and cleaning, relevant 3D structures are optimized from datasets using resolution-based filtering. For example, structures with resolutions lower than 3.0 Å are often discarded to ensure reliable geometric details [46]. Redundancy reduction is carried out by retaining only one representative structure from clusters of highly similar models, preventing the overrepresentation of a single binding conformation. Redundancy can be reduced based on sequence identity or through structural comparison using tools such as Foldseek [56]. Second, structure completion is a crucial preprocessing step that involves cleaning protein structures and imputing missing information. This process involves resolving alternate conformations, adding missing atoms (such as hydrogens) using tools like PDB2PQR [57] or Reduce, and modeling absent loops with homology modeling tools such as MODELLER [58] or structural predictions from AlphaFold. Then, the identification and annotation of metal-binding sites are performed. Metal ions and their coordinating atoms are extracted from PDB or mmCIF files by selecting HETATM records and identifying nearby residues within specific distance thresholds, typically 2.5 to 3.0 Å [46, 49]. Furthermore, geometric calculations are performed, such as determining distances, coordination numbers, and bond angles, to accurately characterize the metal coordination environment [59].

Protein pocket shares several preprocessing steps with structural data, including resolution-based filtering, redundancy reduction, identifying related metal ions, and adding missing atoms. Beyond these shared steps, pocket-specific preprocessing requires defining the spatial boundaries of the protein pocket and selecting the relevant amino acid residues involved in ligand or metal coordination.

Text data preprocessing in protein-metal interaction studies involves several steps to transform raw textual information into a structured and informative format suitable for computational analysis. Text preprocessing begins with extracting relevant content from datasets such as PubMed or UniProt. The raw text is cleaned to remove irrelevant characters and correct formatting inconsistencies. The next step is tokenization, where continuous text is divided into smaller units called tokens, typically words or subword segments, depending on the granularity required. Normalization techniques, such as lowercasing and stemming, are then applied to standardize the text and reduce linguistic variability. Finally, named entity recognition (NER) is employed to identify and classify key biological entities, such as protein names, metal ions, and binding sites [60, 61].

3.4. Feature extraction

Finally, we summarized the unique features that can be extracted from each data modality and presented the type of information they carry, along with their contributions to tumor protein research, as shown in Fig. 2C.

Sequence-based features are extracted directly from a protein's amino acid sequence to determine its metal-binding capabilities. First, the amino acid composition can be represented using one-hot encoding. Second, physiochemical properties, which numerically reflect each amino acid's biochemical characteristics, offer another valuable feature. For example, each residue can be encoded by properties such as hydrophobicity, polarity, charge, molecular weight, or other experimentally derived indices [46, 49, 59]. This transforms the sequence into a vector of biochemical property profiles. In addition, evolutionary conservation profiles, which capture the frequency of amino acids observed in homologous sequences, provide additional information. Examples include position-specific scoring matrices (PSSM) [62] and hidden Markov model matrices [51], both of which are used in methods such as [63]. Finally, deep learning-based sequence embeddings have emerged as a powerful alternative to hand-crafted features. These include word2vec-like approaches such as ProtVec [64] and more advanced protein language models [65, 66]. These embeddings capture subtle sequence-level semantics and long-range dependencies often missed by traditional encoding techniques.

Structure-based features are derived from the 3D structure of proteins. Secondary structure features refer to the local conformations of a protein's backbone, which are primarily organized into alpha-helices, beta-sheets, and random coils or loops. DSSP [67] and STRIDE [68] are some of the tools used to extract these secondary structure features. These features help define the spatial orientation of metal-ligand residues, thereby identifying potential metal-binding sites. Tertiary structure features capture the complete 3D fold of a protein and include aspects such as the curvature distribution of the protein surface, contact maps that show the distances between atoms or residues in a protein chain, and the spatial convergence of residues that are distant in sequence but come together to form metal-binding pockets. Finally, quaternary structure involves organizing multiple protein subunits into a functional complex. This level of structural organization is essential for modulating protein function as it shapes interfacial interactions and cooperative binding behaviors. Features at this level include the geometry of inter-subunit interfaces, arrangements of cooperative binding sites, conformational dynamics upon ligand binding, and residue interaction networks. These various levels of structural features can be represented as 1-dimensional numerical vectors, 2-dimensional distance matrices [49, 59], or in the form of a graph using tools like Graphein [69].

