In this study, we extend the application of the Lee-Yang phase transition theorem to the realm of AdS black hole thermodynamics, thereby deriving a comprehensive complex phase diagram for such systems. Our research augments extant studies on black hole thermodynamic phase diagrams, particularly in the regime above the critical point, by delineating the Widom line of AdS black holes. This boundary segregates the supercritical domain of the phase diagram into two disparate zones. As the system traverses the thermodynamic crossover within the supercritical region, it undergoes a transition from one supercritical phase to another, while maintaining the continuity of its thermodynamic state functions. This behavior is fundamentally different from that below the critical point, where crossing the coexistence line results in discontinuities of thermodynamic state functions. The Widom line enables a thermodynamic crossover between single-phase states without traversing the spinodal that emerges in the critical region.

I. MOTIVATION

Some of our best clues as to how gravity and quantum theory can be reconciled comes from the physics of black holes. In particular, their thermodynamics [1–3] offers revealing perspectives into this notorious problem. In recent years black hole thermodynamics has experienced remarkable growth, greatly deepening our comprehension of the physics governing strong gravitational fields [4–7]. Even more recently the significant accumulation of gravitational wave observations and the rapid advancement of quantum computing have enabled scientists to acquire further knowledge concerning the laws of black hole mechanics and their dynamics within curved spacetime via experimental simulations, thereby providing indirect reinforcement to black hole thermodynamics [8–10].

Research on black hole thermodynamics has primarily focused on phenomena up to the critical point, analyzing the rich landscape of phase structures below the critical point and the scaling behaviour in its vicinity. Little attention has been to exploring which states exist above the critical point. In conventional thermodynamic systems recent research has increasingly explored supercritical behaviour in systems such as van der Waals fluids and water, with significant advancements both theoretically and experimentally [11–13]. Since the analysis of black hole thermodynamic phase transitions is inspired by methodologies used in conventional thermodynamic systems, here we carry out an investigation of supercritical phenomena in black hole thermodynamics, aiming to theoretically uncover more information about black hole thermodynamic systems in the supercritical region.

The rationale for considering supercritical phenomena in black hole thermodynamics is that below the critical point, when a system crosses the coexistence line transitioning from one single phase to another (such as in gas-liquid phase transitions or the small-large black hole phase transitions), it can encounter the spinodal line, which demarcates metastable states of supercooling or superheating. In this sense the coexistence line is not an ideal thermodynamic crossover for single-phase transitions. Methodologically we shall incorporate supercritical behaviour into black hole thermodynamics by employing Lee-Yang phase transition theory. Once the framework for analyzing supercritical behaviour is established, the physical understanding of the associated supercritical characteristics will logically follow.

II. SUPERCRITICALITY FOR THE ADS BLACK HOLE

The Lee-Yang phase transition theory posits that the behaviour of zeros in the grand partition function, known as Lee-Yang zeros, governs the occurrence of phase transitions. Specifically, non-analytical changes in the system's state functions arise exclusively when complex Lee-Yang zeros converge onto the real axis within the thermodynamic limit [14, 15]. Building upon this foundation, Fisher extended the Lee-Yang phase transition theory to the canonical ensemble, introducing the concept of Fisher zeros for the complex temperature [16].

In the context of black hole thermodynamics, a crucial insight emerges from the relationship between the Euclidean path integral and the black hole partition function, which plays a pivotal role in understanding their thermodynamic properties [17]. In the Euclidean approach to quantum gravity, we can relate to the partition function Z through the bridge equation $G = TI = -T \ln Z$, where G is the Gibbs free energy, T is the temperature of the canonical ensemble, and I is Euclidean action. Hence the Lee-Yang phase transition theory for the black hole thermodynamics is equivalent to the following statement,

$$\text{Zeros of Partition function} \xleftrightarrow{G = -T \ln Z} \text{Singularities of Gibbs free energy.} \quad (1)$$

Here we demonstrate that, since the temperature of a black hole thermodynamic system remains non-singular, except for extreme black holes, which correspond to zero temperature, the zeros of the partition function are exclusively associated with the singularities of the Gibbs free energy.

