Abstract

Complex and larger networks are becoming increasingly prevalent in scientific applications in various domains. Although a number of models and methods exist for such networks, cross-validation on networks remains challenging due to the unique structure of network data. In this paper, we propose a general cross-validation procedure called **NETCROP** (**NET**work **CR**oss-Validation using **O**verlapping **P**artitions – [GitHub Repository](#)). The key idea is to divide the original network into multiple subnetworks with a shared overlap part, producing training sets consisting of the subnetworks and a test set with the node pairs between the subnetworks. This train-test split provides the basis for a network cross-validation procedure that can be applied on a wide range of model selection and parameter tuning problems for networks. The method is computationally efficient for large networks as it uses smaller subnetworks for the training step. We provide methodological details and theoretical guarantees for several model selection and parameter tuning tasks using **NETCROP**. Numerical results demonstrate that **NETCROP** performs accurate cross-validation on a diverse set of network model selection and parameter tuning problems. The results also indicate that **NETCROP** is computationally much faster while being often more accurate than the existing methods for network cross-validation.

1 Introduction

Most modern systems involve interactions between multiple agents, often modelled using networks. Network data arise out of various scientific fields such as social networks ([Akhtar](#)

et al. 2013), biomedical networks (Komolafe et al. 2022), epidemiological networks (Dasgupta & Sengupta 2022), etc. Numerous network models, such as stochastic blockmodels (SBMs) (Holland et al. 1983), degree corrected blockmodels (DCBMs) (Karrer & Newman 2011), random dot product graphs (RDPGs) (Athreya et al. 2017) and latent space models (Hoff et al. 2002) among others, are utilized in the analysis of network data. SBM and DCBM categorize nodes into communities, whereas RDPG and latent space models associate nodes with their positions in a latent space. Inference techniques for network models encompass a spectrum of approaches, including spectral methods like spectral clustering and adjacency spectral embedding (Rohe et al. 2011, Lei & Rinaldo 2015, Sarkar & Bickel 2015, Sengupta & Chen 2015), likelihood-based methods (Amini et al. 2013, Nowicki & Snijders 2001, Sengupta & Chen 2018), and Markov chain Monte Carlo methods (Hoff et al. 2002, Handcock et al. 2007), which are applied for parameter estimation in these models.

Given an observed network, selecting an appropriate network model and the corresponding methodology is an indispensable task. Cross-validation is one of the most commonly used statistical tools for such model selection and parameter tuning problems for traditional (non-network) data. In a standard cross-validation, the data is randomly split into a training set and a test set. The candidate models (or tuning parameter values) are trained on the training set and evaluated on the test set to select the most appropriate one. The effectiveness of standard cross-validation follows from its simple and flexible design that covers a variety of settings. For a modern take on cross-validation, and its advantages and disadvantages, see Bates et al. (2024) and the citations therein. However, cross-validation for model selection and parameter tuning in network data is very little explored. The major challenge for a network cross-validation method stems from the complex nature of the data. Usually, only one instance of the network is observed, which makes defining data points for cross-validation difficult. Treating the rows of the observed network adjacency matrix as the data points, Chen & Lei (2018) developed a network cross-validation algorithm, called Network Cross-Validation (NCV), designed specifically for choosing the number of communities in blockmodels with theoretical guarantee for SBM. Li et al. (2020) considered the

node pairs as the data points in their more widely applicable network cross-validation algorithm, called Edge Cross-Validation (**ECV**), which was shown to consistently recover the number of communities in SBM and the latent space dimension in RDPG along with some additional numerical examples.

Both **NCV** and **ECV** suffer from certain drawbacks, leaving a gap in the network cross-validation literature. **NCV** takes each row of the adjacency matrix as a sampling unit and subsamples a proportion of the rows in each fold. For a network with n nodes, it still requires working on rectangular matrices of order $np \times n$ for some fraction p , making the training sets very large and the training steps very slow. It is also specific to estimating the number of communities in blockmodels. In contrast, **ECV** is more general, employing node pair sampling to extract a subset of the adjacency matrix as the training data and using low-rank completion algorithms to impute the missing entries. The candidate models are then estimated from the imputed matrix, and the held-out entries of the adjacency matrix serve as test data. However, if the original network is binary, the imputed values in **ECV** are very likely to be non-binary, making the method unsuitable for estimators that require a binary adjacency matrix as input, such as likelihood-based methods (Zhao et al. 2012, Hoff et al. 2002). Instead, it is primarily applicable to methods that allow non-binary adjacency matrices, such as those based on spectral decomposition (Rohe et al. 2011, Sussman et al. 2012). Furthermore, for the adjacency matrix estimation step to be accurate, it requires a large subsample of node pairs, usually around 90% of all the node pairs in the network. This can potentially cause overfitting of the network and slow computations for large networks. The matrix completion algorithm used in **ECV** affects its theoretical and computational performance as well. The authors of both algorithms recommended repeating their methods for 20 times and choosing the most frequently occurring outcome model to stabilize the results. This stabilization slows down the algorithms even further.

In this paper, we develop a computationally efficient subsampling based network cross-validation procedure. The method is called **NETwork CRoss-Validation using Overlapping Partitions (NETCROP)**. Given an observed network and a candidate set of models, **NETCROP** splits the network into suitably chosen training and test sets, fits all the candidate models

on the training sets, and tests them on the test set using a suitable loss function. **NETCROP** first randomly subsamples a set of *overlap nodes* and partitions the remaining nodes into s *non-overlap partitions*. Then it forms s subsets of nodes, where each subset consists of the overlap nodes and the nodes from the corresponding non-overlap part. The s subnetworks induced by the nodes in each of the s subsets of nodes are the training subnetworks. These subsamples are much smaller than the original samples, which makes the method scalable (Politis et al. 1999, Sengupta et al. 2016, Ganguly et al. 2023). Every candidate model is fitted to each subnetwork to estimate the corresponding model parameters. The parameters are then matched using the overlap nodes. For example, the community labels in a blockmodel are identifiable only up to the permutations of the labels, and the latent positions in RDPG or latent space models are identifiable up to their orthogonal rotations and translations. After matching the parameter estimates using the overlap part, we combine the estimates from the subnetworks. Then, the estimated parameters are used to predict the edge probabilities for the node pairs in test set. This test set consists of the node pairs between the non-overlap parts. Finally, for each candidate model, the test set prediction error is computed using a suitable loss function, and the model with the lowest test set loss is chosen as the outcome.

Since **NETCROP** splits the observed network into a training set and a test set, it inherits the flexible nature of standard cross-validation, making it adaptable to a wide range of network cross-validation problems including model selection and parameter tuning. The unique design of **NETCROP** stabilizes the estimates of the trained model parameters by aggregating estimates from multiple subnetworks (Breiman 1996), thus requiring much less number of repetitions than **NCV** and **ECV** for stability. The inclusion of the overlap nodes makes it possible to match or align the unidentifiable parameter estimates from the subnetworks. These factors, combined, help **NETCROP** avoid the problem of overfitting, while making it significantly faster and more accurate than **NCV** and **ECV**. **NETCROP** is also naturally parallelizable as the computations on different subnetworks can be done on different processors in a multiprocessor system.

This paper proposes **NETCROP** as a versatile network cross-validation tool for model selection and parameter tuning problems. We establish the theoretical consistency of **NETCROP** for selecting the number of communities in SBM, achieving slightly stronger bounds under milder assumptions compared to **NCV**. Additionally, we provide, to the best of our knowledge, the first theoretical consistency result for cross-validation in DCBM. Furthermore, we prove the theoretical consistency of **NETCROP** for selecting the latent space dimension in RDPG. Numerical examples include selecting the degree heterogeneity and the number of communities in blockmodels, the latent space dimensions in RDPG and latent space models, and the tuning parameter for regularized spectral clustering. Although several model based methods exist for estimating the number of communities and assessing the goodness of fit for SBM and DCBM (Lei 2016, Ma et al. 2021, Cerqueira et al. 2024, Deng et al. 2023), there is a scarcity of general and computationally efficient cross-validation technique for network model selection and parameter tuning in the current literature. With this in consideration, we compare **NETCROP** only with the other network cross-validation algorithms (**NCV** and **ECV**) throughout the paper. All codes for **NETCROP** along with other relevant codes are publicly available in this GitHub Repository: <https://github.com/sayan-ch/NETCROP.git>.

The paper is organized as follows. Section 2 contains an overview of **NETCROP**. In Section 3, we discuss applications of **NETCROP** for four model selection and tuning parameter problems. We present theoretical results for the SBM, DCBM, and RDPG cases in Section 4. The numerical performance of **NETCROP** in comparison to other network cross-validation methods for simulated and real networks are in Section 5. Section 6 contains discussion and concluding remarks on this paper.

2 Methodology

First, we introduce some notations that are used throughout the article. The term *simple network* indicates an undirected, unweighted graph without any self-loops or multiple edges between nodes. Although **NETCROP** is described and the theoretical results are derived for simple networks, they can be extended mutatis mutandis for directed or weighted networks. Unless otherwise specified, the word *network* refers to simple network in this paper.

Define $[n] = \{1, \dots, n\}$ and $[n_1 : n_2] = \{n_1, \dots, n_2\}$ for any natural numbers n and $n_1 \leq n_2$. I_n , $\mathbf{1}_n$, and J_n denote the $n \times n$ identity matrix, the $n \times 1$ vector of all 1, and the $n \times n$ matrix of all 1, respectively. The n in the subscript is dropped whenever it is evident from the context. $\mathbf{I}(\cdot)$ denotes the indicator function of the event inside it. For $a \in \mathbb{R}^d$, $\|a\|$ is defined as the ℓ_2 norm. For a matrix M ; $\|M\|$, $\|M\|_F$, $\|M\|_{2,1}$ and $\|M\|_{2,\infty}$ are defined as the spectral norm, the Frobenius norm, matrix 2,1 and 2, ∞ norms, respectively. For any countable set S , $|S|$ denotes its cardinality. For any two subsets $I \subset [n]$ and $J \subset [d]$, M_{IJ} , $M_{I\cdot}$ and $M_{\cdot J}$ denote the submatrices of M with the rows in I and the columns in J , the rows in I and all the columns, and the columns in J and all the rows, respectively. The i th row M_i indicates a $d \times 1$ vector. We define the squared error loss as $\ell_2(a, p) = (a - p)^2$ for $a, p \in \mathbb{R}$. The space of all permutation matrices of order $k \times k$ is denoted by \mathbb{H}_k . The space of all orthogonal matrices of order $d \times d$ is denoted by \mathcal{O}_d . For any two real sequences $\{a_n\}$ and $\{b_n\}$, $a_n = O(b_n)$ or $b_n = \Omega(a_n)$ if $\lim_{n \rightarrow \infty} |a_n/b_n| \leq c$ for some $c > 0$. Similarly, $a_n = o(b_n)$ or $b_n = \omega(a_n)$ if $\lim_{n \rightarrow \infty} a_n/b_n = 0$, and $a_n \asymp b_n$ if $a_n = O(b_n)$ and $b_n = O(a_n)$. For sequences of random variables, the stochastic versions of O , o , Ω , and ω are denoted by O_p , o_p , Ω_p , and ω_p , respectively, and are defined as in [Serfling \(2009, Section 1.2.5\)](#).

Given a network of size n , A represents the corresponding $n \times n$ adjacency matrix. For any $(i, j) \in [n] \times [n]$, $A_{ij} = 1$ if there is an edge between nodes i and j and 0 otherwise. The set of nodes in the network is denoted by $S = [n]$. A subnetwork induced by a subset of nodes $S_0 \subset [n]$ is represented by the subadjacency matrix $A_{S_0} := A_{S_0 S_0}$. Throughout the paper, we assume that A_{ij} 's are independent, conditional on relevant model parameters, Bernoulli random variables with the probability of an edge between two nodes i and j given by $E(A_{ij}) = P_{ij}$. The probability matrix, also called the expected adjacency matrix, is represented by $P = (P_{ij})_{(i,j) \in [n] \times [n]} = E(A)$.

2.1 NETCROP for Cross-Validation

NETCROP aims to select the best model that fits the network or the best tuning parameter for model fitting from a set of candidate models or parameters. In this section, we describe NETCROP in the context of model selection as the same ideas can easily be modified for a

parameter tuning problem. With a set of κ candidate models $\mathcal{M} = \{\mathcal{M}_1, \dots, \mathcal{M}_\kappa\}$ and a loss function ℓ as inputs, NETCROP has four major steps - *division*, *model fitting*, *stitching*, and *loss computation*. The first three steps constitute the model training phase of cross-validation, while the fourth step corresponds to the model testing phase. The division step divides the network into s subnetworks that share a set of overlap nodes. The model fitting step fits each candidate model on each subnetwork. The stitching step combines the model parameter estimates from the subnetworks using the overlap part. Finally, for each candidate model, the stitched model parameter estimates are used to predict the edge probabilities of the node pairs in the test set, and the prediction error is computed as the sum of losses between the predicted edge probability and the observed adjacency matrix. The steps are described in the following paragraphs.

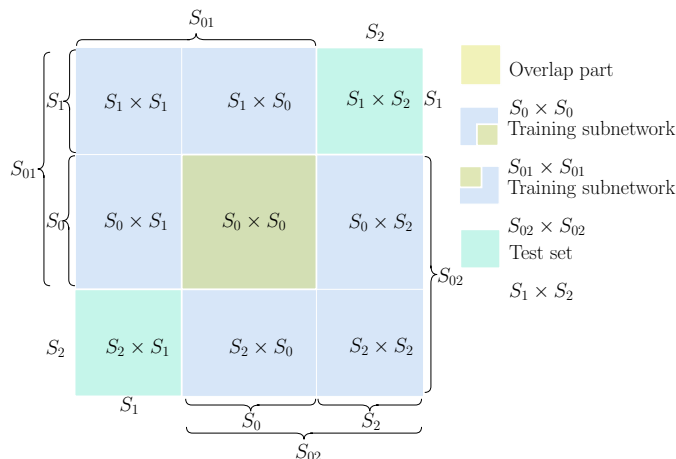

Figure 1: Training subnetworks (S_{01} and S_{02}) and testing set ($S^c = S_1 \times S_2$) of NETCROP with overlap part S_0 of size o and $s = 2$ non-overlap parts S_1 and S_2 ($s = 2$ subnetworks are used for illustration, while NETCROP can be used with $s \geq 2$).

In the division step, the overlap part S_0 is formed by randomly subsampling o nodes from the set of nodes S . Then, the remaining nodes in $S \setminus S_0$ are partitioned into s equally sized non-overlap parts S_1, \dots, S_s . The subsets of nodes are formed as $S_{01} = S_0 \cup S_1, \dots, S_{0s} = S_0 \cup S_s$. Note that the subnetworks are of size $(o + m)$, where $m = (n - o)/s$ is the size of each non-overlap part. NETCROP uses the subnetworks given by the sub-adjacency matrices $A_{S_{01}}, \dots, A_{S_{0s}}$ as the training sets and the node pairs between the non-overlap parts as the

test set. They are defined as

$$\text{Train: } \mathbb{S} := \bigcup_{q=1}^s (S_{0q} \times S_{0q}), \quad \text{Test: } \mathbb{S}^c = (S \times S) \setminus \mathbb{S} = \bigcup_{1 \leq p < q \leq s} (S_p \times S_q).$$

The training and test set splitting of NETCROP with $s = 2$ subnetworks is presented in Figure 1.

In the model fitting step, each candidate model is fitted on each subnetwork $A_{S_{01}}, \dots, A_{S_{0s}}$ to obtain their corresponding parameter estimates. The estimates of the unidentifiable parameters are matched using the overlap nodes by a suitable method. This eliminates any issues due to the unidentifiability of the parameters and ensures that the parameter estimates from the subnetworks are at par. The matching method depends on the model structure. For example, permutation based label matching is needed to match the estimated community labels in a blockmodel. After the parameter matching step, the parameter estimates from each subnetwork are combined for each candidate model. The matching and the combining of the parameter estimates are called stitching. Let the stitched model estimates be denoted by $\hat{\mathcal{M}}_1, \dots, \hat{\mathcal{M}}_\kappa$.

In the final loss computation step, the estimated probabilities for each node pair in the test set are computed for each candidate model. For $(i, j) \in \mathbb{S}^c$, let $\hat{P}_{ij}^{(k)}$ be the predicted edge probability between nodes i and j from the stitched k -th candidate model $\hat{\mathcal{M}}_k$, $k \in [\kappa]$. Let $\hat{P}_{\mathbb{S}^c}^{(k)} = \left(\hat{P}_{ij}^{(k)} \right)_{(i,j) \in \mathbb{S}^c}$. Then the computed losses are obtained as the sum of losses between the entries of the observed adjacency matrix and the predicted edge probabilities from each candidate model over the node pairs in the test set as

$$\hat{L}^{(k)} = L \left(A_{\mathbb{S}^c}, \hat{P}_{\mathbb{S}^c}^{(k)} \right) := \sum_{(i,j) \in \mathbb{S}^c} \ell \left(A_{ij}, \hat{P}_{ij}^{(k)} \right) = \sum_{1 \leq p < q \leq s} \sum_{(i,j) \in S_p \times S_q} \ell \left(A_{ij}, \hat{P}_{ij}^{(k)} \right), \quad k \in [\kappa]. \quad (1)$$

The outcome model $\hat{\mathcal{M}}$ is the model that has the least computed loss on the test set, i.e. $\hat{k} = \arg \min_{k \in [\kappa]} \hat{L}^{(k)}$ and $\hat{\mathcal{M}} = \mathcal{M}_{\hat{k}}$.

NETCROP can be repeated R times with different randomly subsampled overlap nodes and partitions. Majority voting on the R outcome models from the repetitions produce the final output. This optional step is called the *repetition step*. Repetitions are expected to increase the stability of the model selection procedure by eliminating random noise as

new random splits of the data are used for each repetition. A similar use of repetition can be seen in stability selection procedure by [Meinshausen & Bühlmann \(2010\)](#). Algorithm 1 outlines NETCROP for general model selection.

Algorithm 1 NETCROP for Model Selection

Input An $n \times n$ network adjacency matrix A with nodes indexed by $S = [n]$, a set of candidate models $\mathcal{M} = \{\mathcal{M}_1, \dots, \mathcal{M}_\kappa\}$, number of subnetworks s , overlap size o , number of repetitions R , and a loss function $\ell : \mathbb{R}^2 \rightarrow [0, \infty)$.

procedure NETCROP($A, \mathcal{M}, s, o, R, \ell$)

1. **for** (r from 1 to R) {
 - 1.1. Randomly select o nodes from S to form the overlap part S_0 .
 - 1.2. Split $S \setminus S_0$ randomly into s exhaustive parts of equal size $m = (n - o)/s$ as S_1, \dots, S_s .
 - 1.3. Form the subset of nodes $S_{0q} = S_0 \cup S_q$, $q \in [s]$.
 - 1.4. For each $k \in [\kappa]$ and $q \in [s]$, fit \mathcal{M}_k on $A_{S_{0q}}$ to obtain the model estimates $\hat{\mathcal{M}}_k^{(q)}$.
 - 1.5. For each $k \in [\kappa]$, match the model estimates $\hat{\mathcal{M}}_k^{(2)}, \dots, \hat{\mathcal{M}}_k^{(s)}$ with $\hat{\mathcal{M}}_k^{(1)}$ using the overlap nodes and update the model estimates.
 - 1.6. Combine the matched model estimates $\hat{\mathcal{M}}_k^{(1)}, \dots, \hat{\mathcal{M}}_k^{(s)}$ to obtain the final estimate $\hat{\mathcal{M}}_k$ for each $k \in [\kappa]$.
 - 1.7. For each $k \in [\kappa]$, use the stitched model estimate $\hat{\mathcal{M}}_k$ to predict the edge probabilities of node pairs in the test set as $\hat{P}_{ij}^{(k)}$, for each $i \in S_p$ and $j \in S_q$, $1 \leq p < q \leq s$.
 - 1.8. Compute $\hat{L}_r^{(k)} = L\left(A_{S^c}, \hat{P}_{S^c}^{(k)}\right) = \sum_{1 \leq p < q \leq s} \sum_{(i,j) \in S_p \times S_q} \ell\left(A_{ij}, \hat{P}_{ij}^{(k)}\right)$ for each $k \in [\kappa]$.
 - }
 2. Compute $\hat{k}_r = \arg \min_{k \in [\kappa]} \hat{L}_r^{(k)}$, for $r \in [R]$. Select \hat{k} as the mode of $\hat{k}_1, \dots, \hat{k}_R$.
 3. Return $\mathcal{M}_{\hat{k}}$ as the outcome model.
-

2.2 Remarks on the Design of NETCROP

Each training subnetwork in NETCROP, being a subsample from the entire network, can be considered as an observed network of size $o + m = o + (n - o)/s$ from the true model. Thus, any consistency results as $n \rightarrow \infty$, which are applicable on the model estimates from the entire network, should be valid for the estimates from each training subnetwork as long as $o + m \rightarrow \infty$. Fixing the number of subnetworks s with respect to n and assuming the overlap size $o \rightarrow \infty$ and $o = O(n)$, we get $m = s^{-1}(n - o) \asymp n$ and $o + m \asymp n$. These choices of o and m lead to a balance between the training and test subsets, which are both of size $\asymp n^2$. This ensures that the parameter estimates for the true model, obtained from the training subnetworks, are consistent, which in turn lowers the computed loss for the true model. It also guarantees that the effect of fitting a wrong model is captured on a large subset of the test set for the computed loss to be very large for wrong models.

NETCROP requires a choice of the loss function ℓ . From our observation, squared error loss performs well with NETCROP, producing reliable and accurate results in most situations. It is also very fast and easy to compute. We derived all the theoretical results using this loss function due to its algebraic tractability. For unweighted networks with binary adjacency matrices, binomial deviance loss or negative of the area under the receiver operating characteristic curve (AUROC or AUC) can also be used with NETCROP. We noticed that, numerically, the binomial deviance loss produces similar results as the squared error loss, albeit it is a bit slower than the squared error loss. Computation of AUC is very slow for large networks and may offset the computation benefits of NETCROP.

2.3 Computation Complexity

The computation complexity of NETCROP for model selection depends on the sparsity of the network and the complexities of the model fitting, stitching and the loss computation steps. If the probability matrix is of the form $P = P_n = \rho_n P^0$ for some sparsity parameter ρ_n , the complexities of most model fitting procedures are usually polynomials in terms of $n, \log n$ and ρ_n . For the sake of simplicity, we assume that the complexity of fitting the candidate model with the slowest estimation procedure is $O(n^\theta)$ for a network of size n for

some $\theta > 0$. Then the complexity of fitting κ candidate models on s training subnetworks, each of size $(o + m)$, is $O(\kappa s(o + m)^\theta)$.

In the stitching step, the model parameters are matched only using the overlap nodes. Thus, complexity of parameter matching will depend on the overlap size o , the number of matchings $(s - 1)$, the size κ of the candidate set and the dimension of the parameter space. If the complexity of parameter matching based on the overlap nodes for the candidate models is $O(o^\beta)$ for some $\beta \geq 0$, then the overall complexity of the stitching step is $O(\kappa(s - 1)o^\beta)$.

The loss computation step requires as many computations of the loss function as the size of the test set. The test set consists of the node pairs $(i, j) \in (S_p \times S_q)$ for $1 \leq p < q \leq s$. There are $s(s - 1)/2$ pairs of non-overlap parts, where each pair of non-overlap parts contains m^2 node pairs. Thus, the size of the test set is $|S^c| = s(s - 1)m^2/2$. The complexity of this step is $O(\kappa s(s - 1)m^2)$.

The complexity of NETCROP is proportional to the number of repetitions R . Combining the complexities of the individual steps, the complexity of NETCROP with overlap size o , s subnetworks and R repetitions is $O(R\kappa s(o + m)^\theta) + O(R\kappa(s - 1)o^\beta) + O(R\kappa s(s - 1)m^2)$.

In most cases, the model fitting step dominates the parameter matching step i.e. $\theta > \beta$. The model fitting, stitching and loss computation steps can be parallelized on a multi-processor computer. Barring some overhead due to parallelization, complexity of NETCROP is approximately inversely proportional to the number of processors. If NETCROP is applied in parallel over ζ processors, the complexity of NETCROP is $O(\zeta^{-1}R\kappa(s(o + m)^\theta + s^2m^2)) \approx O(\zeta^{-1}R\kappa s^2(o + m)^\theta)$, where the last approximation is based on the fact that $\theta \geq 2$ for most network model fitting tasks.