Protein pocket features mainly contain geometric descriptors and physicochemical features. Geometric descriptors quantitatively capture the physical characteristics of the pockets. These measurements include pocket volume, surface area, depth, and shape descriptors such as sphericity and curvature. Tools such as Fpocket [70], CASTp [71], and PocketAnchor [72] are commonly used to calculate these attributes. Physicochemical features describe the chemical environment within the pocket. For example, the distribution of hydrophobic versus hydrophilic residues, local electrostatic potential, and polarity can be analyzed by examining the amino acid composition of pocket-lining residues. These descriptors can be encoded as numerical vectors, similar to one-hot encoding and physiochemical property encodings used for sequence features. Similarly to structural data, protein pockets can be represented using advanced formats such as graph-based models. In these models, residues that form the binding pocket are treated as nodes, and their spatial proximity or physicochemical interactions are represented as edges. This approach enables the modeling of complex interaction networks that influence metal-binding behavior [49].

Text features provide a valuable modality for representing descriptive biological information associated with proteins. Traditional techniques such as Bag-of-Words (BoW), Term Frequency (TF), and Inverse Document Frequency (IDF) provide a foundational approach for converting text into numerical representations. BoW captures the frequency of words without considering their order, while TF measures the relative occurrence of each word within a document. IDF adjusts these frequencies by down-weighting common terms and emphasizing rarer ones. The combination of TF and IDF, which is TF-IDF, captures the importance of terms within a document relative to the entire corpus. These simple yet effective methods help highlight relevant vocabulary and term significance in protein-related textual descriptions. Recent advances in NLP have led to the development of domain-specific language models such as SciBERT [73], BioBERT [74], and ProtST [75]. These models offer valuable initial representations or embeddings of text related to proteins, which can be used to predict their functions, including their ability to bind to metals. Additionally, relationship extraction techniques are employed to identify and structure relationships between entities. For example, a statement like "protein X binds metal Y at residue Z" can be transformed into a structured relational triplet [76]. Finally, topic modeling can identify broader themes within the text, capturing functional annotations, biological processes, or experimental conditions relevant to protein-metal interactions.

4. Multimodal learning for tumor protein-metal binding

Multimodal learning leverages the idea that complex biological entities, such as tumor proteins, can be represented through diverse data modalities, each offering a distinct perspective. In ML, these sources of information are referred to as modalities, with each modality capturing complementary aspects of the underlying biological phenomenon [77]. Integrating multiple modalities allows models to compensate for the limitations of individual data modalities and supports a more comprehensive understanding of tumor protein-metal interactions [78].

In protein-metal binding prediction, four primary data modalities are particularly relevant: sequence, structure, protein pocket, and text. These modalities offer insights into different levels of protein function and behavior. For example, tumor proteins frequently harbor somatic mutations [79], which can alter their conformation and metal-binding affinity [80]. Metal binding often induces structural changes, influencing downstream biological activity [81]. Capturing both pre- and post-binding conformational states offers a more nuanced view of metal-induced functional shifts in tumor biology. The tumor microenvironment adds further complexity. Increased protein-protein interactions in this environment can promote complex formation or the emergence of new binding pockets. These dynamics highlight the need for models to integrate structural and contextual information. Textual data, in particular, should go beyond basic annotations to include a disease-specific context. For example, the silencing of MT1G in liver cancer, impairing zinc detoxification, illustrates how gene expression changes can reshape metal-binding behavior [82]. Such pathology-specific information enhances the biological relevance of predictive models and supports mechanistic interpretation.

To advance multimodal learning for tumor protein-metal binding, we systematically reviewed existing models developed for tumor protein-metal binding. This section collects available open-source resources, examines commonly used combinations of data modalities, and reviews representative multimodal learning approaches, as shown in Fig. 1B.

4.1. Research advances and open resources

We reviewed existing literature to identify studies that explore the application of ML in tumor protein-metal binding. Table 3 summarizes the key characteristics of these resources based on the following criteria:

- **Programming language** indicates the programming language used, reflecting its popularity and adoption within the field.
- **Modality** presents the types of data modalities the model utilizes. Section 3.2 provides detailed explanations of each modality.
- **Interpretability** specifies whether the model incorporates interpretability analyses beyond basic data validation or model comparison.
- **Creation and last update time** reflect the recency and maintenance status, providing insight into its ongoing usability and relevance.
- **GitHub stars** is a proxy of reputation and influence within the developer and research communities. This criterion is included because most relevant software is hosted and maintained on GitHub [83].
- **Paper citations** reflect the academic impact and visibility of the work.
- Tasks summarize the scope and functional capabilities of each work.