For the charged AdS black hole thermodynamic system, the phase diagram (Fig. 1) exhibits a striking analogy to the phase transition behavior of van der Waals fluids [18]. Below the critical point, black holes undergo a first-order phase transition from small to large black holes, analogous to the gas-liquid phase transition observed in van der Waals fluids. The coexistence line separating the small and large black hole phases can be precisely determined by applying Maxwell's equal area law [19]. This line not only characterizes the phase transition dynamics between small and large black holes but also delineates the distinct single-phase regions corresponding to the small black hole phase and the large black hole phase. Similar to the gas-liquid phase transition, certain thermodynamic state functions—such as enthalpy and free energy—are continuous, but not analytic when the system is cooled along a path that crosses the coexistence line. The thermodynamic nature of the AdS black holes in coexistence region has been studied in [20]. However, in real experimental scenarios, such discontinuity/non-analyticity may not occur precisely at the coexistence line. This is because the system can persist in a supercooled metastable phase until it reaches a limit of stability, known as a spinodal line. This behavior is illustrated by path a in the left panel of Fig. 1.

FIG. 1: A schematic picture of the phase diagram of a typical charged AdS black hole thermodynamic system. The left panel shows the phase diagram of a large black hole (LBH) and a small black hole (SBH) undergoing a phase transition (similar to a gas-liquid phase transition). The right panel shows the supercritical phenomenon of the charged AdS black hole, analogous to conventional supercritical fluids.

To describe the continuous evolution of thermodynamic state functions between different single phases (either theoretically or experimentally), the Widom line is a very useful concept [21]. This line, which extends above the critical point of the gas-liquid phase transition, describes behaviour in the supercritical regime. When a system is

cooled isobarically along a path above the critical point, the thermodynamic state functions transition smoothly from the characteristic values of a high-temperature phase (e.g., a gas-like phase or a large black hole-like phase) to those of a low-temperature phase (e.g., a liquid-like phase or a small black hole-like phase). The Widom line delineates where this smooth transition takes place. This behavior is illustrated by path *b* in the right panel of the Fig. 1.

It is well established that above the critical point, the system enters the supercritical region in the phase diagram, where the distinction between the gas and liquid phases becomes ambiguous or entirely blurred. The Widom line is commonly interpreted as an extension of the coexistence curve into the one-phase region (the two crossover lines intersect at a critical point), serving as a boundary that delineates the supercritical liquid-like and supercritical gas-like phases. Originally, the Widom line was introduced as the locus of maximum correlation length. However, for practical experimental purposes, it is often approximated as the set of states where thermodynamic response functions—such as heat capacity at constant pressure and isothermal compressibility—exhibit extrema [11, 12]. Notably, there is no rigorous method to directly determine the Widom line as the locus of maximum correlation length solely from these response functions, and from the perspective of thermodynamic geometry, the Widom line is also closely linked to thermodynamic curvature, which is proportional to the correlation volume [22, 23].

How can we conceptualize the Widom line within the context of black hole thermodynamic systems? Unlike ordinary fluid systems, where the Widom line is typically defined using thermodynamic response functions—particularly the maximum of the constant pressure heat capacity [11, 12]—the situation for black holes is more nuanced. In black hole thermodynamics, the charged AdS black hole serves as the most representative system. Upon entering the supercritical region, heat capacity at constant pressure does exhibit extremal behavior; however, these extrema are strictly local, with no global maximum present. This behaviour is in stark contrast with that of van der Waals fluid systems, rendering the use of thermodynamic response function maxima unsuitable for defining the Widom line in black hole systems. Fortunately, Lee-Yang phase transition theory provides a robust framework for analytically describing phase transitions in thermodynamic systems. Given that Lee-Yang zeros on the real axis correspond to phase transition points, we propose leveraging Lee-Yang phase transition theory to introduce and define the Widom line for black hole thermodynamic systems:

$$\text{Widom line} \quad \mapsto \quad \text{Projection of complex Lee-Yang zeros on the real phase plane.} \quad (2)$$