With a similar setting, the complexity of NCV with V folds and R repetitions is $O(\zeta^{-1}R\kappa V n^\theta)$ as the most computationally dominating step involves V community detections on rectangular submatrices of order $n(1 - 1/V) \times n$, which is usually of order $O(n^\theta)$, depending on the algorithm used for the singular value decomposition within community detection. The complexity of ECV with V cross validation folds under the same setting is $O(\zeta^{-1}V(n^{\theta_0} + \kappa n^\theta))$, where n^{θ_0} is the complexity of matrix completion using singular value decomposition (SVD)

on a matrix of size n . Depending on the SVD algorithm, usually $\theta_0 \in [2, 3]$.

3 NETCROP for Model Selection and Parameter Tuning

In this section, we present the details for applying NETCROP to four cross-validation tasks: (1) detecting the number of communities and degree heterogeneity in blockmodels, (2) estimating the latent space dimension in RDPG models, (3) estimating the latent space dimension in latent space models, and (4) tuning the regularizing parameter for regularized spectral clustering.

3.1 Model Selection for Blockmodels

Here, we discuss how NETCROP (Algorithm 1) is used for selecting the number of communities and choosing the correct model simultaneously from a candidate set consisting of SBM and DCBM. An SBM with n nodes and K communities is parameterized by (g, B) , where $g \in [K]^n$ and $B \in [0, 1]^{K \times K}$. An edge between nodes i and j is given by $A_{ij} \sim \text{Bernoulli}(P_{ij} = B_{g_i g_j})$ independently for all $i < j$, given g . Define $G_k = \{i \in [n] : g_i = k\}$, $n_k = |G_k|$ for $k \in [K]$ and $C \in [0, 1]^{n \times K}$ such that $C_{ig_i} = 1$ and 0 otherwise. Then $P = CBC^\top$. A DCBM adds a layer of complexity to SBM with a degree heterogeneity parameter $\psi_i > 0$ for the i th node. Define $\Psi \in \mathbb{R}^{n \times K}$ satisfying $\Psi_{ig_i} = \psi_i$ and 0 otherwise. Given the parameters (g, B, Ψ) , $P = \Psi B \Psi^\top$ and $P_{ij} = B_{g_i g_j} \psi_i \psi_j$.

Let $\mathcal{M} = \{(\tilde{K}, \delta) \in [K_{max}] \times \{0, 1\}\}$ be the set of candidate models, where K_{max} is the largest number of communities considered and δ is the degree correction parameter. Here $\delta = 0$ means SBM and $\delta = 1$ DCBM. To adapt NETCROP to select the best $(\hat{K}, \hat{\delta}) \in [K_{max}] \times \{0, 1\}$, the stitching and the test set prediction step need to be adjusted. The method is illustrated using spectral clustering (SC, Algorithm A1 in Appendix A) for SBM and spherical spectral clustering (SSC, Algorithm A2 in Appendix A) for DCBM, but any suitable and reasonably accurate community detection algorithms for SBM and DCBM can be used with NETCROP. We note that this approach was introduced by Chakrabarty et al. (2025) for scalable community detection.

Given the subnetworks S_{01}, \dots, S_{0s} from the division step, both **SC** and **SSC** are applied on each subnetwork with \tilde{K} communities for each $\tilde{K} \in [K_{max}]$. Let the $(o+m) \times \tilde{K}$ output community membership matrices corresponding to the q -th subnetwork be $\hat{C}_q^{(0\tilde{K})}$ and $\hat{C}_q^{(1\tilde{K})}$ from **SC** and **SSC**, respectively, with \tilde{K} communities, $q \in [s]$.

Since the community labels are identifiable only up to their permutations, for each $\tilde{K} \in [K_{max}]$, the columns of the s estimated community membership matrices need to be permuted to match with a standard set of labels. We describe two suitable label matching algorithms, **MatchBF** and **MatchGreedy**, in Appendix A. The overlap nodes are used for the label matching in the stitching step. There are s sets of estimated community labels with shared overlap nodes. We set the estimated labels for the overlap part from the first subnetwork $\hat{C}_{1,S_0}^{(\delta\tilde{K})}$ as the standard labels, and match the labels from $\hat{C}_{2,S_0}^{(\delta\tilde{K})}, \dots, \hat{C}_{s,S_0}^{(\delta\tilde{K})}$ to obtain the best matching permutation matrices $H_2^{(\delta\tilde{K})}, \dots, H_s^{(\delta\tilde{K})} \in \mathbb{H}_{\tilde{K}}$ for $\tilde{K} \in [K_{max}]$ and $\delta \in \{0, 1\}$. The choice of standard labels is arbitrary and any one of the estimated labels can be used as the standard for label matching. Then all the labels in each of the subnetworks are updated using their corresponding permutation matrices as $\hat{C}_q^{(\delta\tilde{K})} \leftarrow \hat{C}_q^{(\delta\tilde{K})} H_q^{(\delta\tilde{K})}$, $q \in [2 : s]$, $\tilde{K} \in [K_{max}]$, $\delta \in \{0, 1\}$.

For the loss computation step, the model parameters (g, B) for SBM and (g, B, Ψ) for DCBM need to be estimated. The estimated vectors of community labels from the subnetworks are directly obtained from the estimated community membership matrices as $\hat{g}_q^{(\delta\tilde{K})} = \hat{C}_q^{(\delta\tilde{K})} \mathbf{1}_{\tilde{K}}$. Define $\hat{G}_{q,k}^{(\delta\tilde{K})} := \{i \in S_{0q} : \hat{g}_{q,i}^{(\delta\tilde{K})} = k\}$ as the set of nodes in the q -th subnetwork that are predicted to be in the k -th community for $q \in [s]$, $k \in [\tilde{K}]$, $\tilde{K} \in [K_{max}]$, $\delta \in \{0, 1\}$.

For SBM, the plug-in estimator of the community connectivity matrix B for the q -th subnetwork and \tilde{K} communities is computed as

$$\hat{B}_{q,kk'}^{(\tilde{K})} = \frac{\sum_{(i,j) \in (S_{0q} \times S_{0q})} A_{ij} \mathbf{I}\left((i,j) \in \hat{\eta}_{q,kk'}^{(0\tilde{K})}\right)}{\left|\hat{\eta}_{q,kk'}^{(0\tilde{K})}\right|}, \quad (2)$$

where

$$\hat{\eta}_{q,kk'}^{(\delta\tilde{K})} = \begin{cases} \left\{ (i, j) \in (S_{0q} \times S_{0q}) : \hat{g}_{q,i}^{(\delta\tilde{K})} = k, \hat{g}_{q,j}^{(\delta\tilde{K})} = k' \right\}, & k \neq k' \\ \left\{ (i, j) \in (S_{0q} \times S_{0q}) : i < j, \hat{g}_{q,i}^{(\delta\tilde{K})} = \hat{g}_{q,j}^{(\delta\tilde{K})} = k \right\}, & k = k' \end{cases}, \quad \delta \in \{0, 1\}, \quad (3)$$

for $q \in [s]$, $k, k' \in [\tilde{K}]$, $\tilde{K} \in [K_{max}]$. Now the estimates of B in (2) are averaged over the subnetworks to obtain the final estimates of community connectivity matrix and the test set edge probabilities as

$$\hat{B}^{(\tilde{K})} = \frac{1}{s} \sum_{q=1}^s \hat{B}_q^{(\tilde{K})} \quad \text{and} \quad \hat{P}_{ij}^{(0\tilde{K})} = \hat{B}_{\hat{g}_{p,i}^{(0\tilde{K})} \hat{g}_{q,j}^{(0\tilde{K})}}^{(\tilde{K})} \quad (4)$$

for $(i, j) \in S_p \times S_q$, $1 \leq p < q \leq s$, $\tilde{K} \in [K_{max}]$.

DCBM has an additional degree heterogeneity parameter ψ_i corresponding to each node i that needs to be estimated along with the community connectivity matrix. The DCBM parameters B and ψ are only identifiable up to some factor. [Chen & Lei \(2018\)](#) used the top K right singular vectors to estimate a community-normalized version of the DCBM parameters as

$$\psi'_i = \frac{\psi_i}{\sqrt{\sum_{j:g_j=g_i} \psi_j^2}}, \quad \text{and} \quad B'_{kk'} = B_{kk'} \sqrt{\sum_{i:g_i=k} \psi_i^2 \sum_{j:g_j=k'} \psi_j^2}. \quad (5)$$

Note that $P_{ij} = B_{g_i g_j} \psi_i \psi_j = B'_{g_i g_j} \psi'_i \psi'_j$. Let $\hat{U}_q^{(\tilde{K})}$ be the $(o+m) \times \tilde{K}$ matrix of eigenvectors of $A_{S_{0q}}$. Then ψ'_i corresponding to the q -th subnetwork is estimated as the ℓ_2 norm of the i th row of $\hat{U}_q^{(\tilde{K})}$, and it is used to compute the corresponding plug-in estimate of B' . The estimates are

$$\hat{\psi}'_i^{(\tilde{K})} = \|\hat{U}_{q,i}^{(\tilde{K})}\|, \quad \text{and} \quad \hat{B}'_{q,kk'}^{(\tilde{K})} = \frac{\sum_{(i,j) \in (S_{0q} \times S_{0q})} A_{ij} \mathbf{I}\left((i, j) \in \hat{\eta}_{q,kk'}^{(1\tilde{K})}\right)}{\sum_{(i,j) \in (S_{0q} \times S_{0q})} \hat{\psi}'_i^{(\tilde{K})} \hat{\psi}'_j^{(\tilde{K})} \mathbf{I}\left((i, j) \in \hat{\eta}_{q,kk'}^{(1\tilde{K})}\right)} \quad (6)$$

for $i \in S_{0q}$, $q \in [s]$, $k, k' \in [\tilde{K}]$, $\tilde{K} \in [K_{max}]$. Finally, the mean of the estimated scaled community connectivity matrices is used along with the estimated scaled degree heterogeneity parameters to predict the edge probabilities of nodes in the test set as

$$\hat{B}^{(\tilde{K})} = \frac{1}{s} \sum_{q=1}^s \hat{B}'_q^{(\tilde{K})}, \quad \text{and} \quad \hat{P}_{ij}^{(1\tilde{K})} = \hat{B}'_{\hat{g}_{p,i}^{(1\tilde{K})} \hat{g}_{q,j}^{(1\tilde{K})}}^{(\tilde{K})} \hat{\psi}'_i \hat{\psi}'_j \quad (7)$$

Algorithm 2 NETCROP for Determining the Number of Communities and Choosing between SBM and DCBM

Input An $n \times n$ network adjacency matrix A with node set S , maximum number of communities K_{max} to consider, number of subnetworks s , overlap size o , number of repetitions R , and a loss function ℓ .

procedure NETCROP($A, K_{max}, s, o, R, \ell$)

1. **for** (r from 1 to R) {
 - 1.1. Randomly select o nodes from S to form the overlap part S_0 .
 - 1.2. Split $S \setminus S_0$ randomly into s exhaustive parts of equal size $m = (n - o)/s$ as S_1, \dots, S_s .
 - 1.3. Form the subset of nodes $S_{0q} = S_0 \cup S_q, q \in [s]$.
 - 1.4. For each $q \in [s]$, compute \hat{U}_q as the $(o+m) \times K_{max}$ matrix with the eigenvectors corresponding to the largest K_{max} eigenvalues of $A_{S_{0q}}$.
 - 1.5. **for** (\tilde{K} from 1 to K_{max}) {
 - 1.5.1. For each $q \in [s]$, compute $\hat{C}_q^{(0\tilde{K})}$ using k -means clustering on $\hat{U}_{q, [\tilde{K}]}$, and $\hat{C}_q^{(1\tilde{K})}$ using k -median spherical clustering on the row normalized version of $\hat{U}_{q, [\tilde{K}]}$.
 - 1.5.2. Compute the best matching permutation matrices as $H_q^{(\delta\tilde{K})} = \arg \min_{H \in \mathbb{H}_{\tilde{K}}} \left\| \hat{C}_{q, S_0}^{(\delta\tilde{K})} H - \hat{C}_{1, S_0}^{(\delta\tilde{K})} \right\|_0, q \in [2 : s], \delta \in \{0, 1\}$ and update $\hat{C}_q^{(\delta\tilde{K})} \leftarrow \hat{C}_q^{(\delta\tilde{K})} H_q^{(\delta\tilde{K})}, q \in [2 : s], \delta \in \{0, 1\}$.
 - 1.5.3. For each $i \in S_p, j \in S_q, 1 \leq p < q \leq s$, predict the edge probabilities for SBM as $\hat{P}_{ij}^{(0\tilde{K})}$ in (4) and for DCBM as either $\hat{P}'_{ij}^{(1\tilde{K})}$ in (7) or $\hat{P}_{ij}^{(1\tilde{K})}$ in (8).
 - 1.5.4. Compute $\hat{L}_r^{(\delta\tilde{K})} = L \left(A_{S^c}, \hat{P}_{S^c}^{(\delta\tilde{K})} \right) = \sum_{1 \leq p < q \leq s} \sum_{\substack{i \in S_p \\ j \in S_q}} \ell \left(A_{ij}, \hat{P}_{ij}^{(\delta\tilde{K})} \right), \delta \in \{0, 1\}. \}$
 2. Compute $(\hat{K}_r, \hat{\delta}_r) = \arg \min_{(\tilde{K}, \delta) \in [K_{max}] \times \{0, 1\}} \hat{L}_r^{(\delta\tilde{K})}, r \in [R]$.
 3. Return $(\hat{K}, \hat{\delta})$ as the most occurring outcome from $\{(\hat{K}_r, \hat{\delta}_r) : r \in [R]\}$.
-

for $(i, j) \in S_p \times S_q, 1 \leq p < q \leq s, \tilde{K} \in [K_{max}]$. An alternate estimator of the probability matrix under DCBM that uses Poisson approximation (Karrer & Newman 2011) is given

as

$$\begin{aligned} \hat{O}_{q,kk'}^{(\tilde{K})} &= \sum_{(i,j) \in (S_{0q} \times S_{0q})} A_{ij} \mathbf{I} \left((i,j) \in \hat{\eta}_{q,kk'}^{(1\tilde{K})} \right), & \hat{\psi}_i &= \left(\sum_{j \in S_{0q}} A_{ij} \right) / \left(\sum_{k=1}^{\tilde{K}} \hat{O}_{q,\hat{g}_{q,i}^{(1\tilde{K})}k}^{(\tilde{K})} \right), \\ \hat{O}^{(\tilde{K})} &= \frac{1}{s} \hat{O}_q^{(\tilde{K})}, & \text{and} & \quad \hat{P}_{ij}^{(1\tilde{K})} = \hat{O}_{\hat{g}_{1,i}\hat{g}_{1,j}}^{(\tilde{K})} \hat{\psi}_i^{\tilde{K}} \hat{\psi}_j^{\tilde{K}} \end{aligned} \quad (8)$$

for $(i, j) \in S_p \times S_q$, $1 \leq p < q \leq s$, $\tilde{K} \in [K_{max}]$.

Empirically, the performance of NETCROP was observed to not depend on the choice of the DCBM parameter estimates. Both the estimators in (7) and (8) provide sufficiently accurate predicted test set edge probabilities. The theoretical derivations for DCBM are done with the Chen & Lei (2018) estimators in (7) as the properties of the network eigenvalues can be exploited to connect the estimators with the scaled versions of the true parameters. However, unless otherwise specified, we used the Karrer & Newman (2011) estimate in (8) for all the numerical examples as it is easier and more intuitive to implement.

With the predicted edge probabilities for SBM and DCBM, the number of communities \hat{K} and the degree correction indicator $\hat{\delta}$ are selected based on the computed losses. In case of multiple repetitions, the best outcome is chosen by majority voting on the outcomes from the repetitions. Algorithm 2 outlines NETCROP for selecting K and degree correction indicator in a blockmodel.

3.2 Estimating Latent Space Dimension of RDPG

Here we describe NETCROP for selecting the latent space dimension of RDPG. An RDPG of size n with latent space dimension d is characterized by an $n \times d$ matrix X , where each row of X is the latent position of the corresponding node in a d -dimensional Euclidean space. The probability matrix is given by $P = XX^\top$ and $A_{ij} \sim \text{Bernoulli}(P_{ij} = X_i^\top X_j)$ independently for all $i < j$, where the rows X_i of the latent position matrix X are treated as $d \times 1$ vectors. We also use the notation $A \sim \text{RDPG}(X)$ to denote this model.

A major inference task for an observed network from RDPG is recovering the latent positions and predicting the edge probabilities. Adjacency spectral embedding, or ASE (Athreya et al. 2017), is a spectral method used to estimate the latent position matrix

using the eigenvalues and the eigenvectors of the network adjacency matrix. Given a latent space dimension d , ASE uses the top d eigenvectors corresponding to the largest d eigenvalues of A to estimate the latent position matrix X . ASE is described in Algorithm A3 in Appendix A.

NETCROP (Algorithm 1) can be modified for the problem of selecting the latent space dimension d from a set of candidate dimensions $\{1, \dots, d_{max}\}$. The division step splits the set of nodes S into s subnetworks S_{01}, \dots, S_{0s} , where the subnetworks share a common overlap part S_0 of size o . The detection and stitching steps are slightly different for RDPG (Chakraborty et al. 2025). Both steps are performed once for $\tilde{d} = d_{max}$ instead of separately for each candidate value. For each \tilde{d} , the first \tilde{d} columns of the estimated latent position matrices from the subnetworks are used to predict the edge probabilities of the test set node pairs. Let \hat{X}_q be the estimated latent position matrix from ASE with latent space dimension d_{max} on the q -th subnetwork, $q \in [s]$.

Since the latent positions are identifiable only up to an orthogonal rotation in the d -dimensional Euclidean space, the estimated latent positions from the subnetworks may not be in the same rotation in \mathbb{R}^d . For example, for any d -dimensional orthogonal matrix $W \in \mathcal{O}_d$, X and $\tilde{X} = XW$ yield the same probability matrix P . To ensure that the estimated latent positions from all the subnetworks are rotated similarly, one of the subnetworks is randomly chosen as the standard and the estimated latent positions of the overlap nodes of the other subnetworks are rotated to match with the latent position of the overlap nodes of the standard subnetwork. Since the choice of the standard subnetwork is arbitrary, we treat the first subnetwork as the standard throughout this paper. We use the standard Procrustes transformation (Gower & Dijkstra 2004) to match the latent positions. For any two $n \times d$ matrices M_1 and M_2 , the Procrustes transformation finds the best orthogonal matrix $W \in \mathcal{O}_d$ that minimizes $\|M_1W - M_2\|_F$. If the singular value decomposition of $M_2^\top M_1 = U\Sigma V^\top$, the minimizer is $W = UV^\top$. Let $\hat{W}_q \in \mathcal{O}_{d_{max}}$ be the Procrustes transformation that matches \hat{X}_{q,S_0} with \hat{X}_{1,S_0} for $q \in [2 : s]$. Then the estimated latent positions from the subnetworks are updated as $\hat{X}_q \leftarrow \hat{X}_q \hat{W}_q$, $q \in [2 : s]$.

In the loss computation step, the edge probabilities are predicted for each candidate

Algorithm 3 NETCROP for Determining the Dimension for RDPGs

Input An $n \times n$ network adjacency matrix A with node set S , maximum latent space dimension d_{max} to consider, number of subnetworks s , overlap size o , number of repetitions R , and a loss function ℓ .

procedure NETCROP($A, d_{max}, s, o, R, \ell$)

1. **for** (r from 1 to R) {
 - 1.1. Randomly select o nodes from S to form the overlap part S_0 .
 - 1.2. Split $S \setminus S_0$ randomly into s exhaustive parts of equal size: S_1, \dots, S_s .
 - 1.3. Form the subset of nodes $S_{0q} = S_0 \cup S_q, q \in [s]$.
 - 1.4. For each $q \in [s]$, compute $\hat{\Lambda}_q = \text{diag}(\hat{\lambda}_{q,1}, \dots, \hat{\lambda}_{q,d_{max}})$ as the diagonal matrix containing the d_{max} largest eigenvalues $\hat{\lambda}_{q,1} \geq \dots \geq \hat{\lambda}_{q,d_{max}}$ and \hat{U}_q as the $(o+m) \times d_{max}$ matrix of the corresponding eigenvectors of $A_{S_{0q}}$.
 - 1.5. Compute $\hat{X}_q = \hat{U}_q \hat{\Lambda}_q^{\frac{1}{2}}, q \in [s]$.
 - 1.6. For each $q \in [2 : s]$, $\hat{W}_q = \arg \min_{W \in \mathcal{O}_{d_{max}}} \left\| \hat{X}_{q,S_0} \cdot W - \hat{X}_{1,S_0} \right\|_F$ and update $\hat{X}_q \leftarrow \hat{X}_q W_q$.
 - 1.7. **for** (\tilde{d} from 1 to d_{max}) {
 - 1.7.1. Set $\hat{X}_q^{(\tilde{d})} = \hat{X}_{q, [\tilde{d}]}$ for $q \in [s]$.
 - 1.7.2. Estimate $\hat{P}_{S_p S_q}^{(\tilde{d})} = \hat{X}_p^{(\tilde{d})} \hat{X}_q^{(\tilde{d})\top}$ for $1 \leq p < q \leq s$.
 - 1.7.3. Compute the loss function $\hat{L}_r^{(\tilde{d})} = L\left(A_{S^c}, \hat{P}_{S^c}^{(\tilde{d})}\right) = \sum_{1 \leq p < q \leq s} \ell\left(A_{S_p S_q}, \hat{P}_{S_p S_q}^{(\tilde{d})}\right)$.
 2. Compute $\hat{d}_r = \arg \min_{\tilde{d} \in [d_{max}]} \hat{L}_r^{(\tilde{d})}$ for $r \in [R]$.
 3. Return \hat{d} as the modal value of $\hat{d}_1, \dots, \hat{d}_R$.
-

dimension $\tilde{d} \in [d_{max}]$ by only using the first \tilde{d} columns of the estimated latent position matrices from the subnetworks. For node pairs between the p -th non-overlap part S_p and the q -th non-overlap part S_q , the predicted latent positions and the edge probabilities for candidate dimension \tilde{d} are

$$\hat{X}_q^{(\tilde{d})} = \hat{X}_{q, [\tilde{d}]}, \quad q \in [s], \quad \text{and} \quad \hat{P}_{S_p S_q}^{(\tilde{d})} = \hat{X}_p^{(\tilde{d})} \left(\hat{X}_q^{(\tilde{d})} \right)^\top \quad (9)$$

for $1 \leq p < q \leq s$ and $\tilde{d} \in [d_{max}]$. Since the test set consists of node pairs from all possible pairs of non-overlap parts, the final losses are computed as the sum of losses between $A_{S_p S_q}$

and $\hat{P}_{S_p S_q}^{(\tilde{d})}$ over $1 \leq p < q \leq s$ for each $\tilde{d} \in [d_{max}]$. Finally the dimension \hat{d} with the lowest computed loss is returned as the estimated latent space dimension. The procedure is repeated R times for stability and the most frequent value of \hat{d} is the final outcome. Algorithm 3 outlines the steps.

3.3 Estimating the Dimension of Latent Space Model

The latent space model (Hoff et al. 2002) assumes that the edge probabilities are inversely related to the distance between the assumed latent positions of the nodes in a low dimensional ($d \ll n$) Euclidean space. Any inference on networks from this model, including estimating the latent positions, requires the knowledge of the latent space dimension d . NETCROP for RDPG (Algorithm 3) can be adapted for detecting the latent space dimension for a network from latent space model by replacing ASE for estimating latent positions in RDPG with the maximum likelihood estimator for the latent space model, and using generalized Procrustes transformation for the matching step as the latent positions are identifiable only up to translations and orthogonal rotations. The outcome dimension is chosen from the candidate set $[d_{max}]$ that has the lowest test set loss. The latent space model along with the specific changes to NETCROP are presented in Appendix A.