We first compiled three recent models designed for tumor protein-metal binding in Table 3A: MCCNN [10], MetalPrognosis [11], and MetalTrans [12]. MCCNN is the first deep learning model designed to predict disease-related mutations at metal-binding sites in metalloproteins, providing a novel platform for exploring the role of metal-binding disruptions in human disease. MCCNN integrates three types of data: protein sequence, 3D structural data of binding sites (including protein structure and pocket features), and metadata in the form of categorical text descriptions. Therefore, MCCNN can be considered a multimodal model incorporating sequence, structure, protein pocket, and text from four protein mutation datasets — MetalPDB [31], CancerResource2 [27], ClinVar [26], and Uniprot Humsavar [99]. MetalPrognosis [11] and MetalTrans [12] were developed to further enhance predictive performance and advance research on tumor protein-metal binding. Both models build upon the MCCNN dataset while introducing architectural improvements to boost accuracy and efficiency. MetalPrognosis eliminates the need for manual feature extraction by using sliding window sequences as input. These sequences are processed through pre-trained protein language models to extract rich semantic representations, which are then fed into a convolutional neural network to capture complex, high-level features. MetalTrans integrates multiple features using concatenation with a Transformer-based framework. MetalTrans enables comprehensive and context-aware feature extraction across modalities, ensuring exhaustive feature extraction.

To our knowledge, MCCNN, MetalPrognosis, and MetalTrans are the only ML models designed for tumor protein-metal binding prediction. Since tumor proteins are not structurally distinct from general proteins, the learning mechanisms in ML models are transferable across both domains. We broadened our analysis to include general protein-metal binding models, evaluating their potential applicability to tumor protein research. As shown in Table 3B, we have compiled 15 recent protein-metal binding prediction models that could be adapted to tumor-specific tasks through training or fine-tuning with tumor protein. For example, LMetalSite [90] and M-Ionic [48] can serve as valuable baselines for evaluating the performance of MetalPrognosis. In addition to binding prediction models, recent advances in foundation models have introduced pretraining on large-scale general datasets followed by fine-tuning for specific downstream tasks. We included four representative protein foundation models use powerful protein language models to extract rich contextual representations and offer promising avenues for enhancing the diversity and depth of tumor protein-metal binding prediction.

4.2. Modality combinations

As shown in Table 3, several unimodal methods have been proposed to investigate protein-metal binding using sequence [41, 47, 48, 85, 86, 90, 91, 94] or structural data [87, 88, 93]. However, reliance on a single modality may limit the ability to capture the full complexity of tumor protein-metal interactions. With the rapid advancement of multimodal fusion, researchers are increasingly recognizing the need to integrate multiple data modalities to improve predictive accuracy, improve model intepretability, and support more comprehensive computational analyses. As illustrated in Table 3, a variety of modality combination schemes exist for protein-metal binding models and protein foundation models. These viable modality fusions offer valuable guidance for the enrichment of tumor protein models. The summary of different modality combinations is outlined below.

Sequence and structure each provide valuable but distinct insights into protein-metal interactions, and the limitations associated with unimodal combinations can be addressed by integrating these two modalities. Sequence data alone may overlook the spatial relationships and binding-site conformations that are critical for accurate metal-binding prediction. Conversely, structural data is often constrained by the limited availability of experimentally validated protein structures, especially for novel or mutated tumor proteins. Greener et al. [100] primarily utilized the metalloprotein sequence data and supplemented it with structural insights derived from the "periodic table" of protein structures, based on Taylor's work. This approach enabled the generation of synthetic sequences corresponding to new protein topologies.

Sequence and text complement each other by allowing the models to access both primary sequence data and biological contextual information. For example, ProteinChat [96] is trained on over 1.5 million carefully curated triplets (protein, text, answer) from the Swiss-Prot dataset, enabling it to capture protein knowledge that mimics expert reasoning.

Sequences, structure, and text can be effectively combined to address annotation gaps in existing protein databases. Currently, approximately 30% of the proteins in UniProt remain unannotated. ProTrek [97] addresses this gap by leveraging this modality combination to predict and annotate the functions of previously uncharacterized proteins. Natural language models further enhance this process by extracting insights from rich textual descriptions while incorporating learning representations of sequence and structural information. For example, ProteinAligner [98] adopts this approach to identify post-translational modifications, capture protein dynamics under different conditions, and map interaction networks directly from the literature.