Using this deductive definition, we can procure a detailed and intricate phase diagram of a black hole thermodynamic system, from which we can derive its pertinent behaviour within the supercritical region. Analogous to the distinction between the small black hole phase (liquid phase) and the large black hole phase (gas phase) in the critical region, the Widom line allows us to introduce and differentiate between a small black hole-like phase and a large black hole-like phase in the supercritical region. This differentiation is facilitated by the Widom line, which enables a thermodynamic crossover between single-phase states without traversing the spinodal line that emerges in the critical region. Combining our definition of the Widom line in this paper and the experimental measurements of Lee-Yang zeros in Refs. [24, 25], it provides us with the possibility of simulating (and ultimately experimentally detecting) the critical point of thermodynamic phase transition in AdS black holes.

We now employ concrete examples to systematically examine supercritical behaviour in black hole thermodynamics, thereby establishing a refined phase diagram that comprehensively characterizes transition patterns for thermodynamic crossover lines.

III. CHARGED ADS BLACK HOLE

In Schwarzschild-like coordinates, the metric of the four-dimensional charged AdS black hole is

$$ds^2 = -f(r)dt^2 + \frac{dr^2}{f(r)} + r^2 (d\theta^2 + \sin^2 \theta d\phi^2),$$

where $f(r) = 1 - 2M/r + r^2/l^2 + Q^2/r^2$, with M the ADM mass, Q the total charge of the black hole, and l the AdS radius. The black hole event horizon is given by the larger root of $f(r_h) = 0$, yielding $M = r_h/2 + 4\pi Pr_h^3/3 + Q^2/(2r_h)$, where P is thermodynamic pressure via $P = 3/(8\pi l^2)$ in the framework of black hole chemistry [4] and the extended phase space, with M the enthalpy. Using the Euclidean trick, we can identify the black hole temperature $T = 1/(4\pi r_h) + 2Pr_h - Q^2/(4\pi r_h^3)$, and the corresponding entropy is $S = \pi r_h^2$. Hence the Gibbs free energy is $G = r_h/4 - 2\pi Pr_h^3/3 + 3Q^2/(4r_h)$. In addition, some thermodynamic response functions, such as constant pressure heat capacity and constant volume heat capacity, are $C_P = 2S(8PS^2 + S - \pi Q^2)/(8PS^2 - S + 3\pi Q^2)$ and $C_V = 0$ [18].

In the extended phase space of the black hole thermodynamics, the charged AdS black hole undergoes the small-large black hole phase transition, where the critical point is

$$T_c = \frac{\sqrt{6}}{18\pi Q}, \quad P_c = \frac{1}{96\pi Q^2}, \quad r_c = \sqrt{6}Q, \quad G_c = \frac{\sqrt{6}Q}{3}, \quad C_{P(c)} \rightarrow \infty. \quad (3)$$

For convenience we introduce the dimensionless reduced parameters $p = P/P_c$, $t = T/T_c$, $z = r_h/r_c$, $g = G/G_c$, and $c_p = C_P \cdot P_c$, indicating that we can obtain some dimensionless reduced thermodynamic quantities

$$t = \frac{3p}{8}z + \frac{3}{4z} - \frac{1}{8z^3}, \quad (4)$$

$$g = \frac{3}{4} \left(z - \frac{p}{6}z^3 + \frac{1}{2z} \right), \quad (5)$$

$$c_p = \frac{z^2(3pz^4 + 6z^2 - 1)}{24(pz^4 - 2z^2 + 1)}, \quad (6)$$

and the small/large coexistence line below the critical point is [19]

$$t = \sqrt{\frac{p(3 - \sqrt{p})}{2}}, \quad (7)$$

which starts from the origin and ends at the critical point (3).

We depict the behavior of the Gibbs free energy g (5) and constant pressure heat capacity c_p (6) for different values of the pressure in Fig. 2. It can be seen that below the critical point, Gibbs free energy exhibits some singularities, namely the two sharp points of the swallowtail structure. These two points correspond to divergent behavior in c_p . After exceeding the critical point, g is continuous and monotonic. c_p is also a continuous function that has some local extrema. As p continuously increases, we see that the extreme behaviour of c_p disappears and becomes a monotonically increasing function.