3.4 Tuning the Regularization Parameter in Regularized Spectral Clustering

Regularized spectral clustering or RSC (Qin & Rohe 2013) is commonly used for community detection in DCBMs. Classical spectral clustering (Algorithm A1) performs poorly in the presence of degree heterogeneity and in sparse networks. RSC addresses this issue by inflating the node degrees by τ times the edge density of the network for a tuning parameter $\tau \geq 0$ while computing the graph Laplacian and applying spectral clustering with row normalization on the modified Laplacian. Cross-validation on networks can be used to perform a grid search on a range of candidate values of τ to select the best tuning parameter for RSC. NETCROP for selecting the tuning parameter is similar to Algorithm

2, except that RSC is applied on each subnetwork with each candidate value of τ . The stitching or label matching step and the testing step remain the same as Algorithm 2. Finally, the value of τ that produces the lowest prediction error on the test set is chosen as the best tuning parameter. Without additional computations, the community labels can be predicted using the matched community labels from the subnetworks with the selected value of τ from NETCROP.

4 Theoretical Results

In this section, we derive theoretical results for accuracy of NETCROP for model selection under some suitable assumptions. In Sections 4.1 and 4.2, we show that the probability of underestimating the number of communities for SBM and DCBM tend to zero as the network size increases. Although NETCROP for blockmodels is designed to detect degree heterogeneity and the number of communities simultaneously and the numerical examples are for such cases, the theoretical results for SBM and DCBM are limited to detecting the number of communities in a candidate set of only SBMs and only DCBMs, respectively. In Section 4.3, we show the same for the latent space dimension of RDPG. The general idea for both cases is that the computed loss between the observed network (adjacency matrix) and the predicted edge probabilities on the test set is much larger for the wrong candidate models, but smaller for the true model. We compare the computed loss with the oracle loss to show this. The oracle loss is defined as the sum of losses between the adjacency matrix and the true edge probabilities over the test set, which can be written as

$$L(A_{\mathbb{S}^c}, P_{\mathbb{S}^c}) = \sum_{(i,j) \in \mathbb{S}^c} \ell(A_{ij}, P_{ij}).$$

For the true model, the computed loss is shown to be concentrated around the oracle loss and for the wrong models, the computed loss is shown to be much larger than the oracle loss with high probabilities. Thus, the true model is chosen with high probability.

All theoretical derivations are for NETCROP with s subnetworks, overlap size o , and $R = 1$ repetition. Since the repetitions are independent, the same consistency results should hold with high probability using the union bound when $R > 1$. We also assume the squared

error loss, defined as $\ell_2(a, b) = (a - b)^2$ for all theoretical results. We only prove one-sided consistency that ensures that the number of communities for SBM, DCBM and latent position dimension for RDPG are not underestimated with NETCROP. Note that most cross-validation methods are not theoretically guaranteed against overestimation (Li et al. 2020, Chen & Lei 2018). For blockmodels, if the candidate number of communities is greater than the true number of communities, a few of the true communities are expected to artificially split into multiple predicted categories. Node pairs from those predicted categories are expected to make the computed loss from NETCROP larger. Similarly for RDPG, using larger candidate dimension than the true dimension will incorporate extra terms in the coordinates of the latent positions that will push the predicted edge probabilities away from the true edge probabilities, eventually increasing the computed loss.

4.1 Theory for SBM

Here we consider the model selection problem of choosing the number of communities \hat{K} from a candidate set of SBM with the number of communities in $[K_{max}]$. NETCROP for blockmodels (Algorithm 2) is applied with SC (Algorithm A1), s subnetworks, overlap size o , $R = 1$ repetition, and the squared error loss. We assume that the true model is SBM.

Since the results for SBM are for candidate set consisting of only SBMs, we use $\hat{P}_{\mathbb{S}^c}^{(\tilde{K})}$ to mean $\hat{P}_{\mathbb{S}^c}^{(0\tilde{K})}$ from (4). The following assumptions are needed to establish the results for SBM.

Assumption 1. (*Model assumptions for SBM*)

- $B = B_n = \rho_n B_0$ such that the rows of B_0 are all distinct, $\min_{k, k' \in [K]} B_{0, kk'} > c_1$ for some $c_1 > 0$, and the smallest eigenvalue of B_0 is strictly positive.
- $\rho_n = \Omega(n^{-1} \log n)$.
- There exists a $\gamma \in (0, 1)$ such that $n_k \geq \gamma n$, for all $k \in [K]$.

We show that the distance between the computed loss and the oracle loss given by $\left| L\left(A_{\mathbb{S}^c}, \hat{P}_{\mathbb{S}^c}^{(K)}\right) - L\left(A_{\mathbb{S}^c}, P_{\mathbb{S}^c}\right) \right|$ is very small for $\tilde{K} = K$ and $L\left(A_{\mathbb{S}^c}, \hat{P}_{\mathbb{S}^c}^{(\tilde{K})}\right) \gg L\left(A_{\mathbb{S}^c}, P_{\mathbb{S}^c}\right)$

for $\tilde{K} < K$. To show the former, we prove that $\hat{P}^{(K)}$, although estimated from the training set \mathbb{S} , is a good estimator of the test set edge probabilities $P_{\mathbb{S}^c}$ as long as the community detection algorithm reasonably accurately recovers the community labels for each subnetwork. To establish accuracy, we use [Chakrabarty et al. \(2025, Theorem 4\)](#) which bounds the error rate of **SC** on a random subset of the network. For the latter case of $\tilde{K} < K$, we use pigeon hole principle to show that there is at least one incidence of multiple true communities merging into one, and the number of node pairs in the test set corresponding to those merged communities is large with high probability. The prediction accuracy is low for these node pairs, making the computed loss very large for $\tilde{K} < K$.

Theorem 1. *If A is the adjacency matrix of an SBM with n nodes, true K communities and community connectivity matrix $B = \rho_n B_0$, then under the conditions in [Assumption 1](#), there exists a fixed constant $c > 0$ such that the following bounds hold with high probability for **NETCROP** with s subnetworks, overlap size $o = O(n)$, squared error loss and a candidate set of SBMs:*

$$L\left(A_{\mathbb{S}^c}, \hat{P}_{\mathbb{S}^c}^{(\tilde{K})}\right) - L(A_{\mathbb{S}^c}, P_{\mathbb{S}^c}) = \Omega_p\left(s(s-1)m^2\rho_n^2\right), \text{ for } \tilde{K} < K, \quad (10)$$

$$\left|L\left(A_{\mathbb{S}^c}, \hat{P}_{\mathbb{S}^c}^{(\tilde{K})}\right) - L(A_{\mathbb{S}^c}, P_{\mathbb{S}^c})\right| = O_p\left(s(s-1)m^2(o+m)^{-1}\rho_n\right), \text{ for } \tilde{K} = K. \quad (11)$$

The proof of this theorem and all the other results are provided in [Appendix B](#). The following consistency result follows directly from [Theorem 1](#).

Theorem 2. *Under the same setup as in [Theorem 1](#) with \hat{K} being the output number of communities from **NETCROP** for SBM, then as $n \rightarrow \infty$,*

$$\mathbf{P}(\hat{K} < K) \rightarrow 0.$$

[Theorems 1](#) and [2](#) provide some insights on the effects of the **NETCROP** parameters. For [\(10\)](#) to be the greater than [\(11\)](#), the training subnetwork size $o + m$ must be greater than the order of ρ_n^{-1} . This holds automatically from the design of **NETCROP** as $o + m \asymp n$ and from the assumption $\rho_n = \Omega(n^{-1} \log n)$. This requirement also implies that for sparser networks with smaller ρ_n , larger training subnetworks are required to ensure separation between the two cases.

Additionally, note that for both $\tilde{K} < K$ and $\tilde{K} = K$ cases, **NETCROP** achieves the same rates for the loss difference as **ECV** under similar assumptions (Li et al. 2020, Theorem 3). **NETCROP** has the same rate for the loss difference as **NCV** for $\tilde{K} < K$ case and a better rate as in (11) compared to the rate $O_p(n)$ for **NCV**. **NCV** also requires a stronger assumption of $\rho_n = \omega(n^{-1/2})$ (Chen & Lei 2018, Theorem 2). Thus, **NETCROP** achieves similar or better rates for the loss difference than the existing methods under milder or equivalent assumptions, and is significantly faster than them.

4.2 Theory for DCBM

Here we consider the model selection problem of choosing the number of communities \hat{K} from a candidate set of DCBM with the number of communities in $[K_{max}]$. **NETCROP** for blockmodels (Algorithm 2) is applied with **SSC** (Algorithm A2), s subnetworks, overlap size o , $R = 1$ repetition, and the squared error loss. We assume that the true model is DCBM. We also assume that the test set edge probabilities are estimated using (7). We need additional identifiability constraints on the degree heterogeneity parameters ψ_i along with similar assumptions as in Assumption 1.

Assumption 2. (*Model assumptions for DCBM*)

- $B = B_n = \rho_n B_0$ such that the rows of B_0 are all distinct, $\min_{k,k' \in [K]} B_{0,kk'} > c_1$ for some $c_1 > 0$, and the smallest eigenvalue of B_0 is strictly positive.
- $\rho_n = \omega(n^{-1/3})$.
- There exists a $\gamma \in (0, 1)$ such that $n_k \geq \gamma n$, for all $k \in [K]$.
- $\max_{i \in G_k} \psi_i = 1$ for all $k \in [K]$.
- There exists a constant $\psi_0 > 0$ such that $\min_{i \in [n]} \psi_i \geq \psi_0$.

For $\tilde{K} < K$, the same argument as SBM is used with some additional steps for adjusting the degree heterogeneity parameter in the distance between the computed loss and the oracle loss. The $\tilde{K} = K$ case for DCBM is different as the type of estimator used to

predict the test set edge probabilities is different from the SBM case. For $\tilde{K} = K$, we follow a similar argument as [Chen & Lei \(2018\)](#) to show that $\hat{B}_q^{(K)}$ and $\psi^{(K)}$ from the q -th subnetwork are good estimates of scaled B' and community normalized ψ' , provided SSC has a low misclustering rate on the subnetwork ([Chakrabarty et al. 2025](#), Theorem 6). This ensures that $\hat{P}_{ij}^{(K)}$ is an accurate estimator of P_{ij} , making the computed loss closely concentrated around the oracle loss.

Theorem 3. *If A is the adjacency matrix of a DCBM with n nodes, true K communities, community connectivity matrix $B = \rho_n B_0$ and degree parameter $\Psi \in \mathbb{R}^n$, then under the conditions in [Assumption 2](#), there exists a fixed constant $c > 0$ such that the following bounds hold for NETCROP with s subnetworks, overlap size $o = O(n)$, squared error loss and a candidate set of DCBMs:*

$$L\left(A_{\mathbb{S}^c}, \hat{P}_{\mathbb{S}^c}^{(\tilde{K})}\right) - L(A_{\mathbb{S}^c}, P_{\mathbb{S}^c}) = \Omega_p\left(s(s-1)m^2\rho_n^2\right), \text{ for } \tilde{K} < K, \quad (12)$$

$$\left|L\left(A_{\mathbb{S}^c}, \hat{P}_{\mathbb{S}^c}^{(\tilde{K})}\right) - L(A_{\mathbb{S}^c}, P_{\mathbb{S}^c})\right| = O_p\left(s(s-1)m^2n^{-\frac{1}{2}}\rho_n^{\frac{1}{2}}\right), \text{ for } \tilde{K} = K. \quad (13)$$

From a direct application of [Theorem 3](#), we have the following theorem.

Theorem 4. *Under the conditions in [Theorem 3](#), we have as $n \rightarrow \infty$,*

$$\mathbf{P}\left(\hat{K} < K\right) \rightarrow 0.$$

Note that the assumption $\rho_n = \omega(n^{-1/3})$ ensures that the lower bound of the difference between the computed loss and the oracle loss in [\(12\)](#) for $\tilde{K} < K$ is of larger order than the upper bound of the same for $\tilde{K} = K$. To the best of our knowledge, these are the only theoretical bounds of the loss difference for detecting the number of communities in a DCBM using cross-validation. NCV has a partial result on the consistency of $\hat{P}_{ij}^{(K)}$ on all but a vanishing subset of node pairs for $\tilde{K} = K$, under the assumption $\rho_n = \omega(n^{-1/3})$ ([Chen & Lei 2018](#), Theorem 4). NETCROP also attains a similar consistency (see [\(B68\)](#) in [Appendix B](#)) under the same assumption. This consistency result is further used to derive the upper bound in [\(13\)](#).

4.3 Theory for RDPG

In this section, we present the theoretical guarantee of NETCROP for selecting the latent space dimension in an RDPG ([Algorithm 3](#)). The theory for RDPG follows a similar track

as that of SBM and DCBM. To establish the bounds on computed loss for RDPG with true and unknown latent space dimension d , we show that the predicted edge probabilities for the node pairs in the test set are inaccurate for the candidate dimension $\tilde{d} < d$ and are accurate when $\tilde{d} = d$.

For $\tilde{d} = d$, Theorem B5 in Appendix B ensures the existence of orthogonal rotation matrices $W_1, \dots, W_s \in \mathcal{O}_d$ such that $\hat{X}_1 W_1 \approx X_{S_{01}}, \dots, \hat{X}_s W_s \approx X_{S_{0s}}$, where the approximate symbol is used as a shorthand to represent that the two vectors are aligned up to a small error. This means that the latent position estimate from the q th subnetwork can be orthogonally rotated using W_q to be close to the true latent position for each $q \in [s]$, i.e., after the orthogonal rotations, all the estimated latent positions from different subnetworks are aligned close to the true positions. Since the true positions are unknown, we align the estimated latent positions from different subnetworks within themselves using Procrustes transformation. An arbitrary subnetwork is chosen as the standard (for this paper, we take the first subnetwork as the standard) and the estimated latent positions of the other subnetworks are aligned with that of the standard subnetwork using the overlap nodes. As defined in Algorithm 3, \hat{W}_q matches \hat{X}_{q, S_0} with \hat{X}_{1, S_0} for $q \in [2 : s]$. Setting $\hat{W}_1 = \mathbf{I}_d$, we have $\hat{X}_1 \hat{W}_1 \approx \dots \approx \hat{X}_s \hat{W}_s$, which, in turn, are closely aligned to XW for some $W \in \mathcal{O}_d$. Since the orthogonal matrix W can be absorbed into the definitions of the theoretical orthogonal rotations W_1, \dots, W_s , we derive the theoretical results for the estimation error of $\hat{X}_q W_q$ for estimating $X_{S_{0q}}$, $q \in [s]$.

For $\tilde{d} < d$, the difference between the computed loss and the oracle loss reduces to the accuracy of $\hat{P}^{(\tilde{d})}$ for estimating P on the test set. Using Lemma B7 in Appendix B, it is shown that the rank \tilde{d} truncated version of P , denoted by $P^{(\tilde{d})}$, is distinct from P on a sufficiently large subset of the test set. We also show that the estimation error of $\hat{P}^{(\tilde{d})}$ for $P^{(\tilde{d})}$ is bounded by the error of estimating P using $\hat{P}^{(d)}$. Finally, we show that the latter is dominated by the former, providing a lower bound for the loss difference.

Next, we state the results establishing the consistency of NETCROP for selecting the latent space dimension in RDPG. Since the predicted edge probabilities are obtained using the largest \tilde{d} eigenvalues and the corresponding eigenvectors, NETCROP requires the eigenvalues

and eigenvectors of the adjacency matrix to be sufficiently distinct. Assumption 3 lists the assumptions on the eigenvalues and the eigenvectors along with the assumptions on the network sparsity.

Assumption 3. (*Model assumptions for RDPG*)

1. $P = \rho_n P^0$ for some sparsity parameter $\rho_n > 0$ such that $\min_{i \in [n]} P_{ij}^0 \geq c_1$ and $\max_{i \in [n]} P_{ij}^0 \leq c_2$ for some $c_1, c_2 > 0$.
2. There exists $a_0 > 0$ and a constant $c_0 > 0$ such that $\rho_n \geq c_0 n^{-1/2} \log^{2+a_0/2}(n)$.
3. If $P^0 = U \Lambda^0 U^\top$ is the eigen decomposition of P^0 with $\Lambda^0 = \text{diag}(\lambda_1^0, \dots, \lambda_d^0)$, where $\lambda_1^0 \geq \dots \geq \lambda_d^0$, there exist $\phi > 0$ and $a > 1$ such that

$$n\phi^{-1} \leq \lambda_d^0 \leq \dots \leq \lambda_1^0 \leq n\phi \quad \text{and} \quad \max_{i \in [n]} \frac{n}{d} \|U_i\|^2 \leq a.$$

The general idea behind the RDPG results is the same as the SBM and the DCBM cases. We show that for a candidate dimension $\tilde{d} < d$, the computed loss is much larger than the oracle loss and for $\tilde{d} = d$, the true latent space dimension, the computed loss is centred closely around the oracle loss.

Theorem 5. *If $A \sim \text{RDPG}(X)$ with $n \geq 1$ nodes, true latent space dimension d and probability matrix $P = \rho_n P_0$, then under the conditions in Assumption 3, the following bounds hold with high probability for **NETCROP** (Algorithm 3) with s subnetworks, overlap size $o = O(n)$ and squared error loss:*

$$L\left(A_{\mathbb{S}^c}, \hat{P}_{\mathbb{S}^c}^{(\tilde{K})}\right) - L(A_{\mathbb{S}^c}, P_{\mathbb{S}^c}) = \Omega_p\left(s(s-1)m^2\rho_n^2\right), \quad \text{for } \tilde{d} < d, \quad (14)$$

$$\left|L\left(A_{\mathbb{S}^c}, \hat{P}_{\mathbb{S}^c}^{(\tilde{K})}\right) - L(A_{\mathbb{S}^c}, P_{\mathbb{S}^c})\right| = O_p\left(s(s-1)m^2\frac{\rho_n \log^2(o+m)}{\sqrt{o+m}}\right), \quad \text{for } \tilde{d} = d. \quad (15)$$

Theorem 6. *Let **NETCROP** for model selection (Algorithm 3) be applied on an RDPG satisfying all the assumptions in Theorem 5 with s subnetworks and overlap size o . Then*

$$\mathbf{P}\left(\hat{d} < d\right) \rightarrow 0. \quad (16)$$

NETCROP has comparable bounds for the difference between the computed loss and the oracle loss as ECV, while being significantly faster, especially for large RDPGs.

5 Numerical Results

We apply NETCROP ([GitHub Repository](#)) for model selection on a few simulated and real networks, comparing its performance with two other cross-validation methods for networks: NCV and ECV. First, we applied NETCROP for detecting the number of communities and degree correction on networks, modeled by SBM and DCBM. Here, NETCROP was compared with both ECV and NCV. In the second part, we applied NETCROP for detecting the latent space dimension of RDPG. In this case, NETCROP was only compared to ECV as NCV was not designed for this problem. In the third part, we applied NETCROP for detecting the latent space dimension in latent space models. We used the authors’ recommended parameters for NCV (3 folds), ECV (3 folds and 10% held-out nodes), and their stabilized versions NCV+St and ECV+St (20 repetitions). All computations were done on a university campus cluster with 20 processors, each with 12 gigabytes of RAM. R version 4.3.1 was used for the computations. The codes for NCV and ECV were taken from the CRAN package *randnet* ([Li et al. 2023](#)). All algorithms were parallelized whenever possible.

5.1 Simulation Examples

Detecting the Number of Communities and Degree Correction in SBM and DCBM

We simulated 100 networks from the true model (SBM or DCBM) with $n = 10000$ nodes and K communities. Each node was randomly assigned one of the K communities. The $K \times K$ community connectivity matrix was formed as $B = \alpha((1 - \beta)I_K + \beta J_K)$. The out-in ratio β is related to the strength of the communities and α determines the sparsity of the network. Additionally, the degree parameters ψ_i ’s were generated from *Beta*(1, 4) distribution, independently for each node. The adjacency matrix was generated as $A_{ij} \sim \text{Bernoulli}(P_{ij})$ for the true model SBM and $A_{ij} \sim \text{Bernoulli}(P_{ij}\psi_i\psi_j)$ for the true model DCBM, independently for each node pair $i < j$. The candidate sets of number of communities for true $K = 5, 10$, and 20 , were $\tilde{K} = [10], [20]$, and $[30]$, respectively. NETCROP for blockmodels (Algorithm 2) with $s = 5$ subnetworks, overlap size o , and $R \in \{1, 5\}$ repetitions, along with

NCV, NCV+St, ECV and ECV+St, were applied on each simulated network. The overlap size in NETCROP was decided based on α and β . For label matching, MatchGreedy (Algorithm A5) was used for faster computations. Spectral clustering (Algorithm A1) and spherical spectral clustering (Algorithm A2) were used to fit SBM and DCBM, respectively. The accuracy of each method is measured by the percentage of times they were able to detect the true K and the degree correction out of the 100 simulations. We also reported the mean absolute deviation (MAD) from the true value of K and the computation time. The simulation results are in Table 1.

Based on the findings presented in Table 1, NETCROP demonstrates superior accuracy compared to ECV and NCV in estimating both the number of communities K and the degree correction across nearly all scenarios. Moreover, NETCROP was observed to be approximately 7 to 100 times faster than the other methods, depending on the network sparsity and the parameters of NETCROP. In scenarios involving a true SBM model with a large $K = 20$, NETCROP achieves an accuracy level of 89% in just 257.9 seconds, whereas ECV, NCV, and their stabilized versions achieve either 0% or close to 0% accuracy with much longer time. Repetition improved the performance of NETCROP significantly in all the simulation scenarios. Only five repetitions were enough to stabilize the outcomes of NETCROP compared to twenty repetitions for NCV and ECV. In the case of true DCBM models, NETCROP demonstrates notably higher accuracy compared to ECV and NCV, while also requiring significantly less computational time. In general, NETCROP achieved lower MADs from the true number of communities compared to the other methods. We also observed that all the methods were able to detect the correct degree heterogeneity (SBM or DCBM) with 100% accuracy in all the simulation settings. Thus, we did not report those accuracies in Table 1.

Estimating the Latent Space Dimension of RDPG

We simulated networks from RDPG with various levels of sparsity and applied NETCROP for RDPG (Algorithm 3), ECV and ECV+St on them. We generated the latent positions of the n nodes as $X_{ik} \sim U(0, 1)$ independently for $i \in [n]$, $k \in [d]$. Then the probability matrix was computed as $P = \zeta XX^\top / \max(XX^\top)$, where ζ was used to control the sparsity of the

Table 1: Results for detecting K and degree Correction in simulated networks from SBM and DCBM.

[†] λ is the mean of the average densities of the simulated networks; [‡]**Accu. %** denotes the percentage of times the correct model was selected out of 100 simulations; [§]**MAD** denotes Mean Absolute Deviation from true K ; ^{§§}**sec.** denotes seconds; ^{*}**Algo.** denotes Algorithm; ^{**}**ECV+St** and **NCV+St** represent the stabilized versions of **ECV** and **NCV**, respectively, with 20 repetitions.

simulated networks. We fixed $n = 10000$ and $d = 10$, and varied the sparsity parameter $\zeta \in \{0.75, 0.70, 0.65\}$ to generate the networks. For each simulation setting, 100 networks were generated. **NETCROP** was applied with s subnetworks, overlap size o , and R repetitions on each simulated network with the largest candidate dimension $d_{max} = 20$. Accuracy is defined as the percentage of times **NETCROP** detects the true dimension out of the 100 simulated networks. For the sparser cases, $s = 2$ subnetworks and for the denser cases

$s = 5$ subnetworks were used. Higher overlap sizes were used for sparser networks. We also reported the MAD from the true latent space dimension. The results are in Table 2.

n	d	ζ	s	o	R	NETCROP		Other Algorithms		
						Accu. % (MAD)	Time (sec.)	Algo.	Accu. % (MAD)	Time (sec.)
10^4	10	0.75	5	3000	1	100% (0)	57.8	ECV	100% (0)	1361.7
					5	100% (0)	126.3	ECV+St	100% (0)	27207.4

					5	100% (0)	84.6	ECV+St	100% (0)	24793.1
10^4	10	0.65	2	8000	1	57% (1.1)	56.1	ECV	45% (1.7)	1337.1
					5	78% (0.4)	80.0	ECV+St	67% (1.2)	26289.4

Table 2: Results for detecting the latent space dimension d in simulated RDPGs.