Sequence, structure, and protein pocket provide a detailed understanding of site-specific information. Trained with AlphaFold-predicted structures [101], ESMBind [84] addresses the challenge of accurately determining the 3D coordinates of metal ions in protein structures, outperforming models such as LMetalSite and M-Ionic, which do not incorporate protein pocket information. ESMBind enables deep learning-based metal-binding prediction at multiple levels, including sequence-level, residue-level, and atomic-level modeling.

Sequence, structure, protein pocket, and text represent a comprehensive integration of previously discussed data modalities. This multimodal combination enables the capture of both low-level molecular features and high-level biological context. The Oneport model [95] exemplifies this framework by generating unified protein representations that support accurate cross-modal retrieval even between modality pairs not explicitly trained together, demonstrating strong generalization and biological relevance. In the context of tumor protein–metal binding, such multimodal combinations are equally applicable. For example, MCCNN effectively organizes and integrates multimodal data for targeted prediction tasks in this domain.

4.3. Multimodal learning

This subsection introduced commonly used multimodal learning methods in medicine and biology and highlighted their potential to guide research on tumor protein-metal interactions. Based on their architectural design, multimodal fusion techniques are mainly classified into early (data-level), intermediate (feature-level), late (decision-level), or hybrid fusion [102, 103]. An additional perspective is the model types used to learn joint feature representations across modalities [104].

Classical ML models, such as decision trees, support vector machines, and random forests, have been applied to multimodal tasks with concatenated features from different modalities [105]. While these models are interpretable and computationally efficient, they are limited in learning complex relationships or representations from high-dimensional and unstructured data. Deep learning models can effectively capture complex, nonlinear relationships within and across data modalities. Convolutional neural networks (CNNs) can identify local patterns in structured inputs. In the context of tumor protein-metal binding, CNNs can be adapted to learn from protein sequences, 3D structures, and descriptive textual information independently or in combination [106–108]. Transformer models [109] use self-attention mechanisms to capture relationships between input features across modalities. ProteinAligner [98] utilizes eight transformer layers to process sequence, structural, and textual data. MetaLATTE [85] further introduces a position-sensitive attention mechanism to predict metal specificity, including zinc, lead, and mercury. Graph neural networks are particularly effective for modeling biological data with intrinsic topological structures, such as molecular interactions and protein conformations. For example, graph convolutional networks (GCNs) [110], which apply convolution operations over graph nodes, have been used to predict residue-level binding affinities between yellow fluorescent proteins and rare earth elements. Multi-omics GCN [111] further demonstrates how GCNs can extract complementary features from multi-omics data (mRNA expression, DNA methylation, and microRNA profiles) for disease classification tasks.

Generative models combine feature learning with reconstruction capabilities and are increasingly used for multimodal representation learning and synthetic data generation. Many generative models are built on encoder–decoder architectures, which transform multimodal inputs into a shared latent space and reconstruct them through a decoder. For example, ESBind [84] uses this architecture to process sequence and structural data for predicting protein–metal binding. Multimodal deep autoencoder [112] learns joint representations by fusing similarities from multiple modalities to support downstream tasks like drug–target interaction. A more advanced variant, Variational Autoencoders [113], incorporates both an inference mechanism and a generative process to model the underlying data distribution and produce compact latent representations of sequence and structural data [100]. In addition to representation learning, generative models can address data scarcity by producing synthetic data, such as generating 3D structures from protein sequences [114] and creating descriptive text to supplement incomplete biological annotations.

Although these multimodal learning methods have not yet been widely applied to tumor protein–metal binding, their use in related biomedical fields underscores their potential. With continued adaptation, these methods could enable deeper biological insights and support more accurate predictions in cancer-related metalloprotein research.

5. Interpretability for tumor protein-metal binding models

Interpretability in ML refers to model transparency, ease of user understanding, and the capacity to foster trust [115]. It is commonly defined as the extent to which the reasoning behind model predictions can be clearly explained [116]. In tumor protein-metal binding, interpretability is particularly important — not only to understand how predictions are made but also to ensure that

these predictions are meaningful and actionable for biologists and clinicians [117].