FIG. 2: The behaviors of dimensionless reduced Gibbs free energy g and constant pressure heat capacity c_p , where black line for $p = 0.50$, red dashed line for $p = 1.00$ (critical point), blue line for $p = 1.20$, orange line for $p = 1.35$, green line for $p = 1.60$, and purple line for $p = 2.00$ for the charged AdS black hole.

We now extend our analysis to the complex domain to investigate the thermodynamic behavior of charged AdS black holes in the supercritical region. In this framework, we treat z as a complex variable, which consequently

makes t a complex variable as well, while p remains a real number [26]. As established in prior analyses, a phase transition in a black hole thermodynamic system is associated with the singularity distribution of the Gibbs free energy. By examining the behavior of the Gibbs free energy as a function of temperature, it becomes evident that the singularities of the free energy are manifest as two distinct sharp points within the swallowtail structure. At these points, the second derivative of the free energy with respect to temperature exhibits a discontinuity. Hence we obtain the singularity distribution of the Gibbs free energy, i.e., the Lee-Yang zeros according to Eq. (1),

$$pz^4 - 2z^2 + 1 = 0. \quad (8)$$

For values of p we depict the singularity distribution of the Gibbs free energy in Fig. 3. We see that these singularities are divided into two categories. One type is located on the real axis, where $p < 1$. Those singularities located on the positive real axis correspond to real phase transition points. The singularities of other type are distributed in the complex plane, corresponding to supercritical phenomena with $p > 1$.

The distribution of Lee-Yang zeros provides crucial insight into the thermodynamic phase behaviour of the system. When no genuine phase transition occurs in the thermodynamic system, as evidenced by the Lee-Yang zeros being distributed exclusively in the complex plane (excluding the real axis), these zeros are consistently observed to reside within the unit circle, in full accordance with the Lee-Yang unit circle theorem. However, upon the occurrence of a phase transition, the Lee-Yang zeros extend beyond the unit circle and distribute along the positive real axis. This distribution pattern fundamentally reflects the analytic properties of the system's phase transition. Notably, based on our previous proposition, the zeros located in the complex plane (excluding the real axis), particularly those in the first quadrant, serve as critical indicators for understanding the supercritical phenomena of the system.

FIG. 3: The singularity distribution of the Gibbs free energy in charged AdS black hole, corresponding to the Lee-Yang zeros, for different pressure values. The gray curve represents the unit circle, while distinct colors denote the four roots of Eq. (8) in the complex domain. Specifically, roots located on the real axis correspond to the critical region ($p < 1$), whereas those in the complex plane (excluding the real axis) are associated with the supercritical region ($p > 1$). There are also singularities in the second derivative of g at $z = \pm 1$, on the unit circle.

Based on Eqs. (4), (7) and (8), we obtain the phase diagram of a charged AdS black hole in the complex domain, shown in Fig. 4. From this, we can infer more diverse phase transition characteristics of the black hole thermodynamic system.

- The coexistence line (red line) between small black hole and large black hole is determined by Eqs. (7), which originates from the zero point and terminates at the critical point. If the system is subject to a cooling process under constant pressure conditions, a phase transition occurs as it traverses the coexistence line, characterized by a shift from the large black hole state to the small black hole state. This transition is accompanied by distinct discontinuities in the thermodynamic state functions.
- The spinodal lines (black and blue lines, respectively corresponding to those in Fig. 3) correspond to singularities of the Gibbs free energy located on the positive real axis in Fig. 3 for $p < 1$. There exist two spinodal lines,

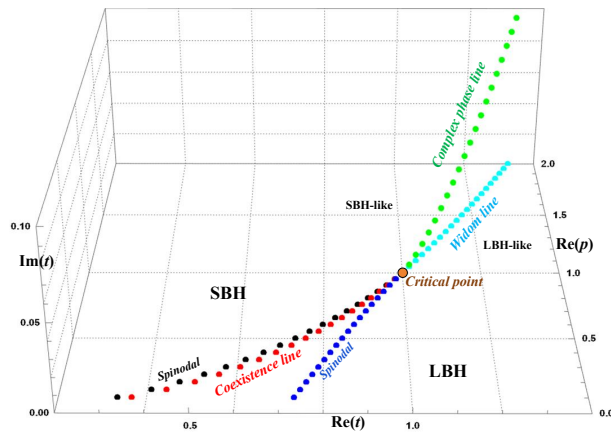

FIG. 4: The complex phase diagram of the charged AdS black hole in a three-dimensional complex space (consisting of the positive real part of temperature $\text{Re } t$, the positive real part of pressure $\text{Re } p$, and the positive imaginary part of temperature $\text{Im } t$) and corresponding supercritical phenomena.