Table 2 shows that in the denser scenario with $\zeta = 0.75$, both approaches achieve perfect accuracy, but NETCROP accomplishes this in only 57.8 seconds, while ECV requires 1361.7 seconds. Similarly, in the moderately sparse case of $\zeta = 0.7$, NETCROP attains higher accuracy than ECV in considerably less time. The stability of NETCROP is achieved with just $R = 5$ repetitions. For the sparsest instance with $\zeta = 0.65$, both methods exhibit moderate accuracy, with NETCROP at 57% and ECV at 45%. After only $R = 5$ repetitions, the accuracy of NETCROP rises to 78%, whereas ECV with stability only reaches 67%. Moreover, NETCROP completes computations in 80 seconds with 5 repetitions, contrasting with ECV requiring 26289.4 seconds with stability. Overall, NETCROP demonstrates superior accuracy and lower MADs compared to ECV and its stabilised version, with significantly reduced computational time (approximately 22 to 330 times faster).

Estimating the Dimension of Latent Space Model

We conducted simulations on networks based on the latent space model outlined in (A1) and used NETCROP to estimate their latent space dimension. We considered two options for the intercept $\alpha \in \{0, 1\}$ and two alternatives for the latent dimension $d \in \{2, 5\}$. 100

networks of size $n = 1000$ were generated using the latent space model for each combination of α and d . Subsequently, NETCROP was applied to each simulated network with specific parameters: $s = 5$, $o = 500$, $\tilde{d} = [5]$ for the $d = 2$ scenario, and $s = 2$, $o = 800$, $\tilde{d} = [10]$ for the $d = 5$ scenario, with $R \in \{1, 5\}$ for each case. For every parameter set of NETCROP, we present the accuracy, defined as the percentage of correct dimension selections out of 100 simulations, the MAD from the true d , and the computation time in seconds. The results are provided in Table 3.

n	α	d	s	o	R	Accu. % (MAD)	Time (sec.)
10^3	0	2	5	500	1	91% (0.09)	1376.4
					5	97% (0.03)	4322.0
10^3	1	2	5	500	1	83% (0.26)	1359.3
					5	92% (0.08)	4588.1
10^3	0	5	2	800	1	67% (5.9)	2892.3
					5	88% (2.0)	7524.2
10^3	1	5	2	800	1	57% (8.6)	2984.5
					5	89% (2.1)	7790.6

Table 3: Results for detecting the latent space dimension d using NETCROP in simulated networks from latent space models.

In Table 3, for $d = 2$, the accuracy of NETCROP is very high that further increases with the number of repetitions. For $d = 5$, the accuracies are 67% for $\alpha = 0$ and 57% for $\alpha = 1$, but they rise to 88% and 89% correspondingly with $R = 5$ repetitions. Overall, NETCROP effectively identified the dimension d in latent space models, with a noticeable improvement in accuracy due to repetitions.

Parameter Tuning for Regularized Spectral Clustering

We applied NETCROP for tuning the regularizing parameter in regularized spectral clustering. We generated 100 DCBM networks with $n = 10000$ nodes, $K = 5$ communities, $\beta = 0.33$, and $\alpha = 0.3$. We then applied NETCROP to find an appropriate value of the tuning parameter τ from a candidate set of $\{0, 0.1, \dots, 2\}$. We used $s = 2$ subnetworks, overlap size $o = 4000$, and repetitions $R \in \{1, 5\}$. For the $R = 5$ case, we used the mean and the mode of the estimated $\hat{\tau}$ from NETCROP. Then, we used those estimated $\hat{\tau}$ to perform regularized spectral clustering on the entire network to compute the average clustering accuracies with $\tau = 0$ (no regularization), the oracle estimator of τ given by the value of τ in the candidate set that produces the highest clustering accuracy, $\hat{\tau}$ selected by NETCROP with $R = 1$, and $\hat{\tau}_{mean}$ and $\hat{\tau}_{mode}$ from NETCROP with $R = 5$. We compared our method with the performance of the Davis-Kahan estimator of τ (Joseph & Yu 2016). We used ℓ_2 loss function for all the implementations of NETCROP. We report these average clustering accuracies and their standard deviations (sd) in Figure 2.

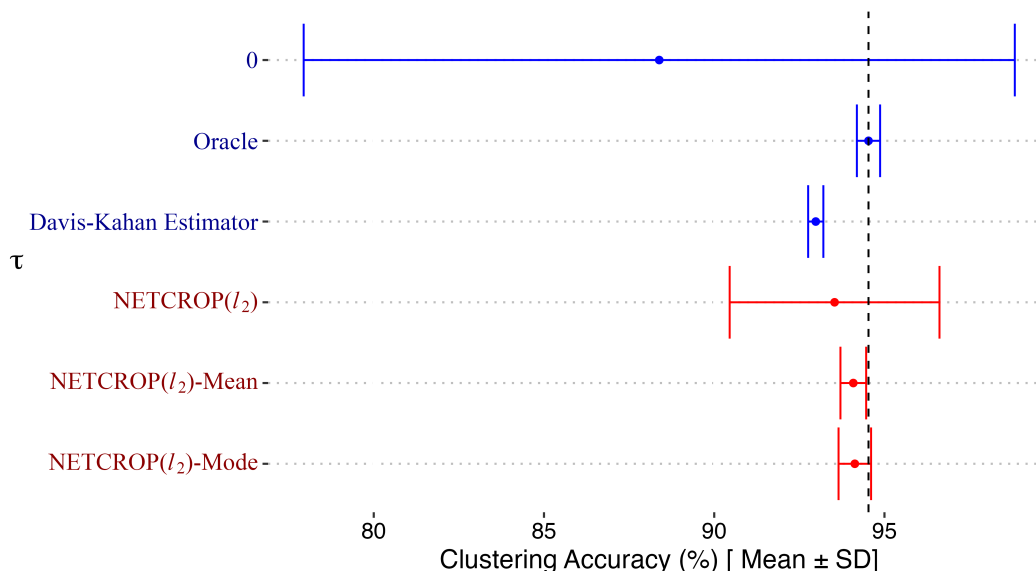

Figure 2: Mean accuracy (%) of regularized spectral clustering with multiple choices of τ and with $\hat{\tau}$ chosen from NETCROP with $R = 1$, and their mean and mode with $R = 5$.

From Figure 2, it can be observed that the average clustering accuracy is at its lowest

when no regularization is applied ($\tau = 0$) with a clustering accuracy of 88.4% with a very large sd of 10.4%. The average accuracies of the oracle and the Davis-Kahan estimator are 94.5% (sd = 0.34%) and 93.0% (sd = 0.22%), respectively. Using $\hat{\tau}$, the clustering accuracy closely matches the oracle at 93.5% with an sd of 3.08%. **NETCROP** with repetitions increases the average accuracy slightly, while reducing the sd. Mean of $\hat{\tau}$ from 5 repetitions of **NETCROP** has average clustering accuracy of 94.1% with sd 0.38%. The same for mode is 94.1% with sd 0.48%. In summary, **NETCROP** effectively selects the optimal tuning parameter that produced average accuracies closest to that of the oracle estimator and combining outcomes from multiple repetitions improved the variation in accuracies significantly. All instances of **NETCROP** outperformed the Davis-Kahan estimator as well.

5.2 Real Data Examples

We considered two real data examples to demonstrate the performance of **NETCROP** for detecting the number of communities and degree correction in a blockmodel. The first dataset is DBLP four-area network. It was curated by [Gao et al. \(2009\)](#) and [Ji et al. \(2010\)](#) and previously analyzed by [Sengupta & Chen \(2015\)](#). The data consist of $n = 4057$ data mining researchers from the research areas of database, data mining, information retrieval, and artificial intelligence. Two nodes are connected if the authors have presented at the same conference, and there are $K = 4$ ground-truth communities representing the research areas. The other real network is Twitch gamers social network ([Sarkar & Rózemberczki 2021](#)). It has $n = 32407$ Twitch users from $K = 20$ language communities. Two Twitch users are connected by an edge if they have a mutual follower.

We applied **NETCROP**, **ECV** and **NCV** for detecting the number of communities and degree correction in blockmodels on DBLP and Twitch networks. The candidate number of communities was $\tilde{K} = [10]$ for DBLP and $\tilde{K} = [10 : 30]$ for Twitch. Community detection was performed on the real networks with the predicted \hat{K} and using spectral clustering if the predicted model was SBM and spherical spectral clustering if it was DCBM. The results are in [Table 4](#).

In [Table 4](#), the performance of **NETCROP** stands out in terms of accurately selecting the

Real		NETCROP				Other Algorithms				
Network	s	o	R	Mode (%Freq.)	Time (sec.)	AUC	Algo.	Mode (%Freq.)	Time (sec.)	AUC

Table 4: Results for detecting the number of communities K and degree correction in DBLP and Twitch networks.

number of communities and achieving a higher AUC compared to ECV, NCV, and their stabilized versions for the DBLP network. Moreover, NETCROP operates significantly faster than the other methods. Both NETCROP and NCV identified DCBM as the expected model, while ECV favored SBM. Notably, NETCROP consistently estimated the number of communities as 4, aligning well with the actual number of communities. In contrast, NCV underestimated the community count at 3, whereas ECV overestimated it at the highest value of 10 within the candidate set. Additionally, NETCROP exhibited superior AUC values compared to ECV and NCV, completing computations in as little as 12.3 seconds, a substantial improvement over the 210.8 and 216.7 seconds required by NCV and ECV without stabilization, respectively. For the Twitch network, NETCROP consistently opted for DCBM with 20 communities in 89% of cases, achieving an average AUC of 0.843. The estimated number of communities corresponded to the actual count. The runtime was 3788.3 seconds for the Twitch network, while NCV and ECV could not be implemented even with a total of 240 gigabytes of RAM.

6 Discussion

In this paper, a subsampling-based computationally efficient general cross-validation technique for networks has been developed. The method is adaptable to a broad range of model selection and parameter tuning problems for networks. The consistency of NETCROP has been theoretically analysed for tasks such as identifying the number of communities in

SBM and DCBM, as well as determining the latent space dimension of RDPG. Extensive empirical evaluations have been conducted using both simulated and real networks to address issues like community detection and degree correction in blockmodels, latent space dimension estimation in RDPG and latent space models, and optimal parameter selection for regularized spectral clustering for community detection in DCBM. The findings from both theoretical analyses and empirical investigations demonstrate that **NETCROP** delivers accurate model selection outcomes in considerably less time compared to existing network cross-validation approaches in the literature.

In future work, it would be of interest to extend the ideas of this paper to directed and weighted networks. Current research lacks adequate methods for subsampling or cross-validation in the context of complex networks like dynamic networks, multilayer networks, hypergraphs, and heterogeneous networks. Broadening the concept of **NETCROP** for inference, model selection, and parameter tuning for these types of networks will also be interesting directions for future research.

Appendix

Appendices [A](#) and [B](#) provide information on additional definitions and algorithms along with proofs of all the theoretical results in this paper.

A Relevant Definitions and Algorithms

A.1 Algorithms for Community Detection

This section describes two community detection algorithms used in the paper to derive the theoretic results and for numerical evaluations of NETCROP. Both are spectral methods that exploit the eigen structure of the graph adjacency matrix or the graph Laplacian to

cluster the nodes in multiple communities. Spectral clustering (SC) is mainly used on SBM networks and spherical spectral clustering (SSC) on DCBM networks.

Spectral Clustering Spectral clustering is a simple community detection method that recovers the underlying community structures of a network using the eigen decomposition of the corresponding adjacency matrix. For an undirected simple network with adjacency matrix A , spectral clustering computes the eigenvectors and eigenvalues of A . Then it clusters the K eigenvectors corresponding to the largest K eigenvalues in terms of their absolute values. Any clustering algorithm can be used at this step. However, we consider K -means clustering at this step. Since solving a K -means clustering problem is NP-hard, we use $(1 + \delta)$ -approximate solution to the K -means problem. Spectral clustering with approximate K -means is summarized in Algorithm A1.

Algorithm A1 Spectral Clustering with Approximate K -means (SC)

Input An adjacency matrix $A_{n \times n}$, number of communities K , and an approximating parameter $\delta > 0$ for K -means clustering.

Output A membership matrix $\hat{C}_{n \times K}$.

procedure SC(A, K)

1. Calculate $\hat{U} \in \mathbb{R}^{n \times K}$ consisting of the leading K eigenvectors (ordered in absolute eigenvalue) of A .
 2. Let $(\hat{C}, \hat{X}) \in \mathcal{C}_{n \times K} \times \mathbb{R}^{K \times K}$ such that $\|\hat{C}\hat{X} - \hat{U}\|_F^2 \leq (1 + \delta) \min_{(C, X) \in \mathcal{C}_{n \times K} \times \mathbb{R}^{K \times K}} \|CX - \hat{U}\|_F^2$, where $\|\cdot\|_F$ is the Frobenius norm.
 3. Output \hat{C} .
-

Spherical K -median Spectral Clustering Community recovery is difficult for a DCBM due to the presence of degree heterogeneity. Small values in ψ makes it hard to identify the community membership of the corresponding nodes as few edges are observed for those nodes. Spherical K -median spectral clustering overcomes this issue by row-normalizing the top K eigenvector matrix \hat{U} and then minimizing the matrix 2, 1 distance between the points and cluster centers. The results on DCBM discussed in [Lei & Rinaldo \(2015\)](#) were

Algorithm A2 Spherical K -median Spectral Clustering (SSC)

Input An adjacency matrix $A_{n \times n}$, the number of communities K , and an approximating parameter $\delta > 0$ for K -median clustering.

Output A membership matrix $\hat{C}_{n \times K}$.

procedure SSC(A, K)

1. Calculate $\hat{U} \in \mathbb{R}^{n \times K}$ consisting of the leading K eigenvectors (ordered in absolute eigenvalue) of A .
 2. Let $I_+ = \{i : \|\hat{U}_{i*}\| > 0\}$ and $\hat{U}^+ = (\hat{U}_{I_+*})$.
 3. Let \hat{U}' be the row-normalized version of \hat{U}^+ .
 4. Let $(\hat{C}^+, \hat{X}) \in \mathcal{C}_{n \times K} \times \mathbb{R}^{K \times K}$ such that $\|\hat{C}^+ \hat{X} - \hat{U}'\|_{2,1} \leq (1 + \delta) \min_{(C, X) \in \mathcal{C}_{n \times K} \times \mathbb{R}^{K \times K}} \|CX - \hat{U}'\|_{2,1}$.
 5. Output \hat{C} with \hat{C}_{i*} being the corresponding row in \hat{C}^+ if $i \in I_+$, and $\hat{C}_{i*} = (1, 0, \dots, 0)$ if $i \notin I_+$.
-

derived for spherical $(1 + \delta)$ -approximate K -median spectral clustering. The algorithm is presented in Algorithm A2.

A.2 Algorithm for RDPG

Here we present adjacency spectral embedding for recovering the latent positions in an RDPG.

Algorithm A3 Adjacency Spectral Embedding (ASE)

Input An adjacency matrix $A_{n \times n}$, latent position dimension d .

Output A latent position matrix $\hat{X}_{n \times d}$ and the estimated edge probability matrix $\hat{P}_{n \times n}$.

procedure ASE(A, d)

1. Calculate $\hat{U} \in \mathbb{R}^{n \times d}$ consisting of the leading d eigenvectors of A , sorted in descending order of the largest d eigenvalues $\hat{\lambda}_1 \geq \dots \geq \hat{\lambda}_d$.
 2. Let $\hat{\Lambda} = \text{diag}(\hat{\lambda}_1 \dots \hat{\lambda}_d)$. Compute $\hat{X} = \hat{U} \hat{\Lambda}^{\frac{1}{2}}$ and $\hat{P} = \hat{X} \hat{X}^\top$.
 3. Output (\hat{X}, \hat{P}) .
-

A.3 Algorithms for Community Label Matching

Here, we present two algorithms for matching two sets of community labels - **MatchBF** (Algorithm A4) and **MatchGreedy** (Algorithm A5). **MatchBF** searches over all possible permutations of the first set of labels to select the permutation that has the least number of mismatched nodes with the second set of labels. Although this algorithm gives the best permutation of the labels, it has a computation complexity of $O(K!)$ for K communities and is not computationally feasible for large K . Algorithm **MatchGreedy** computes the number of nodes in each pair of communities between the two sets of labels. It swaps the communities between the two sets of labels that have the highest number of nodes between them. It has a complexity of $O(K^2)$. **MatchGreedy** is shown to produce the same permutation matrix as **MatchBF** when one of the community membership matrices can be expressed as a permutation of the other plus some error term that satisfies certain conditions (Mukherjee et al. 2021).

Algorithm A4 MatchBF

Input Two community membership matrices C_1 and C_2 with the same number of communities

Output A permutation matrix P that best aligns C_1 with C_2

procedure MATCHBF(C_1, C_2)

$K \leftarrow$ number of columns of C_1

$\mathbf{E}_K \leftarrow$ list of all permutation matrices of order $K \times K$

initialize a vector *mismatch* of length $K!$

$i \leftarrow 1$

for $E \in \mathbf{E}_K$ **do**

$mismatch[i] \leftarrow \|(C_1 E - C_2)\|_0$

$i \leftarrow i + 1$

return $\mathbf{E}_K[\arg \min_i mismatch[i]]$

Algorithm A5 MatchGreedy

Input Two community membership matrices C_1 and C_2 with the same number of communities

Output A permutation matrix P that approximates the best alignment of C_1 with C_2

procedure MATCHGREEDY(C_1, C_2)

$K \leftarrow$ number of columns of C_1

$P \leftarrow \mathbf{0}_{K \times K}$ (null matrix of order $K \times K$)

$M \leftarrow C_1^T C_2$

while there are rows or columns of M left with positive values **do**

find $(i, j) = \arg \max_{i, j} M_{ij}$ (ties are broken arbitrarily)

$P_{ij} \leftarrow 1$

replace the i -th row and the j -th column of M by -1

return P

A.4 NETCROP for Estimating the Dimension of Latent Space Model

The latent space model (Hoff et al. 2002) is a general class of models that assumes that the connection probabilities between the nodes are influenced by the positions of the nodes in an unobserved latent space. Let $z_i \in \mathbb{R}^d$ be the latent position of the i th node. Then in a distance based latent space model, the probability of an edge between nodes i and j is modelled as

$$\eta_{ij} := \text{logodds}(A_{ij} = 1 | z_i, z_j, \alpha) = \log \left(\frac{P_{ij}}{1 - P_{ij}} \right) = \alpha - \|z_i - z_j\|. \quad (\text{A1})$$

This model is inherently symmetric and does not consider any covariate information between the nodes. There are other versions of latent space models that can be asymmetric or have covariates. Given the value of latent dimension d , Hoff et al. (2002) proposed a Markov chain Monte Carlo (MCMC) procedure for sampling from the posterior distribution of the parameters α and Z , the $n \times d$ matrix with z_i as the i th row. Given the prior information on α and Z and using the maximum likelihood estimator (MLE) \hat{Z} as the starting value, the method constructs a Markov chain of the model parameters based on a suitable proposal distribution. This method is shown to accurately estimate small social

networks with $d = 2$ or 3 . However, latent space models with such a low dimension may fail to fit larger and more complex social or other types of networks. Thus, finding the correct dimension is important for fitting latent space models.

NETCROP can be applied for estimating the latent space dimension from a set of candidate dimensions $[d_{max}]$. The method is similar to **NETCROP** for RDPG (Algorithm 3) except for the estimation and stitching steps. Given the subsets S_{01}, \dots, S_{0s} with overlap nodes in S_0 , the method of Hoff et al. (2002) is applied on subnetwork $A_{S_{0q}}$ to obtain $\hat{Z}_q^{(\tilde{d})}$ and $\hat{\alpha}_q^{(\tilde{d})}$ for each $\tilde{d} \in [d_{max}]$ and $q \in [s]$. The latent positions are only identifiable up to rotation, reflection, and translation. We use generalized Procrustes transformation to match the estimated latent positions of the overlap nodes from the subnetworks with respect to an arbitrarily selected standard subnetwork. Then for each candidate dimension $\tilde{d} \in [d_{max}]$ and node pair $(i, j) \in \mathbb{S}^c$ such that $i \in S_p$ and $j \in S_q$, $1 \leq p < q \leq s$, the intercept term is estimated as the average $\hat{\alpha}_{pq}^{(\tilde{d})} = (\hat{\alpha}_p^{(\tilde{d})} + \hat{\alpha}_q^{(\tilde{d})})/2$ and the edge probability is predicted as

$$\hat{\eta}_{ij}^{(\tilde{d})} = \hat{\alpha}_{pq}^{(\tilde{d})} - \|\hat{z}_{p,i}^{(\tilde{d})} - \hat{z}_{q,j}^{(\tilde{d})}\| \text{ and } \hat{P}_{ij}^{(\tilde{d})} = \frac{\exp\left(\hat{\eta}_{ij}^{(\tilde{d})}\right)}{1 + \exp\left(\hat{\eta}_{ij}^{(\tilde{d})}\right)}. \quad (\text{A2})$$

The loss functions are computed as the sum of losses between the predicted edge probabilities and the observed adjacency matrix over the entries in the test set for each candidate $\tilde{d} \in [d_{max}]$. Then, the outcome \hat{d} is chosen as the minimizer of the computed losses. The procedure for selecting the latent space dimension d may be repeated R times and then a majority voting can be used to increase the estimation accuracy as in Algorithm 3.

B Proofs of Theoretical Results

This section presents the proofs of the theorems and results in the paper. Throughout all the proofs, it is assumed that **NETCROP** is applied on a network of size n with s subgraphs and overlap size o . The size of each non-overlap part is $m = (n - o)/s$ with the size of each working subgraph being $(o + m)$. The overlap part is denoted by S_0 and the s non-overlap parts by S_1, \dots, S_s . The subgraphs are spanned by the subsets of nodes $S_{0q} = S_0 \cup S_q$, for

$q \in [s]$. The training and test sets of **NETCROP** are

$$\begin{aligned} \text{Training set} &= \mathbb{S} := \bigcup_{q \in [s]} (S_{0q} \times S_{0q}), \\ \text{Test set} &= \mathbb{S}^c = (S \times S) \setminus \mathbb{S} = \bigcup_{\substack{p < q \\ p, q \in [s]}} (S_p \times S_q). \end{aligned}$$

Note that $|\mathbb{S}^c| = \binom{s}{2} m^2$. Additionally, we redefine the notations for the computed loss and the oracle loss as

$$L(A, \hat{P}) := L(A_{\mathbb{S}^c}, \hat{P}_{\mathbb{S}^c}) \quad \text{and} \quad L(A) := L(A_{\mathbb{S}^c}, P_{\mathbb{S}^c}).$$

We state an upper bound of Bernoulli sums that follows directly from Bernstein's inequality. This bound is used throughout the appendix.

Lemma B1. *Let $M_i \sim \text{Bernoulli}(p_i)$ independently for $i \in [n]$ and $\mu_n = \frac{1}{n} \sum_{i \in [n]} p_i$. Then for any $\delta > 0$, there exists some constant c such that the following bound holds for sufficiently large n*

$$P \left(\sum_{i \in [n]} M_i - n\mu_n \geq \delta n\mu_n \right) \leq \exp \left(-\frac{\delta^2 n\mu_n/2}{\delta/3 + 1} \right) \quad (\text{B1})$$

$$= \exp(-\Omega(\delta n\mu_n)), \text{ provided } \delta = \Omega(1). \quad (\text{B2})$$

Additionally,

$$\left| \frac{1}{n} \sum_{i \in [n]} (M_i - p_i) \right| = O_p \left(\sqrt{\frac{\mu_n}{n}} \right) \text{ as } n \rightarrow \infty. \quad (\text{B3})$$

Proof. From Bernstein's inequality,

$$\begin{aligned} P \left(\sum_{i \in [n]} M_i - n\mu_n \geq \delta n\mu_n \right) &\leq \exp \left(-\frac{\delta^2 n^2 \mu_n^2 / 2}{\delta n\mu_n / 3 + \sum_{i \in [n]} p_i (1 - p_i)} \right) \\ &\leq \exp \left(-\frac{\delta^2 n^2 \mu_n^2 / 2}{\delta n\mu_n / 3 + n\mu_n} \right) \\ &= \exp \left(-\frac{\delta^2 n\mu_n / 2}{\delta / 3 + 1} \right). \end{aligned}$$

Recall the definition of O_p in [Serfling \(2009, Section 1.2.5\)](#). For a sequence of random variables X_n and a sequence of positive real numbers a_n , $X_n = O_p(a_n)$ if for every $\epsilon > 0$, there exist $M(\epsilon)$ and $N(\epsilon)$ such that $P(|X_n| \geq M(\epsilon)a_n) \leq \epsilon$ for any $n \geq N(\epsilon)$.