As shown in Table 3, current models place limited emphasis on interpretability, particularly in the context of tumor protein–metal binding. We first emphasized the universal importance of interpretability and its specific relevance to tumor protein–metal binding. To address gaps in existing methods, we then organized and presented interpretability approaches aimed at enhancing model transparency and facilitating more meaningful biological insights.

5.1. Importance of interpretability

Complex ML models, particularly deep learning models, are often considered "black boxes" because of their complexity and lack of interpretability [118]. While these models can achieve high predictive accuracy, their opacity poses significant challenges in understanding the underlying biological mechanisms of protein-metal binding sites and limits their utility in scientific discovery [119]. The bias embedded in these models can lead to unfair or misleading results, which is especially concerning in biomedical research [120]. Additionally, deep learning frequently yields inconsistent results in different datasets or experimental conditions, further complicating validation and reproducibility efforts [121].

Interpretability methods can address these issues by demystifying the decision-making process of models, enabling researchers to verify the biological mechanisms captured by the models and establish a scientific basis for predictions [119]. These methods also help identify and reduce bias, ensuring that the models are fair and reliable [120]. Furthermore, by providing clear and understandable explanations of the behavior of the model, interpretability methods improve reproducibility and facilitate the verification of prediction results [122]. An interpretable model can promote new scientific discoveries by offering detailed insights into the biological processes modeled, thereby advancing scientific progress [123–126].

Enhancing the interpretability of ML models can help scientists gain deeper insights into the interactions between metal ions and tumor proteins, including binding sites, binding modes, and downstream biological effects. Interpretability techniques help highlight key structural features and amino acid residues, offering precise targets for the design and optimization of anti-tumor drugs. By predicting potential binding relationships between novel tumor proteins and metal ions and by evaluating the reliability of these predictions, interpretable models support more informed decision-making. As a result, they can potentially improve the efficiency of drug development while reducing both experimental costs and time.

5.2. Interpretability analyses

To our knowledge, very few studies, either in tumor protein-metal binding or broader protein-metal binding, focus on model interpretability. Instead, most models demonstrate reliability and superiority indirectly, through performance comparisons with previous models or validation against benchmark datasets. While such evaluations reflect predictive capability, they often overlook interpretability, particularly within a biological context. For example, it often remains unclear whether improved performance stems from a deeper understanding of underlying biological mechanisms or simply from better pattern recognition in the data. A model that performs well on general datasets may not maintain its accuracy or biological relevance when applied to tumor-specific scenarios. To address these challenges, we review existing interpretability methods and their potential to enhance biological understanding and domain-specific reliability, as shown in Fig. 1C.

The existing methods are mainly categorized into two groups: inherently interpretable models and

post-hoc interpretive methods [115]. Inherently interpretable models are designed with interpretability and transparency in mind from the outset. Their architecture enables direct insight into the decision-making process, making it easier to understand how predictions are derived. **Linear models**, for example, use a simple combination of features with coefficients that clearly indicate each feature's impact. **Decision trees** classify or regress data via hierarchical rules and nodes, making their process intuitive and easy to understand [127]. **Generalized additive models (GAMs)** combine non-linear functions of multiple features to capture complex relationships while remaining interpretable, allowing for independent interpretation of each feature's functional form [128]. **Rule-based models** use a series of "if-then" rules to trigger predictions, simplifying both understanding and validation [129]. **Sparse models** limit the number of features with non-zero coefficients, thus highlighting key contributions and streamlining interpretation [130]. **Modular models** decompose the prediction process into distinct, independent components, enabling detailed analysis of each module as well as the overall model behavior [131].

In contrast, post-hoc interpretability methods aim to uncover the inner workings of models through analytical techniques, making them especially practical for complex "black-box" models. They assess models from various perspectives, each tailored to specific situations and offering distinct benefits. Feature importance techniques, such as Local Interpretable Model-agnostic Explanations (LIME) [122], SHapley Additive exPlanations (SHAP) [132], Integrated Gradients [133], Permutation-based Feature Importance Test [134], and Permutation Feature Importance [135], assist users in comprehending the influence of individual features on predictions. For example, LIME approximates the behavior of a complex model by constructing a simple interpretable model within a local region of the model, which can reveal which features the model focuses on when predicting the binding of a certain tumor protein to a metal, such as specific amino acid sequences or domains of the protein. Example-based methods, including SimplEx [136] and Deep k-Nearest Neighbors (DKNN) [137]. SimplEx approximates the model's prediction for the current input by selecting a set of examples from the training set and combining them in a weighted manner. DKNN, on the other hand, links the prediction of an example with its nearest neighbors in the latent variable space (latent space). Conceptual methods, such as Concept Activation Vectors (CAV) [138] and Concept Activation Regions (CAR) [139], enable evaluation of whether the model utilizes specific concepts. Input-output analysis methods encompass symbolic regression [140] and counterfactual explanations [141]. Symbolic regression methods are employed to directly acquire succinct and comprehensible mathematical expressions from data. These methods are widely utilized to augment the interpretability of neural networks. Counterfactual explanations elucidate which alterations in input features can result in divergent outcomes, thereby assisting users in comprehending how to modify features to attain distinct predictions.