and the regions between them and the coexistence line correspond to the super-cooled and the super-heated metastable phases, respectively.

- The complex phase line (green line, corresponding to the green line in Fig. 3) is determined by the singularity of the Gibbs free energy in the first quadrant of the complex plane in Fig. 3. It is a new phase diagram line residing in a three-dimensional complex space, which reflects the analytical properties of phase transitions and encapsulates significant information about the system in the supercritical region.
- The projection of the complex phase line onto the real phase plane is known as the Widom line (cyan line, based on Eq. (2)), and falls within the supercritical region which emanates from the critical point. This crossover line divides the phase diagram above the critical point into regions with distinct physical characteristics, namely, the small black hole-like phase and the large black hole-like phase. These regions can be connected without encountering any thermodynamic singularities.

The other lines in Fig. 3, located in the second to fourth quadrants of the complex plane, correspond to cases where the real or imaginary part of z is negative, in which case the real or imaginary part of the corresponding complex temperature is respectively negative. We therefore do not consider these physically meaningless situations and limit our analysis to the case presented in the first quadrant of Fig. 3.

IV. SUMMARY

We have shown how to establish a crossover line, the Widom line, within the supercritical region of a black hole thermodynamic system, partitioning it into two distinct phases with disparate physical characteristics, designated as the small black hole-like phase and the large black hole-like phase. When the system is cooled through an isobaric process within the supercritical region, crossing Widom line signifies a transition from one supercritical phase to another, during which the thermodynamic state functions of the system vary continuously. Conversely, within the critical region, traversing the coexistence line results in a phase transition accompanied by discontinuities in the thermodynamic state functions.

Moreover, the Widom line in the supercritical region and the coexistence line in the critical region converge at the critical point, providing a reference pathway for the detection of the critical point. In the critical region, crossing the coexistence line results in discontinuities in the thermodynamic state functions. By contrast, crossing the Widom line in the supercritical region does not induce singular behavior in the thermodynamic functions. Therefore, the behavior

of the Widom line near the critical point can be utilized to extract relevant characteristics of the system's critical point, offering the possibility for laboratory simulations of black hole thermodynamic phase transitions.

Indeed, for conventional supercritical fluid systems, the Widom line has been primarily proposed based on the extremal characteristics of the system's thermodynamic response functions, and extensive research has been conducted both theoretically and experimentally. However, when we shift our perspective to black hole thermodynamic systems, the situation becomes different. Although the analysis of black hole thermodynamics draws on the phase transition theory of ordinary thermodynamics, due to its inherent peculiarities, many thermodynamic phenomena exhibit significant differences from those in ordinary thermodynamic systems. For the charged AdS black hole thermodynamic system under consideration, it is known that the constant-pressure heat capacity in the supercritical region does not exhibit a maximum but rather local extrema. Therefore, defining the Widom line solely based on the conventional supercritical fluid systems is not feasible. Fortunately, in addition to Landau's phase transition theory, we have the Lee-Yang phase transition theorem, which provides a profound understanding of phase transitions in the complex domain.

The distribution of Lee-Yang zeros on the positive real axis indicates that the system will undergo a phase transition. Adhering to the core idea of the Lee-Yang phase transition theorem, we have extended analysis of black hole thermodynamics to the complex domain. By establishing the fundamental correspondence through Eqs. (1) and (2), we introduce the Widom line for the black hole thermodynamic system. This extension of black hole thermodynamics into the supercritical region allows us to establish a thermodynamic crossover line within this area, thereby enriching the supercritical phase diagram of black hole thermodynamics.