For any $\epsilon > 0$, define $M(\epsilon) = \epsilon^{-\frac{1}{2}}$ and $N(\epsilon) = 1$. Then by Chebyshev's inequality and for $n = 1, 2, \dots$,

$$P\left(\left|\frac{1}{n}\sum_{i \in [n]}(M_i - p_i)\right| \geq M(\epsilon)\sqrt{\text{Var}\left(\frac{1}{n}\sum_{i \in [n]}(M_i - p_i)\right)}\right) \leq \epsilon. \quad (\text{B4})$$

Thus from the earlier definition,

$$\left|\frac{1}{n}\sum_{i \in [n]}(M_i - p_i)\right| = O_p\left(\sqrt{\text{Var}\left(\frac{1}{n}\sum_{i \in [n]}(M_i - p_i)\right)}\right) = O_p\left(\sqrt{\sum_{i \in [n]}\frac{p_i(1-p_i)}{n^2}}\right) = O_p\left(\sqrt{\frac{\mu_n}{n}}\right).$$

□

B.1 Proof of Theorem 1

In this section, we prove the bounds on the difference between computed loss and the oracle loss for SBM. Case 1 deals with the scenario $\tilde{K} < K$ and Case 2 is for $\tilde{K} = K$ case. We reintroduce and redefine some of the notations for the proof. Recall that g_i is the true community label of the i -th node and G_k consists of the nodes in true community k , $i \in [n]$ and $k \in [K]$. For a candidate value $\tilde{K} \in [K_{max}]$, the predicted community label of the i -th node from NETCROP with \tilde{K} communities is $\hat{g}_i^{(\tilde{K})}$ and the set of nodes in the predicted k -th community is $\hat{G}_k^{(\tilde{K})}$, $i \in [n]$, and $k \in [\tilde{K}]$. The superscript is dropped for \hat{P} , \hat{g} and \hat{G} whenever it is clear from the context. We also define the following quantities -

$$\begin{aligned} T_{k,k',l,l'} &= \{(i, j) \in \mathbb{S}^c : i \neq j \text{ and } i \in \hat{G}_k \cap G_l, j \in \hat{G}_{k'} \cap G_{l'}\}, \\ T_{k,k',l,l'}^{(pq)} &= \{(i, j) \in S_p \times S_q : i \neq j \text{ and } i \in \hat{G}_k \cap G_l, j \in \hat{G}_{k'} \cap G_{l'}\}, \\ T_{ll'} &= \{(i, j) \in \mathbb{S}^c : i \neq j \text{ and } i \in G_l, j \in G_{l'}\}, \\ \hat{T}_{kk'} &= \{(i, j) \in \mathbb{S}^c : i \neq j \text{ and } i \in \hat{G}_k, j \in \hat{G}_{k'}\}, \\ \mathcal{U}_{ll'} &= \{(i, j) \in \mathbb{S} : i \neq j \text{ and } i \in G_l, j \in G_{l'}\}, \end{aligned}$$

$$\begin{aligned}
\mathcal{U}_{ll'}^{(q)} &= \{(i, j) \in S_{0q} \times S_{0q} : i \neq j \text{ and } i \in G_l, j \in G_{l'}\}, \\
\hat{\mathcal{U}}_{kk'} &= \{(i, j) \in \mathbb{S} : i \neq j \text{ and } i \in \hat{G}_k, j \in \hat{G}_{k'}\}, \\
\hat{\mathcal{U}}_{kk'}^{(q)} &= \{(i, j) \in S_{0q} \times S_{0q} : i \neq j \text{ and } i \in \hat{G}_k, j \in \hat{G}_{k'}\}.
\end{aligned} \tag{B5}$$

We restate a few results from [Chakrabarty et al. \(2025\)](#) that are used in the proofs of [Theorem 1](#). The first lemma bounds the sizes of the smallest and the largest communities in a subnetwork from a blockmodel. The next theorem bounds the error rate of spectral clustering on a subnetwork from SBM. All the results have been modified based on [Assumption 1](#) and switched to the notations used in this paper.

Lemma B2. ([Chakrabarty et al. 2025, Lemma S3](#)) *Let \tilde{n}_{min} and \tilde{n}_{max} be the sizes of the smallest and the largest communities in a random subnetwork of size η from an SBM or a DCBM with n nodes and K communities. Let $\{n_1, \dots, n_K\}$ be the expected sizes of the communities in the entire network satisfying $\min_{k \in [K]} n_k > \gamma n$ for some $\gamma > 0$. Then the following bounds hold*

$$\tilde{n}_{min} \geq \frac{\eta\gamma}{1+\gamma} \quad \text{and} \quad \tilde{n}_{max} \leq \frac{\eta(1-\gamma)}{\gamma}, \tag{B6}$$

each with probability tending to 1 as $\eta/n > c$ for some $c > 0$ and $n \rightarrow \infty$.

Theorem B1. ([Chakrabarty et al. 2025, Theorem 4](#)) *Under [Assumption 1](#), the number of misclustered nodes from [SC](#) ([Algorithm A1](#)) on $A_{S_{0q}}$, where A is from SBM with n nodes and K communities, is $O_p(\rho_n^{-1})$ for $q \in [s]$, as $o/n > c$ for some $c > 0$ and $n \rightarrow \infty$.*

Next we state a lemma bounding sum of A_{ij} 's over node pairs in different communities.

Lemma B3. *Let $\mathbb{S}_{kk'} \subset G_k \times G_{k'}$ be an arbitrary subset of node pairs from a blockmodel with n nodes and K communities with G_k being the set of all nodes in the k -th community. If $|\mathbb{S}_{kk'}| \geq cn^2$ for some $c > 0$ and $n\rho_n = \omega(1)$ as $n \rightarrow \infty$, then*

$$\frac{1}{|\mathbb{S}_{kk'}|} \sum_{(i,j) \in \mathbb{S}_{kk'}} (A_{ij} - B_{kk'}) = O_p \left(\sqrt{\frac{\rho_n}{|\mathbb{S}_{kk'}|}} \right), \tag{B7}$$

$$\text{and} \quad \frac{1}{|\mathbb{S}_{kk'}|} \sum_{(i,j) \in \mathbb{S}_{kk'}} A_{ij} = O_p(\rho_n). \tag{B8}$$

Proof. Note that $E(A_{ij}) = B_{kk'}$ for all $(i, j) \in \mathbb{S}_{kk'}$ and $|\mathbb{S}_{kk'}|B_{kk'} = \Omega(n^2\rho_n) = \omega(n)$. Then from Lemma B1, as $n \rightarrow \infty$, for any $k, k' \in [K]$, we have

$$\left| \frac{1}{|\mathbb{S}_{kk'}|} \sum_{(i,j) \in \mathbb{S}_{kk'}} (A_{ij} - B_{kk'}) \right| = O_p \left(\sqrt{\frac{B_{kk'}}{|\mathbb{S}_{kk'}|}} \right). \quad (\text{B9})$$

For any $\delta > 0$, we have

$$P \left(\sum_{(i,j) \in \mathbb{S}_{kk'}} (A_{ij} - B_{kk'}) \geq \delta |\mathbb{S}_{kk'}| B_{kk'} \right) \leq \exp \left(-\frac{\delta^2 |\mathbb{S}_{kk'}| B_{kk'} / 2}{\delta / 3 + 1} \right).$$

Setting $\delta = 1/2$, we get

$$P \left(\frac{1}{|\mathbb{S}_{kk'}|} \sum_{(i,j) \in \mathbb{S}_{kk'}} A_{ij} \geq \frac{3}{2} B_{kk'} \right) \leq \exp(-\Omega(|\mathbb{S}_{kk'}| B_{kk'} / 2)). \quad (\text{B10})$$

As $B_{kk'} = \rho_n B_{kk'}^0 \asymp \rho_n$, we get the bounds in the lemma as $n \rightarrow \infty$. \square

The following lemma uses Hoeffding bound and pigeon hole principle to show that there exists a set of node pairs between two predicted communities from NETCROP that has a large intersection with the set of node pairs between three true communities. These sets of node pairs will be later used to derive a lower bound for the distance between the computed loss of NETCROP and the oracle loss.

Lemma B4. *Consider a blockmodel with n nodes, K communities of sizes $n_1, \dots, n_K > \gamma n$ for some $\gamma > 0$, community connectivity matrix $B = \rho_n B_0$ with all distinct rows. Then for each pair of distinct non-overlap parts S_p and S_q , $1 \leq p < q \leq s$, there exist $k_1, k_2 \in [\tilde{K}]$, $l_1, l_2, l_3 \in [K]$, depending on p, q , and a constant $\tilde{c} > 0$ such that the following inequalities hold for $\tilde{K} < K$ with high probability -*

1. $|T_{k_1, k_2, l_1, l_3}^{(pq)}| \geq \tilde{c} m^2$
2. $|T_{k_1, k_2, l_2, l_3}^{(pq)}| \geq \tilde{c} m^2$
3. $B_0(l_1, l_3) \neq B_0(l_2, l_3)$.

Proof. Recall that $|G_l| = n_l > \gamma n$ and $|S_p| = m$. For any $p \in [s]$, note that $|G_l \cap S_p| \sim \text{Hyp}(n, n_l, m)$. Then by hypergeometric tail bound,

$$\begin{aligned}
P\left(|G_l \cap S_p| \geq \frac{\gamma m}{2}\right) &= P\left(|G_l \cap S_p| \geq \frac{m}{2n} \gamma n\right) \\
&\geq P\left(|G_l \cap S_p| \geq \frac{mn_l}{2n}\right) \\
&= P\left(|G_l \cap S_p| \geq \frac{1}{2} E(|G_l \cap S_p|)\right) \\
&\geq 1 - \exp\left(-\frac{2E(|G_l \cap S_p|)^2}{2^2 m}\right) \\
&= 1 - \exp\left(-\frac{mn_l^2}{2n^2}\right) \\
&\geq 1 - \exp\left(-\frac{\gamma^2 m}{2}\right). \tag{B11}
\end{aligned}$$

Thus, as $m \rightarrow \infty$, $|G_l \cap S_p| \geq \frac{\gamma m}{2}$ with probability going to 1. Note that this bound is uniform over all communities $l \in [K]$ as K is fixed.

For $\tilde{K} < K$ and any $p \in [s]$, by the pigeon hole principle, there exist $1 \leq l_1 \neq l_2 \leq K$ and $k_1 \in [\tilde{K}]$ such that the following holds with high probability using the bound in (B11)

$$\begin{aligned}
|\hat{G}_{k_1} \cap G_{l_1} \cap S_p| &\geq \frac{|G_{l_1} \cap S_p|}{\tilde{K}} > \frac{\gamma m}{2K}, \\
\text{and } |\hat{G}_{k_1} \cap G_{l_2} \cap S_p| &\geq \frac{|G_{l_2} \cap S_p|}{\tilde{K}} > \frac{\gamma m}{2K}. \tag{B12}
\end{aligned}$$

Since the rows of B_0 are distinct, there exists $l_3 \in [K]$ such that $B_{0,l_1 l_3} \neq B_{0,l_2 l_3}$. Then there exists k_2 such that for any $q > p$ and $q \in [s]$

$$|\hat{G}_{k_2} \cap G_{l_3} \cap S_q| \geq \frac{|G_{l_3} \cap S_q|}{\tilde{K}} > \frac{\gamma m}{2K}. \tag{B13}$$

Construct $T_{k_1, k_2, l_1, l_3}^{(pq)} := (\hat{G}_{k_1} \cap G_{l_1} \cap S_p) \times (\hat{G}_{k_2} \cap G_{l_3} \cap S_q)$ and $T_{k_1, k_2, l_2, l_3}^{(pq)} := (\hat{G}_{k_1} \cap G_{l_2} \cap S_p) \times (\hat{G}_{k_2} \cap G_{l_3} \cap S_q)$. Then

$$\begin{aligned}
|T_{k_1, k_2, l_1, l_3}^{(pq)}| &> \frac{\gamma^2 m^2}{4K^2}, \\
\text{and } |T_{k_1, k_2, l_2, l_3}^{(pq)}| &> \frac{\gamma^2 m^2}{4K^2}. \tag{B14}
\end{aligned}$$

Taking $\tilde{c} = \gamma^2/4K^2$, the lemma follows. □

Proof of Theorem 1 for SBM: Case 1: ($\tilde{K} < K$) Without loss of generality assume $k_1 = 1, k_2 = 2, l_1 = 1, l_2 = 2, l_3 = 3$ in Lemma B4 for any $1 \leq p < q \leq s$. Also, define the following quantities:

$$\begin{aligned}\hat{p}_{k,k',l,l'}^{(pq)} &= \frac{1}{|T_{k,k',l,l'}^{(pq)}|} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} A_{ij} \\ \lambda &= \frac{|T_{1,2,1,3}^{(pq)}|}{|T_{1,2,1,3}^{(pq)}| + |T_{1,2,2,3}^{(pq)}|}, \\ \hat{p} &= \frac{1}{|T_{1,2,1,3}^{(pq)}| + |T_{1,2,2,3}^{(pq)}|} \sum_{(i,j) \in T_{1,2,1,3}^{(pq)} \cup T_{1,2,2,3}^{(pq)}} A_{ij} = \lambda \hat{p}_{1,2,1,3}^{(pq)} + (1 - \lambda) \hat{p}_{1,2,2,3}^{(pq)}.\end{aligned}$$

Consider the difference between the loss function and the oracle loss on $S_p \times S_q$ for any $1 \leq p < q \leq s$:

$$\begin{aligned}& L^{(pq)}(A, \hat{P}^{(\tilde{K})}) - L^{(pq)}(A) \\ &= \sum_{(i,j) \in S_p \times S_q} \left[(A_{ij} - \hat{P}_{ij}^{(\tilde{K})})^2 - (A_{ij} - P_{ij})^2 \right] \\ &= \sum_{(k,k',l,l') \in [\tilde{K}]^2 \times [K]^2} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \left[(A_{ij} - \hat{B}_{kk'}^{(\tilde{K})})^2 - (A_{ij} - B_{ll'})^2 \right] \\ &= \sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} \left[(A_{ij} - \hat{B}_{12}^{(\tilde{K})})^2 - (A_{ij} - B_{13})^2 \right] \\ &\quad + \sum_{(i,j) \in T_{1,2,2,3}^{(pq)}} \left[(A_{ij} - \hat{B}_{12}^{(\tilde{K})})^2 - (A_{ij} - B_{23})^2 \right] \\ &\quad + \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,2,3)\}} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \left[(A_{ij} - \hat{B}_{kk'}^{(\tilde{K})})^2 - (A_{ij} - B_{ll'})^2 \right] \\ &\geq \sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} \left[(A_{ij} - \hat{p})^2 - (A_{ij} - B_{13})^2 \right] \\ &\quad + \sum_{(i,j) \in T_{1,2,2,3}^{(pq)}} \left[(A_{ij} - \hat{p})^2 - (A_{ij} - B_{23})^2 \right] \\ &\quad + \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,2,3)\}} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \left[(A_{ij} - \hat{p}_{k,k',l,l'}^{(pq)})^2 - (A_{ij} - B_{ll'})^2 \right]\end{aligned}$$

$$=I + II + III. \tag{B15}$$

Then,

$$\begin{aligned}
I &= \sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} [(A_{ij} - \hat{p})^2 - (A_{ij} - B_{13})^2] \\
&= \sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} [A_{ij}^2 - 2A_{ij}\hat{p} + \hat{p}^2 - A_{ij}^2 + 2A_{ij}B_{13} - B_{13}^2] \\
&= -2\hat{p} \sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} A_{ij} + |T_{1,2,1,3}| \hat{p}^2 + 2B_{13} \sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} A_{ij} - |T_{1,2,1,3}| B_{13}^2 \\
&= |T_{1,2,1,3}| \left(\hat{p}^2 - 2\hat{p}\hat{p}_{1,2,1,3}^{(pq)} + (\hat{p}_{1,2,1,3}^{(pq)})^2 - (\hat{p}_{1,2,1,3}^{(pq)})^2 + 2\hat{p}_{1,2,1,3}^{(pq)}B_{13} - B_{13}^2 \right) \\
&= |T_{1,2,1,3}| \left[(\hat{p} - \hat{p}_{1,2,1,3}^{(pq)})^2 - (\hat{p}_{1,2,1,3}^{(pq)} - B_{13})^2 \right] \\
&= |T_{1,2,1,3}| \left[(1 - \lambda)^2 (\hat{p}_{1,2,1,3}^{(pq)} - \hat{p}_{1,2,2,3}^{(pq)})^2 - (\hat{p}_{1,2,1,3}^{(pq)} - B_{13})^2 \right] \\
&\geq |T_{1,2,1,3}| \left[\frac{(1 - \lambda)^2}{2} (B_{13} - B_{23})^2 - (1 - \lambda)^2 ((\hat{p}_{1,2,1,3}^{(pq)} - B_{13}) - (\hat{p}_{1,2,2,3}^{(pq)} - B_{23}))^2 \right. \\
&\qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \left. - (\hat{p}_{1,2,1,3}^{(pq)} - B_{13})^2 \right] \\
&\qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \left(\text{as } (a + b)^2 \geq \frac{b^2}{2} - a^2 \right) \\
&\geq |T_{1,2,1,3}| \left[\frac{(1 - \lambda)^2}{2} (B_{13} - B_{23})^2 - 2(1 - \lambda)^2 (\hat{p}_{1,2,1,3}^{(pq)} - B_{13})^2 \right. \\
&\qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \left. - 2(1 - \lambda)^2 (\hat{p}_{1,2,2,3}^{(pq)} - B_{23})^2 - (\hat{p}_{1,2,1,3}^{(pq)} - B_{13})^2 \right] \\
&\qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \left(\text{as } (a - b)^2 \leq 2(a^2 + b^2) \right). \tag{B16}
\end{aligned}$$

From Lemma B4,

$$\tilde{c}m^2 \leq |T_{1,2,1,3}^{(pq)}| \leq |S_p \times S_q| = m^2 \text{ and } \tilde{c}m^2 \leq |T_{1,2,2,3}^{(pq)}| \leq |S_p \times S_q| = m^2.$$

Then

$$\frac{(1 - \lambda)^2}{2} (B_{13} - B_{23})^2 = \frac{|T_{1,2,2,3}^{(pq)}|^2}{2(|T_{1,2,2,3}^{(pq)}| + |T_{1,2,2,3}^{(pq)}|)^2} (B_{13} - B_{23})^2 \geq c_1 \rho_n^2.$$

For $(k, k', l, l') \in \{(1, 2, 1, 3), (1, 2, 2, 3)\}$, using Lemma B1 we have

$$|\hat{p}_{k,k',l,l'}^{(pq)} - B_{ll'}| = O_p \left(\sqrt{\frac{B_{ll'}}{|T_{k,k',l,l'}^{(pq)}|}} \right) = O_p \left(\sqrt{\frac{\rho_n}{|T_{k,k',l,l'}^{(pq)}|}} \right).$$

From Equation B16, we have

$$I \geq c_1 m^2 \rho_n^2 - O_p(\rho_n). \quad (\text{B17})$$

Similarly,

$$II \geq c_1 m^2 \rho_n^2 - O_p(\rho_n). \quad (\text{B18})$$

Let \hat{p}' be the average of A_{ij} over $(i, j) \in T_{k,k',l,l'}^{(pq)}$ for all $(k, k', l, l') \notin \{(1, 2, 1, 3), (1, 2, 2, 3)\}$.

Then,

$$\begin{aligned} III &= \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,2,3)\}} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} [(A_{ij} - \hat{p}_{k,k',l,l'})^2 - (A_{ij} - B_{ll'})^2] \\ &= \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,2,3)\}} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} [A_{ij}^2 - 2A_{ij}\hat{p}_{k,k',l,l'} + \hat{p}_{k,k',l,l'}^2 - A_{ij}^2 + 2A_{ij}B_{ll'} - B_{ll'}^2] \\ &= \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,2,3)\}} \left| T_{k,k',l,l'}^{(pq)} \right| [-2\hat{p}_{k,k',l,l'}^2 + \hat{p}_{k,k',l,l'}^2 + 2B_{ll'}\hat{p}_{k,k',l,l'} - B_{ll'}^2] \\ &= - \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,2,3)\}} \left| T_{k,k',l,l'}^{(pq)} \right| (\hat{p}_{k,k',l,l'} - B_{ll'})^2 \\ &= -O_p(\rho_n), \end{aligned} \quad (\text{B19})$$

where the last inequality follows from Lemma B1 since the sum can be split into $(K - 1)^2$ many sums, each taken over $n_l^{(p)} n_{l'}^{(q)} \geq \gamma^2(o + m)^2 \geq c^2 \gamma^2 n^2$ many terms for each $(k, k', l, l') \notin \{(1, 2, 1, 3), (1, 2, 2, 3)\}$. Combining

$$L^{(pq)}(A, \hat{P}) - L^{(pq)}(A) \geq I + II + III \geq c m^2 \rho_n^2 - O_p(\rho_n). \quad (\text{B20})$$

Now consider the difference of computed loss and the oracle loss over the entire test set

$$\mathbb{S}^c = \bigcup_{1 \leq p < q \leq s} (S_p \times S_q) \text{ as}$$

$$\begin{aligned} L(A, \hat{P}^{(\tilde{K})}) - L(A) &= \sum_{1 \leq p < q \leq s} \left[L(A, \hat{P}^{(\tilde{K})})^{(pq)} - L^{(pq)}(A) \right] \\ &\geq cs(s-1)m^2 \rho_n^2 - O_p(s(s-1)\rho_n). \end{aligned} \quad (\text{B21})$$

Case 2: ($\tilde{K} = K$ for SBM) Define $\epsilon_n = \sup_{1 \leq l, l' \leq K} |\hat{B}_{ll'} - B_{ll'}|$. The absolute difference between computed loss and oracle loss is

$$\begin{aligned}
|L(A, \hat{P}) - L(A)| &\leq \sum_{l, l' \in [K]} \sum_{(i, j) \in T_{ll'}} \left| (A_{ij} - \hat{B}_{ll'})^2 - (A_{ij} - B_{ll'})^2 \right| \\
&\quad + \sum_{\substack{(k, k') \neq (l, l') \\ \in [K]}} \sum_{(i, j) \in T_{k, k', l, l'}} \left| (A_{ij} - \hat{B}_{kk'})^2 - (A_{ij} - B_{ll'})^2 \right| \\
&= \sum_{l, l' \in [K]} \sum_{(i, j) \in T_{ll'}} \left| -2A_{ij}(\hat{B}_{ll'} - B_{ll'}) + (\hat{B}_{ll'} + B_{ll'})(\hat{B}_{ll'} - B_{ll'}) \right| + V \\
&\leq \sum_{l, l' \in [K]} \sum_{(i, j) \in T_{ll'}} [2\epsilon_n A_{ij} + (2B_{ll'} + \epsilon_n)\epsilon_n] + V \\
&= IV + V. \tag{B22}
\end{aligned}$$