In conclusion, inherently interpretable models ensure transparency from the design stage and complement post-hoc interpretability methods, enhancing the credibility of ML models. In research on the binding of tumor proteins to metals, modular interpretable models, combined with local interpretability analysis or counterfactual explanations of input-output relationships, hold promising prospects.

6. Perspectives and future directions

In this section, we summarized key challenges that hinder progress in interpretable multimodal learning for tumor protein-metal binding. We then discussed potential solutions based on insights from previous sections. Beyond these solutions, we highlighted two emerging research directions that extend current efforts and have the potential to advance this domain further.

6.1. Challenges and perspectives for tumor protein-metal binding prediction

Several technical and practical barriers remain unresolved in this domain. First, the scarcity of high-quality, tumor-specific datasets limits the training and generalization capabilities of ML models. Second, integrating diverse data modalities, such as protein sequences, structures, binding pockets, and textual annotations, introduces complexity, as each carries distinct formats and levels of biological insights. Developing robust fusion strategies that preserve meaningful signals across modalities remains an open problem. Finally, the "black-box" nature of complex ML models complicates the interpretation of their decision-making processes. This lack of transparency is particularly concerning in biomedical research, where model interpretability is critical for ensuring scientific credibility and facilitating clinical translation.

To address these challenges, we discussed the following perspectives on potential solutions:

- 1. **Integrating cancer-related and protein metal-binding datasets**: Combining existing tumor protein datasets (e.g., TCGA) with metal-binding datasets (e.g., PDB, MetalPDB) can help address data scarcity and generate more diverse, informative training datasets for ML model development.
- 2. Adapting existing models for tumor-specific prediction: General protein-metal binding models (e.g., LMetalSite, M-Ionic) can be retrained on tumor-specific data to support targeted prediction tasks. Additionally, pre-trained protein foundation models can be fine-tuned for tumor-relevant applications.
- 3. Leveraging multimodal learning with structured data workflows: Implementing a well-defined data processing and feature extraction workflow ensures high-quality inputs for ML models. Pairing structured workflows with appropriate multimodal fusion strategies and ML models can maximize the complementary strengths of diverse data modalities, leading to improved model performance and robustness.
- 4. **Improving model interpretability**: Incorporating inherently interpretable models (e.g., decision trees, linear models) and applying post-hoc explanation techniques (e.g., LIME, SHAP) can help uncover biologically meaningful insights and promote trust in ML-driven predictions.

In addition to the proposed solutions, we identified two emerging directions that promise to advance tumor protein-metal binding prediction by deepening biological insight and expanding modeling capabilities. In particular, integrating protein-protein interaction (PPI) data can provide structural context for metal-binding events, while modeling post-binding structure changes in tumor proteins offers new insight into how metal coordination alters protein function. These directions represent promising extensions of current efforts, with the potential to enhance both mechanistic understanding and therapeutic development.

6.2. Integrating protein-protein interactions into tumor protein-metal binding prediction

Protein-protein interaction (PPI) networks are essential in cellular function, and tumor proteins often exert their effects through these networks. Incorporating PPI information can provide valuable functional context for understanding the biological significance and functional impact of metal-binding events. For example, the organoarsenic drug Darinaparsin (ZIO-101) has demonstrated anticancer activity across various tumor cell lines. Studies has shown that ZIO-101 can bind to histone H3.3, affecting the function of histone H3.3 in the cell nucleus [142]. PPI analysis reveals that histone H3.3 closely interacts with histone deacetylase 1 (HDAC1). HDAC1 can regulate the level of histone acetylation, a process that further affects the expression of cyclin-dependent kinase inhibitor 1A (CDKN1A), ultimately leading to the overexpression of tumor necrosis factor-related genes and