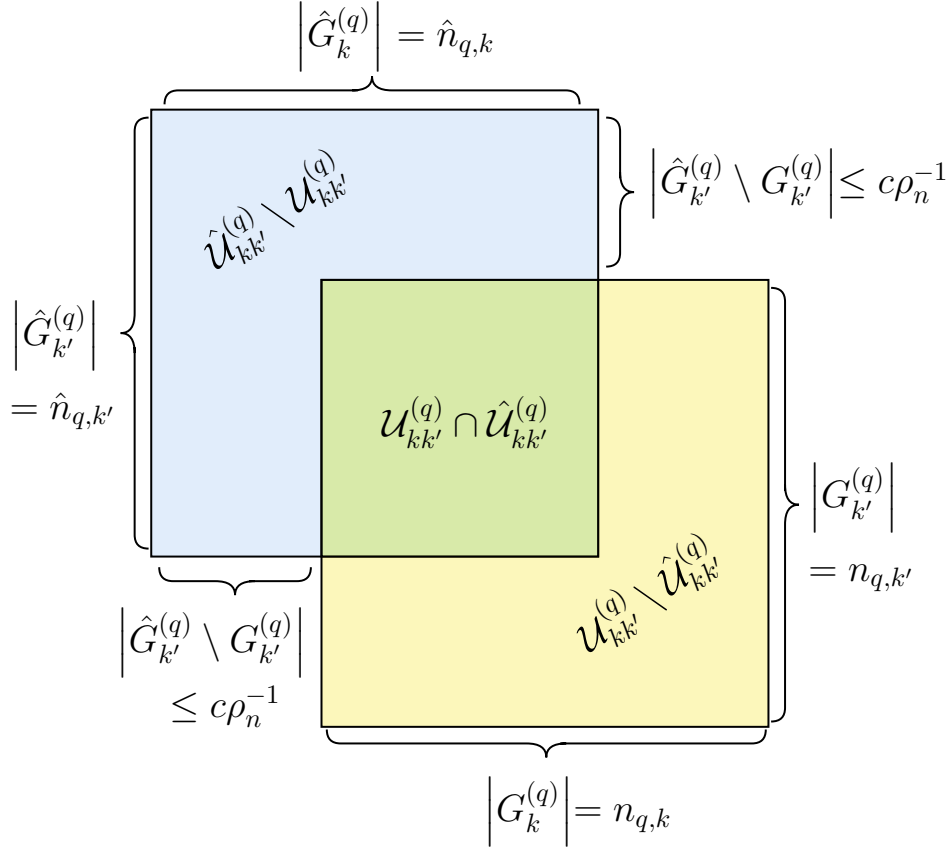

Figure B3: Intersecting sets of $\mathcal{U}_{kk'}^{(q)}$ and $\hat{\mathcal{U}}_{kk'}^{(q)}$ for SBM

Let $n_{q,k}$ and $\hat{n}_{q,k}$ be the number of nodes in the true and predicted k -th community in S_{0q} , respectively. Using Fig. B3 and Theorem B1, we get

$$\begin{aligned}
|\hat{\mathcal{U}}_{kk'}^{(q)} \Delta \mathcal{U}_{kk'}^{(q)}| &= |\hat{\mathcal{U}}_{kk'}^{(q)} \setminus \mathcal{U}_{kk'}^{(q)}| + |\mathcal{U}_{kk'}^{(q)} \setminus \hat{\mathcal{U}}_{kk'}^{(q)}| \\
&\leq |\hat{G}_k^{(q)}| |\hat{G}_k^{(q)} \setminus G_k^{(q)}| + |\hat{G}_{k'}^{(q)}| |\hat{G}_{k'}^{(q)} \setminus G_{k'}^{(q)}| \\
&\quad + |G_k^{(q)}| |G_k^{(q)} \setminus \hat{G}_k^{(q)}| + |G_{k'}^{(q)}| |G_{k'}^{(q)} \setminus \hat{G}_{k'}^{(q)}| \\
&= (\hat{n}_{q,k} + \hat{n}_{q,k'} + n_{q,k} + n_{q,k'}) O_p(\rho_n^{-1}) \\
&= O_p((o+m)\rho_n^{-1}). \tag{B23}
\end{aligned}$$

We also have with high probability

$$\begin{aligned}
(o+m)^2 &\geq |\mathcal{U}_{kk'}^{(q)}| = n_{q,k} n_{q,k'} \geq \frac{\gamma^2 (o+m)^2}{(1+\gamma)^2} = \Omega_p((o+m)^2), \\
\text{and } (o+m)^2 &\geq |\hat{\mathcal{U}}_{kk'}^{(q)}| \geq |\mathcal{U}_{kk'}^{(q)} \cap \hat{\mathcal{U}}_{kk'}^{(q)}| \geq |\mathcal{U}_{kk'}^{(q)}| - |\mathcal{U}_{kk'}^{(q)} \setminus \hat{\mathcal{U}}_{kk'}^{(q)}| \\
&\geq \Omega_p((o+m)^2) - O_p((o+m)\rho_n^{-1}) = \Omega_p((o+m)^2).
\end{aligned}$$

Thus, $|\mathcal{U}_{kk'}^{(q)}| \asymp (o+m)^2$ and $|\hat{\mathcal{U}}_{kk'}^{(q)}| \asymp (o+m)^2$. Then

$$\begin{aligned}
\left| |\hat{\mathcal{U}}_{kk'}^{(q)}| - |\mathcal{U}_{kk'}^{(q)}| \right| &\leq |\hat{\mathcal{U}}_{kk'}^{(q)} \Delta \mathcal{U}_{kk'}^{(q)}| = O_p((o+m)\rho_n^{-1}) \\
\Rightarrow \frac{|\mathcal{U}_{kk'}^{(q)}|}{|\hat{\mathcal{U}}_{kk'}^{(q)}|} &= 1 + O_p((o+m)^{-1}\rho_n^{-1}). \tag{B24}
\end{aligned}$$

Consider the difference

$$\begin{aligned}
|\hat{B}_{kk'} - B_{kk'}| &= \left| \frac{1}{s} \sum_{q \in [s]} \frac{1}{|\hat{\mathcal{U}}_{kk'}^{(q)}|} \sum_{(i,j) \in \hat{\mathcal{U}}_{kk'}^{(q)}} A_{ij} - B_{kk'} \right| \\
&\leq \frac{1}{s} \sum_{q \in [s]} \left| \frac{1}{|\hat{\mathcal{U}}_{kk'}^{(q)}|} \sum_{(i,j) \in \hat{\mathcal{U}}_{kk'}^{(q)}} A_{ij} - B_{kk'} \right| \\
&\leq \frac{1}{s} \sum_{q \in [s]} \left(\frac{|\mathcal{U}_{kk'}^{(q)}|}{|\hat{\mathcal{U}}_{kk'}^{(q)}|} \left| \frac{1}{|\mathcal{U}_{kk'}^{(q)}|} \sum_{(i,j) \in \mathcal{U}_{kk'}^{(q)}} A_{ij} - B_{kk'} \right| + \left| \frac{|\mathcal{U}_{kk'}^{(q)}|}{|\hat{\mathcal{U}}_{kk'}^{(q)}|} - 1 \right| B_{kk'} \right)
\end{aligned}$$

$$+ \frac{1}{|\hat{\mathcal{U}}_{kk'}^{(q)}|} \sum_{(i,j) \in \hat{\mathcal{U}}_{kk'}^{(q)} \Delta \mathcal{U}_{kk'}^{(q)}} A_{ij} \quad (\text{B25})$$

$$\leq \frac{1}{s} \sum_{q \in [s]} [Q_{1q} + Q_{2q} + Q_{3q}] \quad (\text{say}). \quad (\text{B26})$$

Then

$$\begin{aligned} Q_{1q} &= \frac{|\mathcal{U}_{kk'}^{(q)}|}{|\hat{\mathcal{U}}_{kk'}^{(q)}|} \left| \frac{1}{|\mathcal{U}_{kk'}^{(q)}|} \sum_{(i,j) \in \mathcal{U}_{kk'}^{(q)}} A_{ij} - B_{kk'} \right| \\ &= (1 + O_p((o+m)^{-1} \rho_n^{-1})) O_p \left(\sqrt{\frac{\rho_n}{(o+m)^2}} \right) \\ &= O_p(\rho_n^{1/2} (o+m)^{-1}), \end{aligned} \quad (\text{B27})$$

where the first bound follows from (B24) and the second bound follows from (B7).

$$Q_{2q} = \left| \frac{|\mathcal{U}_{kk'}^{(q)}|}{|\hat{\mathcal{U}}_{kk'}^{(q)}|} - 1 \right| B_{kk'} = O_p((o+m)^{-1} \rho_n^{-1}) O(\rho_n) = O_p((o+m)^{-1}). \quad (\text{B28})$$

From (B8),

$$\begin{aligned} Q_{3q} &= \frac{1}{|\hat{\mathcal{U}}_{kk'}^{(q)}|} \sum_{(i,j) \in \hat{\mathcal{U}}_{kk'}^{(q)} \Delta \mathcal{U}_{kk'}^{(q)}} A_{ij} \leq \frac{|\hat{\mathcal{U}}_{kk'}^{(q)} \Delta \mathcal{U}_{kk'}^{(q)}|}{|\hat{\mathcal{U}}_{kk'}^{(q)}|} \frac{1}{|\hat{\mathcal{U}}_{kk'}^{(q)} \Delta \mathcal{U}_{kk'}^{(q)}|} \sum_{(i,j) \in \hat{\mathcal{U}}_{kk'}^{(q)} \Delta \mathcal{U}_{kk'}^{(q)}} A_{ij} \\ &= O_p((o+m)^{-1} \rho_n^{-1}) O_p(\rho_n) = O_p((o+m)^{-1}). \end{aligned} \quad (\text{B29})$$

Thus, for any $k, k' \in [K]$,

$$|\hat{B}_{kk'} - B_{kk'}| = O_p((o+m)^{-1}). \quad (\text{B30})$$

Continuing from (B22),

$$\begin{aligned} IV &= \sum_{l, l' \in [K]} \sum_{(i,j) \in T_{ll'}} [2\epsilon_n A_{ij} + (2B_{ll'} + \epsilon_n) \epsilon_n] \\ &= O_p \left((o+m)^{-1} \sum_{l, l' \in [K]} \sum_{(i,j) \in T_{ll'}} A_{ij} \right) \end{aligned}$$

$$= O_p(s(s-1)m^2(o+m)^{-1}\rho_n), \quad (\text{B31})$$

where the last bound follows from Lemma B3.

Now,

$$\begin{aligned} V &= \sum_{\substack{(k,k') \neq (l,l') \\ \in [K]}} \sum_{(i,j) \in T_{k,k',l,l'}} \left| (A_{ij} - \hat{B}_{kk'})^2 - (A_{ij} - B_{ll'})^2 \right| \\ &\leq \sum_{\substack{(k,k') \neq (l,l') \\ \in [K]}} \sum_{(i,j) \in T_{k,k',l,l'}} 2 \left(A_{ij} + B_{ll'} + |\hat{B}_{kk'} - B_{ll'}| \right) |\hat{B}_{kk'} - B_{ll'}|. \end{aligned} \quad (\text{B32})$$

Consider for any $(k, k') \neq (l, l') \in [K]$

$$|\hat{B}_{kk'} - B_{ll'}| \leq |\hat{B}_{kk'} - B_{kk'}| + |B_{kk'}| + |B_{ll'}| = O_p((o+m)^{-1}) + O(\rho_n) = O_p(\rho_n). \quad (\text{B33})$$

Following a similar argument as in Fig. B3, it can be shown that for any $(k, k') \neq (l, l') \in [K]$

$$|T_{k,k',l,l'}| = |\hat{T}_{kk'} \cap T_{ll'}| \leq |\hat{T}_{ll'} \Delta T_{ll'}| = O_p(m\rho_n^{-1}),$$

where the inequality follows from the fact that the node pairs in $\hat{T}_{kk'} \cap T_{ll'}$ are contained in the set of node pairs that are mislabelled in $T_{ll'}$ by the community detection algorithm.

Therefore,

$$V = O_p(m\rho_n). \quad (\text{B34})$$

Combining (B31) and (B34), we get

$$\begin{aligned} |L(A, \hat{P}) - L(A)| &= O_p(s(s-1)m^2(o+m)^{-1}\rho_n) + O_p(m\rho_n) \\ &= O_p(s(s-1)m^2(o+m)^{-1}\rho_n). \end{aligned} \quad (\text{B35})$$

B.2 Proof of Theorem 3

In this section, we prove the bounds on the difference between computed loss and the oracle loss for DCBM. Case 1 deals with the scenario $\tilde{K} < K$ and Case 2 is for $\tilde{K} = K$ case. The same notations and the definitions for the subsets of node pairs in (B5) are used in this

subsection as well. We would also like to note that Lemma B2 is also applicable for the DCBM case. First, we restate a result on upper bound of the misclustering rate of SSC (Algorithm A2) on subnetworks of DCBM from Chakrabarty et al. (2025).

Theorem B2. (Chakrabarty et al. 2025, Theorem 6) Under Assumption 2 except for $\rho_n = \omega(n^{-1} \log n)$, the number of misclustered nodes from SSC (Algorithm A2) on $A_{S_{0q}}$, where A is from DCBM with n nodes and K communities, is $o_p\left(\sqrt{n\rho_n^{-1}}\right)$ for $q \in [s]$, as $o/n > c$ for some $c > 0$ and $n \rightarrow \infty$.

The following lemma bounds the distance between the eigenvectors of principal submatrices of A and P . The proof is based on Chen & Lei (2018, Lemma 6,7) and Lei & Rinaldo (2015, Theorem 5.2).

Lemma B5. For any subnetwork spanned by nodes in $\mathcal{S} \subset [n]$ of size η from a DCBM with n nodes and K communities satisfying Assumption 2, let $\hat{U}_{\mathcal{S}}$ and $U_{\mathcal{S}}$ be the matrix of top K eigenvectors of $A_{\mathcal{S}}$ and $P_{\mathcal{S}}$, respectively. Then for some constant c'' ,

$$\|\hat{U}_{\mathcal{S}} - U_{\mathcal{S}}\|_F \leq \frac{c''}{\sqrt{n\rho_n}} \quad \text{with probability} \geq 1 - \frac{1}{n}, \quad (\text{B36})$$

as $\eta/n > c$ for some $c > 0$ and $n \rightarrow \infty$.

Proof. From Assumption 2,

$$n \max_{i,j} P_{ij} \leq n\rho_n \max_{kk'} B_{0,kk'} (\max_i \Psi)^2 \leq b_0 n\rho_n, \quad (\text{B37})$$

for some constant $b_0 > 0$. Thus $b = b_0 n\rho_n \geq b_1 n \times n^{-1/3} = b_1 n^{2/3} \geq b_1 \log n$ for some constant $b_1 > 0$. Therefore, from Lei & Rinaldo (2015, Theorem 5.2),

$$P(\|A - P\| \leq C\sqrt{n\rho_n}) \geq 1 - \frac{1}{n}, \quad (\text{B38})$$

where $C = C(C_b, b)$.

Note that $\|A_{\mathcal{S}} - P_{\mathcal{S}}\| = \sigma_1(A_{\mathcal{S}} - P_{\mathcal{S}}) \leq \sigma_1(A - P) = \|A - P\|$, where $\sigma_1(\cdot)$ is the largest singular value of a matrix and the inequality follows from interlacing of singular vectors (Thompson 1972, Theorem 1). Then

$$P\left(\|A_{\mathcal{S}} - P_{\mathcal{S}}\| \leq \frac{C}{\sqrt{c}}\sqrt{\eta\rho_n}\right) \geq P(\|A - P\| \leq C\sqrt{n\rho_n}) \geq 1 - \frac{1}{n}. \quad (\text{B39})$$

Let $\Psi_{\mathcal{S}}$ be the $\eta \times K$ matrix of the degree parameters of the nodes in \mathcal{S} such that the i -th row contains all 0 except ψ_i at the g_i -th position. Let $\lambda_K(M)$ denote the K -th largest eigenvalue of any matrix M . Note that $\Psi_{\mathcal{S}}^{\top} \Psi_{\mathcal{S}} = \text{diag} \left(\sum_{i \in \mathcal{S} \cap G_1} \psi_i^2, \dots, \sum_{i \in \mathcal{S} \cap G_K} \psi_i^2 \right)$. If $B_0 = \beta \Gamma \beta^{\top}$ is the eigen decomposition of B_0 , then $\Psi_{\mathcal{S}} B_0 \Psi_{\mathcal{S}}^{\top} = (\Psi_{\mathcal{S}} \beta) \Gamma (\Psi_{\mathcal{S}} \beta)^{\top} = (\Psi'_{\mathcal{S}} \beta) \Gamma' (\Psi'_{\mathcal{S}} \beta)^{\top}$ is an eigen decomposition of $\Psi B_0 \Psi^{\top}$, where $\Psi'_{\mathcal{S}}$ and Γ' are correspondingly scaled. Then

$$\begin{aligned} \lambda_K(P_{\mathcal{S}}) &= \rho_n \lambda_K(P_{0\mathcal{S}}) = \rho_n \lambda_K(\Psi_{\mathcal{S}} B_0 \Psi_{\mathcal{S}}^{\top}) \\ &= \rho_n \lambda_K(B_0) \sum_{i \in \mathcal{S}} \psi_i^2 \geq \psi_0^2 \eta \rho_n \lambda_K(B_0) \geq \psi_0^2 c' n \rho_n, \end{aligned} \quad (\text{B40})$$

where the last inequality follows from Assumption 2. Next, using Chen & Lei (2018, Lemma 7) along with (B39) and (B40), we have

$$\|\hat{U}_{\mathcal{S}} - U_{\mathcal{S}}\|_F \leq \frac{2\sqrt{2}\|A_{\mathcal{S}} - P_{\mathcal{S}}\|}{\lambda_K(P_{\mathcal{S}})} \leq \frac{c''}{\sqrt{n\rho_n}} \quad \text{with probability} \geq 1 - \frac{1}{n}. \quad (\text{B41})$$

□

Lemma B6. For any $(a_i, p_i, w_i) \in \mathbb{R}^2 \times [0, \infty)$, $i \in [n]$,

$$\sum_{i=1}^n (a_i - p_i)^2 w_i \geq \sum_{i=1}^n (a_i - \bar{a}_w)^2 w_i - 2 \sum_{i=1}^n (a_i - \bar{a}_w) p_i w_i, \quad (\text{B42})$$

where $\bar{a}_w = \sum_{i=1}^n a_i w_i / \sum_{i=1}^n w_i$.

Proof. Consider

$$\begin{aligned} \sum_{i=1}^n (a_i - p_i)^2 w_i &= \sum_{i=1}^n ((a_i - \bar{a}_w) + (\bar{a}_w - p_i))^2 w_i \\ &= \sum_{i=1}^n (a_i - \bar{a}_w)^2 w_i + \sum_{i=1}^n (\bar{a}_w - p_i)^2 w_i + 2 \sum_{i=1}^n (a_i - \bar{a}_w)(\bar{a}_w - p_i) w_i \\ &\geq \sum_{i=1}^n (a_i - \bar{a}_w)^2 w_i + 2\bar{a}_w \sum_{i=1}^n (a_i - \bar{a}_w) w_i - 2 \sum_{i=1}^n (a_i - \bar{a}_w) p_i w_i \\ &= \sum_{i=1}^n (a_i - \bar{a}_w)^2 w_i - 2 \sum_{i=1}^n (a_i - \bar{a}_w) p_i w_i. \end{aligned} \quad (\text{B43})$$

□

Proof of Theorem 3 for DCBM

Case 1: ($\tilde{K} < K$ for DCBM) Recall that the test set is structured as $\mathbb{S}^c = \bigcup_{1 \leq p < q \leq s} (S_p \times S_q)$, where the union is disjoint. For $\tilde{K} < K$ and any specific $1 \leq p < q \leq s$, let $l_1, l_2, l_3 \in [K]$ and $k_1, k_2 \in [\tilde{K}]$ be the indices from Lemma B4. Without loss of generality, assume $l_1 = 1, l_2 = 2, l_3 = 3, k_1 = 1, k_2 = 2$ in Lemma B4 for some specific $1 \leq p < q \leq s$. Define

$$\begin{aligned} \Psi_{k,k',l,l'}^{(pq)} &= \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \psi_i^2 \psi_j^2 \\ \lambda &= \frac{\Psi_{1,2,1,3}^{(pq)}}{\Psi_{1,2,1,3}^{(pq)} + \Psi_{1,2,2,3}^{(pq)}} = \frac{\sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} \psi_i^2 \psi_j^2}{\sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} \psi_i^2 \psi_j^2 + \sum_{(i,j) \in T_{1,2,2,3}^{(pq)}} \psi_i^2 \psi_j^2}, \\ \hat{P}_{k,k',l,l'}^{(pq)} &= \frac{\sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} A_{ij} \psi_i \psi_j}{\sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \psi_i^2 \psi_j^2}, \\ \text{and } \hat{p} &= \lambda \hat{p}_{1,2,1,3}^{(pq)} + (1 - \lambda) \hat{p}_{1,2,2,3}^{(pq)} = \frac{\sum_{(i,j) \in T_{1,2,1,3}^{(pq)} \cup T_{1,2,2,3}^{(pq)}} A_{ij} \psi_i \psi_j}{\Psi_{1,2,1,3}^{(pq)} + \Psi_{1,2,2,3}^{(pq)}}. \end{aligned}$$

The superscript (pq) is dropped from $\hat{p}_{k,k',l,l'}^{(pq)}$ from the computations related to $L^{(pq)}(A, \hat{P})$ for notational simplicity. Now, consider the difference between the computed loss and the oracle loss within $S_p \times S_q$ as -

$$\begin{aligned} &L^{(pq)}(A, \hat{P}'^{(\tilde{K})}) - L^{(pq)}(A) \\ &= \sum_{(i,j) \in S_p \times S_q} \left[\left(A_{ij} - \hat{P}'_{ij}^{(\tilde{K})} \right)^2 - \left(A_{ij} - P_{ij} \right)^2 \right] \\ &= \sum_{(k,k',l,l') \in [\tilde{K}]^2 \times [K]^2} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \left[\left(A_{ij} - \hat{P}'_{ij}^{(\tilde{K})} \right)^2 - \left(A_{ij} - \psi_i \psi_j B_{ll'} \right)^2 \right] \\ &= \sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} \left[\left(\frac{A_{ij}}{\psi_i \psi_j} - \frac{\hat{P}'_{ij}^{(\tilde{K})}}{\psi_i \psi_j} \right)^2 \psi_i^2 \psi_j^2 - \left(\frac{A_{ij}}{\psi_i \psi_j} - B_{13} \right)^2 \psi_i^2 \psi_j^2 \right] \end{aligned}$$

$$\begin{aligned}
& + \sum_{(i,j) \in T_{1,2,2,3}^{(pq)}} \left[\left(\frac{A_{ij}}{\psi_i \psi_j} - \frac{\hat{P}'_{ij}(\bar{K})}{\psi_i \psi_j} \right)^2 \psi_i^2 \psi_j^2 - \left(\frac{A_{ij}}{\psi_i \psi_j} - B_{23} \right)^2 \psi_i^2 \psi_j^2 \right] \\
& + \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,2,3)\}} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \left[\left(\frac{A_{ij}}{\psi_i \psi_j} - \frac{\hat{P}'_{ij}(\bar{K})}{\psi_i \psi_j} \right)^2 \psi_i^2 \psi_j^2 - \left(\frac{A_{ij}}{\psi_i \psi_j} - B_{ll'} \right)^2 \psi_i^2 \psi_j^2 \right] \\
\geq & \sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} \left[\left(\frac{A_{ij}}{\psi_i \psi_j} - \hat{p} \right)^2 \psi_i^2 \psi_j^2 - \left(\frac{A_{ij}}{\psi_i \psi_j} - B_{13} \right)^2 \psi_i^2 \psi_j^2 \right] \\
& + \sum_{(i,j) \in T_{1,2,2,3}^{(pq)}} \left[\left(\frac{A_{ij}}{\psi_i \psi_j} - \hat{p} \right)^2 \psi_i^2 \psi_j^2 - \left(\frac{A_{ij}}{\psi_i \psi_j} - B_{23} \right)^2 \psi_i^2 \psi_j^2 \right] \\
& + \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,2,3)\}} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \left[\left(\frac{A_{ij}}{\psi_i \psi_j} - \hat{p}_{k,k',l,l'} \right)^2 \psi_i^2 \psi_j^2 - \left(\frac{A_{ij}}{\psi_i \psi_j} - B_{ll'} \right)^2 \psi_i^2 \psi_j^2 \right] \\
& - \sum_{(i,j) \in T_{1,2,1,3}^{(pq)} \cup T_{1,2,2,3}^{(pq)}} \left(\frac{A_{ij}}{\psi_i \psi_j} - \hat{p} \right) \hat{P}'_{ij}(\bar{K}) \psi_i^2 \psi_j^2 \tag{B44} \\
& - \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,2,3)\}} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \left(\frac{A_{ij}}{\psi_i \psi_j} - \hat{p}_{k,k',l,l'} \right) \hat{P}'_{ij}(\bar{K}) \psi_i^2 \psi_j^2
\end{aligned}$$