Figure 3 | Post-binding structural prediction in tumor protein-metal complexes. First, binding sites are predicted using established tumor protein–metal binding models. Next, the post-binding structure is modeled using the protein, metal ion, and predicted binding sites as input. To enhance structural accuracy, the framework incorporates reference metalloprotein structures and known metal-specific structural variations. This approach aims to generate biologically meaningful predictions of metalloprotein conformations associated with tumors.

triggering apoptosis, thus inhibiting tumor growth. Focusing solely on the binding of histone H3.3 to arsenic without considering its interaction with HDAC1 would fail to fully grasp the anticancer mechanism of arsenic compounds and could overlook potential therapeutic strategies targeting HDAC1 [142]. These examples highlight that PPI often influence the formation, stability, and function of metal-binding sites. PPI data can enhance model accuracy by providing biologically relevant context [98]. However, current prediction models make limited use of PPI information. Therefore, we encourage future research to integrate PPI networks to improve the functional relevance and interpretability of tumor protein–metal binding predictions.

Recent advances in bioinformatics have provided a solid foundation for this integration. Public datasets, such as STRING [143] and PINA [144], have accumulated extensive PPI data that can be mined to extract interaction networks relevant to tumor protein-metal binding functions. Meanwhile, computational methods such as molecular docking and molecular dynamics simulation allow researchers to model protein-protein interactions and complexes, and examine how metal-binding sites are altered in these contexts [145]. In addition, experimental techniques such as yeast two-hybrid screening and co-immunoprecipitation can validate predicted interactions, providing strong experimental support for ML models [146, 147]. User-friendly PPI network analysis platforms improve accessibility for researchers with limited programming expertise, facilitating broader adoption of PPI-informed modeling strategies [148].

6.3. Post-binding structural prediction in tumor protein-metal complexes

The 3D structure of a protein determines its cellular function, including catalysis, signal transduction, and structural support. When binding to a metal ion, proteins often undergo structural changes that

alter their function. This also holds for tumor proteins, where metal binding may disrupt or modulate oncogenic processes. Metal-based drugs, such as platinum-based drugs, exploit this mechanism to alter tumor protein structures and induce cell death.

To model this process computationally, we propose leveraging existing protein-metal binding predictive methods and extend them to estimate structural changes in tumor proteins after metal binding. These models can serve as valuable tools for assessing therapeutic potential, accelerating drug development, and overcoming the limitations of experimental structural determination. Existing models for studying protein-metal interactions operate within a ternary framework composed of three key components: the protein, its binding site(s), and the associated metal ions. For example, models using protein and binding sites data as inputs can predict the types of metal that may bind. Conversely, models using protein and metal information can identify whether a protein functions as a metalloprotein and locate its potential binding sites. Through these modular configurations, models can infer conformational changes even with incomplete input data, enabling structure prediction under conditions where structural data are missing or limited [98].

Based on the insights from recent studies [84, 149], we propose a framework for post-binding structural prediction in tumor protein-metal complexes, as shown in Fig. 3. The framework operates in two stages: first, it predicts binding sites using tumor protein and metal ion inputs; then, it uses the protein, metal, and predicted binding sites to model the post-binding structure. To enhance prediction accuracy, the framework incorporates prior knowledge from known metalloprotein structures and metal-specific structural effects. Additionally, domain-specific constraints, such as chirality and geometric coordination rules, are applied to ensure biological plausibility. This framework supports the predictive modeling of metal-bound tumor protein structures and offers a pathway toward structure-guided drug design targeting metal–protein interactions in cancer.

7. Conclusion

Interpretable multimodal learning offers a promising approach to improving the efficiency of wet-lab experiments in tumor protein-metal binding research while ensuring model transparency and predictive accuracy. In this paper, we presented our perspective on advancing this field by drawing insights from existing protein-metal binding studies among data, multimodal learning, and interpretability. We highlighted data modalities and key data processing steps for conducting tumor protein-metal binding research, including standardizing data acquisition, optimizing multimodal learning, and improving interpretability. Building on these insights, we proposed two additional considerations for advancing future research in tumor protein-metal binding: integrating protein-protein interaction data and developing models capable of predicting structural changes in tumor proteins after metal binding. We believe that implementing these perspectives will establish a strong foundation for future interdisciplinary research and will require close collaboration among clinicians, biologists, and machine learning researchers.