(from Lemma B6)

$$= I + II + III - E - F \text{ (say)}. \tag{B45}$$

Then,

$$\begin{aligned}
I &= \sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} \left[\left(\frac{A_{ij}}{\psi_i \psi_j} - \hat{p} \right)^2 \psi_i^2 \psi_j^2 - \left(\frac{A_{ij}}{\psi_i \psi_j} - B_{13} \right)^2 \psi_i^2 \psi_j^2 \right] \\
&= -2\hat{p} \sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} A_{ij} \psi_i \psi_j + \hat{p}^2 \Psi_{1,2,1,3}^{(pq)} + 2B_{13} \sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} A_{ij} \psi_i \psi_j - B_{13}^2 \Psi_{1,2,1,3}^{(pq)} \\
&= \Psi_{1,2,1,3}^{(pq)} (\hat{p}^2 - 2\hat{p}\hat{p}_{1,2,1,3} + \hat{p}_{1,2,1,3}^2 - \hat{p}_{1,2,1,3}^2 + 2\hat{p}_{1,2,1,3}B_{13} - B_{13}^2) \\
&= \Psi_{1,2,1,3}^{(pq)} [(\hat{p} - \hat{p}_{1,2,1,3})^2 - (\hat{p}_{1,2,1,3} - B_{13})^2] \\
&= \Psi_{1,2,1,3}^{(pq)} [(1-\lambda)^2 (\hat{p}_{1,2,1,3} - \hat{p}_{1,2,2,3})^2 - (\hat{p}_{1,2,1,3} - B_{13})^2] \\
&\geq \Psi_{1,2,1,3}^{(pq)} \left[\frac{(1-\lambda)^2}{2} (B_{13} - B_{23})^2 - (1-\lambda)^2 ((\hat{p}_{1,2,1,3} - B_{13}) - (\hat{p}_{1,2,2,3} - B_{23}))^2 \right]
\end{aligned}$$

$$\begin{aligned}
& \left. - (\hat{p}_{1,2,1,3} - B_{13})^2 \right] \\
& \left(\text{as } (a+b)^2 \geq \frac{b^2}{2} - a^2 \right) \\
\geq & \Psi_{1,2,1,3}^{(pq)} \left[\frac{(1-\lambda)^2}{2} (B_{13} - B_{23})^2 - 2(1-\lambda)^2 (\hat{p}_{1,2,1,3} - B_{13})^2 \right. \\
& \left. - 2(1-\lambda)^2 (\hat{p}_{1,2,2,3} - B_{23})^2 - (\hat{p}_{1,2,1,3} - B_{13})^2 \right] \\
& \left(\text{as } (a-b)^2 \leq 2(a^2 + b^2) \right). \tag{B46}
\end{aligned}$$

From Assumption 2,

$$\begin{aligned}
\Psi_{1,2,1,3}^{(pq)} &= \sum_{(i,j) \in T_{1,2,1,3}^{(pq)}} \psi_i^2 \psi_j^2 \geq \psi_0^4 |T_{1,2,1,3}^{(pq)}| \geq \tilde{c} \psi_0^4 m^2, \\
\text{and } \Psi_{1,2,1,3}^{(pq)} &\leq |T_{1,2,1,3}^{(pq)}| \leq |S_p \times S_q| = m^2.
\end{aligned}$$

Thus, $\Psi_{1,2,1,3}^{(pq)} \asymp m^2$. Similarly, $\Psi_{1,2,2,3}^{(pq)} \asymp m^2$. From Lemma B4,

$$\frac{(1-\lambda)^2}{2} (B_{13} - B_{23})^2 = \frac{(\Psi_{1,2,2,3}^{(pq)})^2}{2(\Psi_{1,2,1,3}^{(pq)} + \Psi_{1,2,2,3}^{(pq)})^2} (B_{13} - B_{23})^2 \geq c_1 \rho_n^2. \tag{B47}$$

For $(k, k', l, l') \in \{(1, 2, 1, 3), (1, 2, 2, 3)\}$, we have

$$\begin{aligned}
|\hat{p}_{k,k',l,l'} - B_{ll'}| &= \left| \frac{\sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} A_{ij} \psi_i \psi_j}{\sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \psi_i^2 \psi_j^2} - B_{ll'} \right| \\
&= \frac{\sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} |A_{ij} - B_{ll'} \psi_i \psi_j| \psi_i \psi_j}{\sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \psi_i^2 \psi_j^2} \\
&\leq \frac{1}{\psi_0^4 |T_{k,k',l,l'}^{(pq)}|} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} |A_{ij} - B_{ll'} \psi_i \psi_j| \\
&= \frac{1}{\psi_0^4 |T_{k,k',l,l'}^{(pq)}|} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} |A_{ij} - E(A_{ij})|
\end{aligned}$$

$$= O_p \left(\sqrt{\frac{\rho_n}{|T_{k,k',l,l'}^{(pq)}|}} \right) \quad (\text{from Lemma B3}). \quad (\text{B48})$$

Plugging in the inequalities in (B47) and (B48) in (B46), we get

$$I \geq \tilde{c}\psi_0^4 m^2 \rho_n^2 - O_p(\rho_n).$$

Similarly,

$$II \geq \tilde{c}\psi_0^4 m^2 \rho_n^2 - O_p(\rho_n).$$

$$\begin{aligned} III &= \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,1,2)\}} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \left[\left(\frac{A_{ij}}{\psi_i \psi_j} - \hat{p}_{k,k',l,l'} \right)^2 \psi_i^2 \psi_j^2 - \left(\frac{A_{ij}}{\psi_i \psi_j} - B_{ll'} \right)^2 \psi_i^2 \psi_j^2 \right] \\ &= \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,1,2)\}} \sum_{(i,j) \in T_{k,k',l,l'}^{(pq)}} \left[A_{ij}^2 - 2\hat{p}_{k,k',l,l'} A_{ij} \psi_i \psi_j + \hat{p}_{k,k',l,l'}^2 \psi_i^2 \psi_j^2 \right. \\ &\quad \left. - A_{ij}^2 + 2B_{ll'} A_{ij} \psi_i \psi_j - B_{ll'}^2 \psi_i^2 \psi_j^2 \right] \\ &= \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,1,2)\}} \Psi_{k,k',l,l'}^{(pq)} \left[-2\hat{p}_{k,k',l,l'}^2 + \hat{p}_{k,k',l,l'}^2 + 2B_{ll'} \hat{p}_{k,k',l,l'} - B_{ll'}^2 \right] \\ &= - \sum_{(k,k',l,l') \notin \{(1,2,1,3), (1,2,1,2)\}} \Psi_{k,k',l,l'}^{(pq)} (\hat{p}_{k,k',l,l'} - B_{ll'})^2 \\ &= - \sum_{(l,l') \notin \{(1,2), (1,3)\}} \sum_{(k,k') \neq (1,2)} \Psi_{k,k',l,l'}^{(pq)} (\hat{p}_{k,k',l,l'} - B_{ll'})^2, \\ &= -O_p(\rho_n), \end{aligned} \quad (\text{B49})$$

where the last inequality follows from applying Lemma B1 on the inner sum as it contains averages of $\Omega(n^2)$ independent Bernoulli random variables.

Note that $E(A_{ij}) = B_{ll'} \psi_i \psi_j$ for any $(i, j) \in T_{k,k',l,l'}$. Also note that the quantity E in (B45) deals with the case where the node pairs are from $T_{1,2,1,3}^{(pq)} \cup T_{1,2,2,3}^{(pq)}$. Define the events $\Gamma_{k,k',l,l'}^{(pq)} = \{(i, j) \in T_{k,k',l,l'}^{(pq)}\}$. We have that the events $\Gamma_{1,2,1,3}^{(pq)}$ and $\Gamma_{1,2,2,3}^{(pq)}$ are disjoint. Consider the following conditional expectation

$$E_{ij} := E \left[\frac{A_{ij}}{\psi_i \psi_j} \mid \Gamma_{1,2,1,3}^{(pq)} \cup \Gamma_{1,2,2,3}^{(pq)} \right]$$

$$\begin{aligned}
&= \frac{1}{\psi_i \psi_j} P \left(A_{ij} = 1 \mid \Gamma_{1,2,1,3}^{(pq)} \cup \Gamma_{1,2,2,3}^{(pq)} \right) \\
&= \frac{1}{\psi_i \psi_j} \left[P \left(\{A_{ij} = 1\} \cap \Gamma_{1,2,1,3}^{(pq)} \mid \Gamma_{1,2,1,3}^{(pq)} \cup \Gamma_{1,2,2,3}^{(pq)} \right) + P \left(\{A_{ij} = 1\} \cap \Gamma_{1,2,2,3}^{(pq)} \mid \Gamma_{1,2,1,3}^{(pq)} \cup \Gamma_{1,2,2,3}^{(pq)} \right) \right] \\
&= \frac{1}{\psi_i \psi_j} \left[P \left(\{A_{ij} = 1\} \mid \Gamma_{1,2,1,3}^{(pq)} \right) P \left(\Gamma_{1,2,1,3}^{(pq)} \mid \Gamma_{1,2,1,3}^{(pq)} \cup \Gamma_{1,2,2,3}^{(pq)} \right) \right. \\
&\quad \left. + P \left(\{A_{ij} = 1\} \mid \Gamma_{1,2,2,3}^{(pq)} \right) P \left(\Gamma_{1,2,2,3}^{(pq)} \mid \Gamma_{1,2,1,3}^{(pq)} \cup \Gamma_{1,2,2,3}^{(pq)} \right) \right] \\
&= B_{13} P \left(\Gamma_{1,2,2,3}^{(pq)} \mid \Gamma_{1,2,1,3}^{(pq)} \cup \Gamma_{1,2,1,3}^{(pq)} \right) + B_{23} P \left(\Gamma_{1,2,2,3}^{(pq)} \mid \Gamma_{1,2,1,3}^{(pq)} \cup \Gamma_{1,2,2,3}^{(pq)} \right) \\
&\approx \lambda B_{13} + (1 - \lambda) B_{23} = \mu \text{ (say)}. \tag{B50}
\end{aligned}$$

We also show that

$$E \left[\hat{p} \mid \Gamma_{1,2,1,3}^{(pq)} \cup \Gamma_{1,2,2,3}^{(pq)} \right] = \frac{\sum_{(i,j) \in T_{1,2,1,3}^{(pq)} \cup T_{1,2,2,3}^{(pq)}} E \left[\frac{A_{ij}}{\psi_i \psi_j} \mid \Gamma_{1,2,1,3}^{(pq)} \cup \Gamma_{1,2,2,3}^{(pq)} \right] \psi_i^2 \psi_j^2}{\sum_{(i,j) \in T_{1,2,1,3}^{(pq)} \cup T_{1,2,2,3}^{(pq)}} \psi_i^2 \psi_j^2} = \mu. \tag{B51}$$

Then conditional under the event $\Gamma_{1,2,1,3}^{(pq)} \cup \Gamma_{1,2,2,3}^{(pq)}$

$$\begin{aligned}
E &= \sum_{(i,j) \in T_{1,2,1,3}^{(pq)} \cup T_{1,2,2,3}^{(pq)}} \left(\frac{A_{ij}}{\psi_i \psi_j} - \hat{p} \right) \hat{p}'_{ij}(\tilde{K}) \psi_i^2 \psi_j^2 \\
&\leq \sum_{(i,j) \in T_{1,2,1,3}^{(pq)} \cup T_{1,2,2,3}^{(pq)}} \left| \frac{A_{ij}}{\psi_i \psi_j} - \mu \right| + \sum_{(i,j) \in T_{1,2,1,3}^{(pq)} \cup T_{1,2,2,3}^{(pq)}} |\hat{p} - \mu| \\
&= \left| T_{1,2,1,3}^{(pq)} \cup T_{1,2,2,3}^{(pq)} \right| O_p \left(\sqrt{\frac{\mu}{\left| T_{1,2,1,3}^{(pq)} \cup T_{1,2,2,3}^{(pq)} \right|}} \right) \text{ (from Lemma B1)} \\
&= O_p(m\sqrt{\rho_n}). \tag{B52}
\end{aligned}$$

Using a similar argument

$$F = O_p(m\sqrt{\rho_n}). \tag{B53}$$

Combining all the cases, we have

$$\begin{aligned}
L^{(pq)}(A, \hat{P}) - L^{(pq)}(A) &\geq I + II + III - E - F \geq \tilde{c} \psi_0^4 m^2 \rho_n^2 - O_p(\rho_n) - O_p(m\sqrt{\rho_n}) \\
&= \Omega_p(m^2 \rho_n^2), \tag{B54}
\end{aligned}$$

as the assumption $\rho_n = \omega(n^{-1/3})$ implies that the first term dominates.

Then the difference between the computed loss and the oracle loss over the entire test set satisfies

$$L(A, \hat{P}) - L(A) = \sum_{1 \leq p < q \leq s} \left[L^{(pq)}(A, \hat{P}) - L^{(pq)}(A) \right] = \Omega_p(s(s-1)m^2\rho_n^2). \quad (\text{B55})$$

Case 2.2: DCBM ($\tilde{K} = K$) For any $q \in [s]$, the community normalized versions of the connectivity matrix and the degree heterogeneity parameters for the q -th subgraph are defined as

$$\psi'_{q,i} = \frac{\psi_i}{\sqrt{\sum_{j \in S_{0q}: g_j = g_i} \psi_j^2}} \quad \text{and} \quad B'_{q,kk'} = B_{kk'} \sqrt{\sum_{i \in S_{0q}: g_i = k} \psi_i^2 \sum_{j \in S_{0q}: g_j = k'} \psi_j^2}. \quad (\text{B56})$$

From Assumption 2, for any $q \in [s]$, we have

$$\begin{aligned} \psi'_{q,i} &= \frac{\psi_i}{\sqrt{\sum_{j \in S_{0q}: g_j = g_i} \psi_j^2}} \leq \frac{\psi_i}{\sqrt{(o+m)\psi_0}} \\ \text{and } \psi'_{q,i} &= \frac{\psi_i}{\sqrt{\sum_{j \in S_{0q}: g_j = g_i} \psi_j^2}} \geq \frac{\psi_i}{\sqrt{o+m}}. \end{aligned} \quad (\text{B57})$$

Thus, $\psi'_{p,i} \asymp (o+m)^{-1/2}\psi_i$ and $\psi'_{q,j} \asymp (o+m)^{-1/2}\psi_j$.

Recall that $\psi'_{q,i} = \|U_{q,i}\|$ and $\hat{\psi}'_i = \|\hat{U}_{q,i}\|$ for $i \in S_{0q}$, $q \in [s]$. Define $\hat{\psi}''_q$ and ψ'_q as $(o+m) \times 1$ vectors, whose i th elements are $\hat{\psi}'_i$ and $\psi'_{q,i}$, respectively for $i \in S_{0q}$, $q \in [s]$. Then by triangle inequality and Cauchy-Schwarz inequality

$$\begin{aligned} \|\hat{\psi}''_q - \psi'_q\|_1 &= \sum_{i \in S_{0q}} \left| \|\hat{U}_{q,i}\| - \|U_{q,i}\| \right| \leq \sum_{i \in S_{0q}} \|\hat{U}_{q,i} - U_{q,i}\| \\ &\leq \sqrt{o+m} \|\hat{U}_q - U_q\|_F \\ &\leq C\sqrt{o+m}/\sqrt{n\rho_n} \quad (\text{with high probability from Lemma B5}) \\ &\leq C\rho_n^{-1/2} \quad \text{for all } q \in [s]. \end{aligned} \quad (\text{B58})$$

We also have $\min_{i \in S_{0q}} \psi'_{q,i} \geq \psi_0(o+m)^{-1/2}$, $q \in [s]$ from Assumption 2. For $\alpha \in (0, 1)$ and $q \in [s]$, define the following subset of nodes as

$$\mathcal{S}_{\alpha q} := \left\{ i \in S_{0q} : |\hat{\psi}'_i - \psi'_{q,i}| \leq (o+m)^{-1/2}(n^\alpha \rho_n)^{-1/2} \right\}.$$

Then for all $i \in \mathcal{S}_{\alpha q}$ and $q \in [s]$ and $\rho_n = \omega(n^{-\alpha})$ for some $\alpha \in (0, 1)$, from (B58), we have

$$\begin{aligned} |\hat{\psi}'_i - \psi'_{q,i}| &= o((o+m)^{-1/2}) \quad \text{for all } i \in \mathcal{S}_{\alpha q}, \\ \text{and } \frac{|\mathcal{S}_{\alpha q}^c|}{o+m} &\leq \frac{\|\hat{\psi}'_q - \psi'_q\|_1}{(o+m)^{1/2}n^{-\alpha/2}\rho_n^{1/2}} \leq \frac{C\rho_n^{-1/2}}{(o+m)^{1/2}n^{-\alpha/2}\rho_n^{-1/2}} \leq C'n^{-(1-\alpha)/2}. \end{aligned} \quad (\text{B59})$$

Setting $\alpha = 1/3$ and using the assumption $\rho_n = \omega(n^{-1/3})$ (Assumption 2), on all but a vanishing proportion of nodes $i \in \mathcal{S}_{0q}$, $q \in [s]$,

$$\hat{\psi}'_i = (1 + o(1))\psi'_{q,i} \asymp (1 + o(1))(o+m)^{-1/2}\psi_i. \quad (\text{B60})$$

Consider the following oracle estimator of the normalized community probability matrix defined as

$$\begin{aligned} B_{q,kk'}^{t*} &:= \frac{\sum_{(i,j) \in (S_{0q} \times S_{0q})} A_{ij} \mathbf{I}(g_i = k, g_j = k')}{\sum_{(i,j) \in (S_{0q} \times S_{0q})} \psi'_{q,i} \psi'_{q,j} \mathbf{I}(g_i = k, g_j = k')} \\ &= \frac{O_p((o+m)B_{kk'})}{\Omega_p((o+m)^{-1}(o+m))} = O_p((o+m)B_{kk'}), \end{aligned} \quad (\text{B61})$$

where the numerator follows from Lemma B3, and the denominator from (B57) and Lemma B2. Now, consider the following ratio for any $k, k' \in [K]$ and $q \in [s]$

$$\frac{\hat{B}'_{q,kk'}}{B_{q,kk'}^{t*}} = \frac{\sum_{(i,j) \in \hat{\mathcal{U}}_{kk'}^{(q)}} A_{ij}}{\sum_{(i,j) \in \hat{\mathcal{U}}_{kk'}^{(q)}} \hat{\psi}'_i \hat{\psi}'_j} \times \frac{\sum_{(i,j) \in \mathcal{U}_{kk'}^{(q)}} \psi'_{q,i} \psi'_{q,j}}{\sum_{(i,j) \in \mathcal{U}_{kk'}^{(q)}} A_{ij}} = \frac{\hat{\Sigma}}{\hat{\Sigma}_{\Psi}} \times \frac{\Sigma_{\Psi}}{\Sigma}, \quad (\text{say}). \quad (\text{B62})$$

Using Theorem B2 and Figure B4, we have $|\hat{\mathcal{U}}_{kk'}^{(q)} \setminus \mathcal{U}_{kk'}^{(q)}| = O_p((o+m)n^{1/2}\rho_n^{-1/2})$. We also have $|\mathcal{U}_{kk'}^{(q)}| \asymp |\hat{\mathcal{U}}_{kk'}^{(q)}| \asymp (o+m)^2$. Using these bounds and Lemma B3, we get

$$\begin{aligned} \frac{\hat{\Sigma}}{\Sigma} &= 1 + \frac{\hat{\Sigma} - \Sigma}{\Sigma} \leq 1 + \frac{|\hat{\mathcal{U}}_{kk'}^{(q)} \setminus \mathcal{U}_{kk'}^{(q)}|}{|\mathcal{U}_{kk'}^{(q)}| B_{kk'}} \\ &\leq 1 + \frac{O_p((o+m)n^{1/2}\rho_n^{-1/2})}{c'(o+m)^2 B_{kk'}} \\ &= 1 + O\left(\frac{n^{1/2}\rho_n^{-1/2}}{(o+m)\rho_n}\right) = 1 + O_p(n^{-1/2}\rho_n^{-3/2}). \end{aligned} \quad (\text{B63})$$

Figure B4: Intersecting sets of $\mathcal{U}_{kk'}^{(q)}$ and $\hat{\mathcal{U}}_{kk'}^{(q)}$ for DCBM

Then under the event of $\mathcal{S}_{\frac{1}{3}q}$,

$$\frac{\Sigma_{\Psi}}{\hat{\Sigma}_{\Psi}} = O\left(\frac{|\mathcal{U}_{kk'}^{(q)}|(o+m)^{-1}}{|\hat{\mathcal{U}}_{kk'}^{(q)}|(o+m)^{-1}}\right) = O(1). \quad (\text{B64})$$

Thus, we have

$$\hat{B}'_{q,kk'} = \left(1 + O_p\left(n^{-\frac{1}{2}}\rho_n^{-\frac{3}{2}}\right)\right) B'_{q,kk'}^*. \quad (\text{B65})$$

Using (B61) and (B65), we get

$$\begin{aligned} \hat{B}'_{q,kk'} &= \left(1 + O_p\left(n^{-\frac{1}{2}}\rho_n^{-\frac{3}{2}}\right)\right) (o+m)B_{kk'} \\ \text{and } \hat{B}'_{kk'} &= \frac{1}{s} \sum_{q \in [s]} \hat{B}'_{q,kk'} = \left(1 + O_p\left(n^{-\frac{1}{2}}\rho_n^{-\frac{3}{2}}\right)\right) (o+m)B_{kk'} \\ \implies \left|\hat{B}'_{kk'} - (o+m)B_{kk'}\right| &= O_p\left(n^{-\frac{1}{2}}\rho_n^{-\frac{3}{2}}(o+m)B_{kk'}\right) = O_p\left((o+m)n^{-\frac{1}{2}}\rho_n^{-\frac{3}{2}}\rho_n\right) \end{aligned}$$

$$= O_p \left((o+m)n^{-\frac{1}{2}}\rho_n^{-\frac{1}{2}} \right). \quad (\text{B66})$$

Combining (B60) and (B66), for $1 \leq p < q \leq s$ and $i \in S_p \cap S_{\frac{1}{3}p}, j \in S_q \cap S_{\frac{1}{3}q}$ such that $(i, j) \in T_{l, l', l, l'}$, we have

$$\hat{P}'_{ij}{}^{(K)} = \hat{B}'_{ll'} \hat{\psi}'_i \hat{\psi}'_j = \left(1 + O_p \left(n^{-\frac{1}{2}} \rho_n^{-\frac{3}{2}} \right) \right) (1 + o(1)) B_{ll'} \psi_i \psi_j = \left(1 + O_p \left(n^{-\frac{1}{2}} \rho_n^{-\frac{3}{2}} \right) \right) P_{ij}. \quad (\text{B67})$$

Let $\mathbb{S}'_{pq} := \left(S_p \cap \mathcal{S}_{\frac{1}{3}p} \right) \times \left(S_q \cap \mathcal{S}_{\frac{1}{3}q} \right)$. Then (B67) holds uniformly over all $(i, j) \in \mathbb{S}'_{pq} \cap T_{l, l', l, l'}$, using union bound on (B66) over K^2 pairs of communities $(l, l') \in [K]^2$ and the fact that (B60) always holds for the node pairs $(i, j) \in \mathbb{S}'_{pq}$. Thus,

$$\max_{(i, j) \in \mathbb{S}'_{pq} \cap T_{l, l', l, l'}} \left| \hat{P}'_{ij}{}^{(K)} - P_{ij} \right| = O_p \left(n^{-\frac{1}{2}} \rho_n^{-\frac{3}{2}} \right) P_{ij} = O_p \left(n^{-\frac{1}{2}} \rho_n^{-\frac{1}{2}} \right) \text{ for any } 1 \leq p < q \leq s. \quad (\text{B68})$$

From (B59), for any $q \in [s]$,

$$\left| \mathcal{S}_{\frac{1}{3}q} \right| = |S_{0q}| - \left| \mathcal{S}_{\frac{1}{3}q}^c \right| \geq (o+m) - C'(o+m)n^{-\frac{1}{3}} \geq (o+m)(1 - C'n^{-\frac{1}{3}}) \geq C_1 n(1 - o(1)). \quad (\text{B69})$$

From Lemma B2, $|S_q \cap G_l| \geq m\gamma/(1+\gamma)$. Then using a similar argument as in (B11), for any $q \in [s]$, $\left| S_q \cap \mathcal{S}_{\frac{1}{3}q} \cap G_l \right| = \Omega_p(m)$ as $n \rightarrow \infty$. Thus, $c_1 m^2 \leq |\mathbb{S}'_{pq} \cap T_{ll'}| \leq |S_p \times S_q| = m^2$ for some constant $c_1 > 0$ and sufficiently large n for any $1 \leq p < q \leq s$. Then using Lemma B3,

$$\sum_{(i, j) \in \mathbb{S}'_{pq} \cap T_{l, l', l, l'}} A_{ij} \leq \sum_{(i, j) \in \mathbb{S}'_{pq} \cap T_{ll'}} A_{ij} = O_p(m^2 \rho_n). \quad (\text{B70})$$

For any $(k, k'), (l, l') \in [K]^2$ such that $(k, k') \neq (l, l')$ and $1 \leq p < q \leq s$, using a similar argument as in Figure B4 but for the corresponding subsets of the test set and Theorem B2, we get

$$|T_{k, k', l, l'}^{(pq)}| = |\hat{T}_{k, k'}^{(pq)} \cap T_{l, l'}^{(pq)}| \leq |\hat{T}_{l, l'}^{(pq)} \Delta T_{l, l'}^{(pq)}| = O_p \left(mn^{\frac{1}{2}} \rho_n^{-\frac{1}{2}} \right). \quad (\text{B71})$$

Additionally, for any $(k, k') \neq (l, l')$, consider

$$\left| \hat{B}'_{kk'} - (o+m)B_{ll'} \right| \leq \left| \hat{B}'_{kk'} - (o+m)B_{kk'} \right| + (o+m)B_{kk'} + (o+m)B_{ll'}$$

$$= O_p \left((o+m)n^{-\frac{1}{2}}\rho_n^{-\frac{1}{2}} \right) + O((o+m)\rho_n) = O_p((o+m)\rho_n), \quad (\text{B72})$$

as $\rho_n = \omega(n^{-1/3})$ and the first O_p term follows from (B66). For any $(i, j) \in \mathcal{S}'_{pq} \cap T_{k,k',l,l'}^{(pq)}$ such that $(k, k') \neq (l, l')$ and $1 \leq p < q \leq s$,

$$\begin{aligned} \left| \hat{P}'_{ij}^{(K)} - P_{ij} \right| &= \left| \hat{B}'_{kk'} \hat{\psi}'_i \hat{\psi}'_j - B_{ll'} \psi_i \psi_j \right| \\ &\leq \left| \hat{B}'_{kk'} - (o+m)B_{ll'} \right| \hat{\psi}'_i \hat{\psi}'_j + B_{ll'} \left| (o+m)\hat{\psi}'_i \hat{\psi}'_j - \psi_i \psi_j \right| \\ &= O_p((o+m)\rho_n) (1+o(1))(o+m)^{-1} + O(\rho_n)(o+m)(1+o(1))(o+m)^{-1} \\ &= O_p(\rho_n). \end{aligned} \quad (\text{B73})$$

The above bound is uniform over all $(i, j) \in \mathcal{S}'_{pq} \cap T_{k,k',l,l'}^{(pq)}$ for any $1 \leq p < q \leq s$ using uniform bound over all possible $(k, k') \neq (l, l')$ and using the fact that (B60) holds surely for $(i, j) \in \mathcal{S}'_{pq}$. Thus,

$$\max_{(i,j) \in \mathcal{S}'_{pq} \cap T_{k,k',l,l'}^{(pq)}} \left| \hat{P}'_{ij}^{(K)} - P_{ij} \right| = O_p(\rho_n). \quad (\text{B74})$$

Also define $\mathbb{S}''_{pq} := \left(S_p \setminus \mathcal{S}_{\frac{1}{3}p} \right) \times \left(S_q \setminus \mathcal{S}_{\frac{1}{3}q} \right)$. Then from (B59),

$$\begin{aligned} \left| S_p \setminus \mathcal{S}_{\frac{1}{3}p} \right| &\leq \left| \mathcal{S}_{\frac{1}{3}p}^c \right| \leq C'(o+m)n^{-\frac{1}{3}} = O(n^{\frac{2}{3}}) \text{ for any } p \in [s], \\ \text{and } \left| \mathbb{S}''_{pq} \right| &= O\left(n^{\frac{4}{3}}\right). \end{aligned} \quad (\text{B75})$$

Note that $S_p \times S_q = \mathbb{S}'_{pq} \cup \mathbb{S}''_{pq}$ for any $p, q \in [s]$. Now, consider the absolute difference between the computed loss and the oracle loss as

$$\begin{aligned} &\left| L\left(A_{\mathbb{S}^c}, \hat{P}'_{\mathbb{S}^c}^{(K)}\right) - L\left(A_{\mathbb{S}^c}\right) \right| \\ &= \left| \sum_{(i,j) \in \mathbb{S}^c} \left((A_{ij} - \hat{P}'_{ij}^{(K)})^2 - (A_{ij} - P_{ij})^2 \right) \right| \\ &\leq \sum_{(i,j) \in \mathbb{S}^c} \left| A_{ij}^2 - 2A_{ij}\hat{P}'_{ij}^{(K)} + \hat{P}'_{ij}^{(K)2} - A_{ij}^2 + 2A_{ij}P_{ij} - P_{ij}^2 \right| \\ &= \sum_{(i,j) \in \mathbb{S}^c} \left| -2A_{ij}(\hat{P}'_{ij}^{(K)} - P_{ij}) + (\hat{P}'_{ij}^{(K)} + P_{ij})(\hat{P}'_{ij}^{(K)} - P_{ij}) \right| \\ &\leq \sum_{1 \leq p < q \leq s} \sum_{(i,j) \in S_p \times S_q} \left| \hat{P}'_{ij}^{(K)} - P_{ij} \right| \left(2A_{ij} + 2P_{ij} + \left| \hat{P}'_{ij}^{(K)} - P_{ij} \right| \right) \end{aligned}$$

$$\begin{aligned}
&\leq \sum_{1 \leq p < q \leq s} \sum_{(i,j) \in \mathbb{S}'_{pq}} \left| \hat{P}_{ij}^{(K)} - P_{ij} \right| \left(2A_{ij} + 2P_{ij} + \left| \hat{P}_{ij}^{(K)} - P_{ij} \right| \right) \\
&\quad + \sum_{1 \leq p < q \leq s} \sum_{(i,j) \in \mathbb{S}''_{pq}} \max_{(i,j) \in \mathbb{S}''_{pq}} \left| \hat{P}_{ij}^{(K)} - P_{ij} \right| \left(2A_{ij} + 2P_{ij} + \max_{(i,j) \in \mathbb{S}''_{pq}} \left| \hat{P}_{ij}^{(K)} - P_{ij} \right| \right) \\
&= \sum_{1 \leq p < q \leq s} \sum_{(l,l') \in [K]^2} \sum_{(i,j) \in \mathbb{S}'_{pq} \cap T_{ll'}^{(pq)}} \max_{(i,j) \in \mathbb{S}'_{pq} \cap T_{ll'}^{(pq)}} \left| \hat{P}_{ij}^{(K)} - P_{ij} \right| \left(2A_{ij} + 2P_{ij} + \max_{(i,j) \in \mathbb{S}'_{pq} \cap T_{ll'}^{(pq)}} \left| \hat{P}_{ij}^{(K)} - P_{ij} \right| \right) \\
&\quad + \sum_{1 \leq p < q \leq s} \sum_{\substack{(k,k') \neq (l,l') \\ \in [K]^2}} \sum_{(i,j) \in \mathbb{S}'_{pq} \cap T_{k,k',l,l'}^{(pq)}} \max_{(i,j) \in \mathbb{S}'_{pq} \cap T_{k,k',l,l'}^{(pq)}} \left| \hat{P}_{ij}^{(K)} - P_{ij} \right| \left(2A_{ij} + 2P_{ij} \right. \\
&\quad \quad \quad \left. + \max_{(i,j) \in \mathbb{S}'_{pq} \cap T_{k,k',l,l'}^{(pq)}} \left| \hat{P}_{ij}^{(K)} - P_{ij} \right| \right) \\
&\quad + \sum_{1 \leq p < q \leq s} \sum_{(i,j) \in \mathbb{S}''_{pq}} \max_{(i,j) \in \mathbb{S}''_{pq}} \left| \hat{P}_{ij}^{(K)} - P_{ij} \right| \left(2A_{ij} + 2P_{ij} + \max_{(i,j) \in \mathbb{S}''_{pq}} \left| \hat{P}_{ij}^{(K)} - P_{ij} \right| \right) \\
&= V + VI + VII \text{ (say)}. \tag{B76}
\end{aligned}$$

Combining (B68) and (B70), we get

$$V = \frac{s(s-1)}{2} O_p \left(n^{-\frac{1}{2}} \rho_n^{-\frac{1}{2}} m^2 \rho_n \right) = O_p \left(s(s-1) m^2 n^{-\frac{1}{2}} \rho_n^{\frac{1}{2}} \right). \tag{B77}$$

Combining (B71), (B74) and the fact that $m \asymp n$, we get

$$\begin{aligned}
VI &\leq \sum_{1 \leq p < q \leq s} \max_{(k,k') \neq (l,l')} \left| T_{k,k',l,l'}^{(pq)} \right| O_p(\rho_n) = O_p \left(s(s-1) m n^{\frac{1}{2}} \rho_n^{-\frac{1}{2}} \rho_n \right) \\
&= O_p \left(s(s-1) m^2 n^{-\frac{1}{2}} \rho_n^{\frac{1}{2}} \right). \tag{B78}
\end{aligned}$$

From (B75) and $\rho_n = \omega(n^{-1/3})$, we get

$$VII \leq \frac{s(s-1)}{2} \max_{1 \leq p < q \leq s} |\mathbb{S}''_{pq}| = O \left(s(s-1) n^{\frac{4}{3}} \right) = o \left(s(s-1) m^2 n^{-\frac{1}{2}} \rho_n^{\frac{1}{2}} \right). \tag{B79}$$

Combining (B77), (B78) and (B79), we get

$$\left| L \left(A_{\mathbb{S}^c}, \hat{P}_{\mathbb{S}^c}^{(K)} \right) - L \left(A_{\mathbb{S}^c} \right) \right| = O_p \left(s(s-1) m^2 n^{-\frac{1}{2}} \rho_n^{\frac{1}{2}} \right). \tag{B80}$$

B.3 Proof of Theorem 6

We show that the computed loss is closely concentrated around the oracle loss for $\tilde{d} = d$ in Case 1 of this proof and much larger than the oracle loss for $\tilde{d} = d - 1$ in Case 2 of this

proof. Induction like argument follows for the cases $\tilde{d} \leq d - 2$. First, we state some results used in the proof. First, we state some of the results that will be used in the main proof. The following theorem is a slightly modified version of [Athreya et al. \(2017, Theorem 26\)](#).

Theorem B3. *Let $A \sim RDPG(X)$ with $n \geq 1$ nodes be a sequence of random dot product graphs where X is assumed to be of rank d for all n sufficiently large. Denote by \hat{X} the adjacency spectral embedding of A using [Algorithm A3](#). Then under the conditions [1](#) and [2](#) of [Assumption 3](#), with probability tending to 1 as $n \rightarrow \infty$, there exists a fixed constant $C > 0$ and an orthogonal transformation $W \in \mathcal{O}_d$ such that*

$$\max_{i \in [n]} \left\| \hat{X}_i - W X_i \right\| \leq \frac{C \sqrt{d} \log^2 n}{\sqrt{\delta(P)}}, \quad (\text{B81})$$

where $\delta(P) := \max_{i \in [n]} \sum_{j \in [n]} P_{ij}$.

Proof. Let λ_d be the d^{th} largest eigenvalue of P . Then [Athreya et al. \(2017, Theorem 26\)](#) requires the the existence of some constants $a_0 > 0$ and $c_0 > 0$ such that

$$\delta(P) \geq \log^{4+a_0}(n) \quad \text{and} \quad \lambda_d \geq c_0 \delta(P). \quad (\text{B82})$$

From [Condition 1](#) of [Assumption 3](#), there exist a constant c_1 such that

$$\delta(P) = \rho_n \max_{i \in [n]} \sum_{j \in [n]} P_{ij}^0 \geq c_1 n \rho_n \geq c_1 n \rho_n^2 \geq c_1 \log^{4+a_0}(n). \quad (\text{B83})$$

Also, note that from [Condition 3](#) of [Assumption 3](#), we have

$$\delta(P) \leq c_2 n \rho_n \quad \text{and} \quad \lambda_d = \rho_n \lambda_d^0 \geq \phi^{-1} n \rho_n \geq \phi^{-1} c_2^{-1} \delta(P). \quad (\text{B84})$$

□

Theorem B4. *Let \mathcal{S} be a random subset of nodes of size η of $A \sim RDPG(X)$ with $n \geq 1$ nodes and sparsity parameter ρ_n . If $\hat{X}^{\mathcal{S}}$ is the adjacency spectral embedding of $A_{\mathcal{S}}$, then under [Assumption 3](#) and for η such that η/n is bounded away from 0, there exist constants C, C' and an orthogonal matrix W such that the following bound holds with probability tending to 1 as $\eta \rightarrow \infty$*

$$\max_{i \in \mathcal{S}} \left\| \hat{X}_i^{\mathcal{S}} - W X_i \right\| \leq \frac{C \sqrt{d} \log^2 \eta}{\sqrt{\eta \rho_n}}. \quad (\text{B85})$$

Proof. The theorem follows from the fact that the subnetwork with adjacency matrix A_S is still an RDPG and the estimated latent positions from adjacency spectral embedding on A_S satisfy the bound in Theorem B3, provided the subnetwork satisfies the conditions in (B82). Consider

$$\delta(P_S) = \max_{i \in \mathcal{S}} \sum_{j \in \mathcal{S}} P_{ij} \geq c_1 \eta \rho_n \geq c_1 \eta \rho_n^2 \geq c_1 c_0 \frac{\eta}{n} \log^{4+a_0}(n) \geq c' \log^{4+a_0}(\eta), \quad (\text{B86})$$

as η/n is bounded away from 0 and for sufficiently large η . Let $\lambda_d(M)$ of a matrix M denote the d -th largest eigenvalue of M . From sublinear time algorithm result (Bhattacharjee et al. 2024, Theorem 1), bounding eigenvalues of random principal submatrix, for any $\epsilon, \delta > 0 > 0$ and $\eta \geq \frac{c \log(1/\epsilon\delta) \log^3 n}{\epsilon^3 \delta}$, the following holds with probability $\geq 1 - \delta$

$$\lambda_d(P_S) \geq \frac{\eta}{n} \lambda_d(P) - \epsilon n \|P\|_\infty \quad (\text{B87})$$

$$\geq \frac{\eta}{n} \lambda_d(P) - c_2 \epsilon \eta \rho_n \quad (\text{B88})$$

$$\geq \phi^{-1} \eta \rho_n - c_2 \epsilon \eta \rho_n. \quad (\text{B89})$$

We also have

$$\delta(P_S) = \max_{i \in \mathcal{S}} \sum_{j \in \mathcal{S}} P_{ij} \leq c_2 \eta \rho_n. \quad (\text{B90})$$

Take $\epsilon = \frac{\phi^{-1}}{2c_2}$. Then combining (B89) and (B90)

$$\lambda_d(P_S) \geq \frac{1}{2} \phi^{-1} c_2^{-1} \delta(P_S). \quad (\text{B91})$$

Taking $\delta = n^{-1/2}$, the above holds with probability $\geq 1 - \frac{1}{\sqrt{n}}$ for $\eta \geq \frac{c \sqrt{n} \log(\sqrt{n}/\epsilon) \log^3 n}{\epsilon^3} \approx c'' \sqrt{n} \log^4 n$, which is satisfied for all sufficiently large n from theorem assumption.

Thus, the assumptions of Athreya et al. (2017, Theorem 26) are satisfied for adjacency spectral embedding on A_S and the bound in this theorem follows from Theorem B3. \square

Theorem B5. *Let $A_{S_{01}}, \dots, A_{S_{0s}}$ be the subadjacency matrices used in NETCROP with s subgraphs and overlap size o . Assume that \hat{X}_q is the estimated latent positions using adjacency spectral embedding on $A_{S_{0q}}$ for $q \in [s]$. Then under Assumption 3, there exist*

orthogonal matrices $W_1, \dots, W_s \in \mathcal{O}_d$ and a constant $C > 0$ such that the following holds with probability going to 1

$$\max_{q \in [s]} \max_{i \in S_{0q}} \left\| W_q \hat{X}_{q,i} - X_i \right\| \leq \frac{C\sqrt{d} \log^2(o+m)}{\sqrt{(o+m)\rho_n}}. \quad (\text{B92})$$

Proof. From Theorem B4 for the q th subnetwork of NETCROP, there exist $H_q \in \mathcal{O}_d$ and constant $C_q > 0$ such that

$$\max_{i \in S_{0q}} \left\| \hat{X}_{q,i} - H_q X_i \right\| \leq \frac{C_q \sqrt{d} \log^2(o+m)}{\sqrt{(o+m)\rho_n}}, \quad q \in [s]. \quad (\text{B93})$$

Set $W_1 = H_1^\top, \dots, W_s = H_s^\top$. Then $W_q \in \mathcal{O}_d$ for any $q \in [s]$. This implies

$$\max_{q \in [s]} \max_{i \in S_{0q}} \left\| W_q \hat{X}_{q,i} - X_i \right\| = \max_{q \in [s]} \max_{i \in S_{0q}} \left\| \hat{X}_{q,i} - H_q X_i \right\| \leq \frac{C\sqrt{d} \log^2(o+m)}{\sqrt{(o+m)\rho_n}}, \quad (\text{B94})$$

where $C = \max\{C_1, \dots, C_s\}$. The above bound is uniform as s is fixed. \square

The following lemma states that the d -th signal in the eigen decomposition of P is positive on a large subset of the test set. Define $P^{0(\tilde{d})} := U_{\cdot[\tilde{d}]} \Lambda_{[\tilde{d}]}^0 U_{\cdot[\tilde{d}]}^\top$, the \tilde{d} -truncated version of P for any $\tilde{d} < d$.

Lemma B7. *Let $A \sim \text{RDPG}(X)$ with n nodes and latent space dimension d . Let $P^{0(\tilde{d})}$ be the \tilde{d} rank truncated version of P^0 . Then there exist constants $\phi', \kappa > 0$ such that the following holds with very high probability.*

$$\left| \left\{ (i, j) \in \mathbb{S}^c : \left| P_{ij}^0 - P_{ij}^{0(\tilde{d})} \right| \geq \phi' \right\} \right| \geq \kappa s(s-1)m^2,$$

for any $\tilde{d} < d$, where \mathbb{S}^c is the test set of NETCROP.

Proof. By definition, for any $i, j \in [n]$, we have

$$\begin{aligned} \left| P_{ij}^0 - P_{ij}^{0(\tilde{d})} \right| &= \left| \sum_{k=\tilde{d}+1}^d \lambda_k^0 U_{ik} U_{jk} \right| \\ &\leq \phi n \left| \sum_{k=\tilde{d}+1}^d U_{ik} U_{jk} \right| \end{aligned}$$

$$\begin{aligned}
&\leq \phi n \left(\sum_{k=\tilde{d}+1}^d U_{ik}^2 \sum_{k=\tilde{d}+1}^d U_{jk}^2 \right)^{\frac{1}{2}} \\
&\leq \phi n \|U_i\| \|U_j\| \\
&\leq \phi n \frac{da}{n} = \phi da.
\end{aligned} \tag{B95}$$

From the same assumption, we also have

$$\sum_{i,j \in [n]} \left| P_{ij}^0 - P_{ij}^{0(\tilde{d})} \right|^2 = \left\| P^0 - P^{0(\tilde{d})} \right\|_F^2 = \sum_{k=\tilde{d}+1}^d (\lambda_k^0)^2 \geq \phi^{-2} (d - \tilde{d}) n^2. \tag{B96}$$

Thus, for (B95) and (B96) to simultaneously occur, there must exist constants $\phi', \kappa' > 0$ and a subset of node pairs $\Delta_{\tilde{d}} \subset [n] \times [n]$ such that

$$|\Delta_{\tilde{d}}| := \left| \left\{ (i, j) : i \leq j, \left| P_{ij}^0 - P_{ij}^{0(\tilde{d})} \right| \geq \phi' \right\} \right| \geq \kappa' n^2. \tag{B97}$$

For each node $i \in [n]$, define $T_i := \{j \in [n] : (i, j) \in \Delta_{\tilde{d}}\}$. Then $\Delta_{\tilde{d}} = \bigcup_{i \in [n]} \{i\} \times T_i$. For (B97) to hold, there must exist a subset of nodes $T \subset [n]$ satisfying $|T| \geq \kappa_1 n$ for some $\kappa_1 > 0$ such that $|T_i| \geq \kappa_2 n$ for all $i \in T$.

Using a similar hypergeometric tail bound as in (B11), replacing G_l by T and T_i and for any non-overlap part S_p , $p \in [s]$, we have

$$|T \cap S_p| \geq \frac{\kappa_1 m}{2} \quad \text{and} \quad |T_i \cap S_p| \geq \frac{\kappa_2 m}{2} \quad \text{for all } i \in A, \tag{B98}$$

both with probability going to 1 as $m \rightarrow \infty$. For any $1 \leq p < q \leq s$, consider the size of the following subset of nodes in the test set

$$\begin{aligned}
\left| \bigcup_{i \in T \cap S_p} \{i\} \times (T_i \cap S_q) \right| &= \sum_{i \in T \cap S_p} |T_i \cap S_q| \\
&\geq |T \cap S_p| \frac{\kappa_2 m}{2} \quad \text{with high probability} \\
&\geq \frac{\kappa_1 \kappa_2 m^2}{4} \quad \text{with high probability.}
\end{aligned} \tag{B99}$$

As the test set \mathbb{S}^c is given by the disjoint union $\mathbb{S}^c = \bigcup_{1 \leq p < q \leq s} (S_p \times S_q)$, the subset of the test set in the lemma is given by

$$T_{\mathbb{S}^c} := \bigcup_{1 \leq p < q \leq s} \bigcup_{i \in T \cap S_p} \{i\} \times (T_i \cap S_q). \tag{B100}$$

It satisfies $|T_{\mathbb{S}^c}| \geq \binom{s}{2} \frac{\kappa_1 \kappa_2 m^2}{4}$ with probability going to 1 as $m \rightarrow \infty$ and for every $(i, j) \in T_{\mathbb{S}^c}$, $|P_{ij}^0 - P_{ij}^{0(\tilde{d})}| \geq \phi'$.

□

Proof of Theorem 5

Case 1: ($\tilde{d} = d$) Before deriving the upper bound for the difference between the computed loss and the oracle loss, we bound the norm of the i th latent position, which will be used in multiple places in this proof.

$$\|X_i\| = \left(\sum_{k=1}^d X_{ik}^2 \right)^{\frac{1}{2}} = \sqrt{\rho_n} \left(\sum_{k=1}^d \lambda_k^0 U_{ik}^2 \right)^{\frac{1}{2}} \leq \sqrt{\rho_n \lambda_1^0 \frac{d}{n}} \left(\max_i \frac{n}{d} \|U_i\|^2 \right)^{\frac{1}{2}} \leq \sqrt{\phi a \rho_n d}. \quad (\text{B101})$$

Consider the absolute difference between the computed loss and the oracle loss

$$\left| L(A, \hat{P}^{(d)}) - L(A) \right| \leq \sum_{(i,j) \in \mathbb{S}^c} \max_{(i,j) \in \mathbb{S}^c} \left| \hat{P}_{ij}^{(d)} - P_{ij} \right| \left(2A_{ij} + 2P_{ij} + \max_{(i,j) \in \mathbb{S}^c} \left| \hat{P}_{ij}^{(d)} - P_{ij} \right| \right). \quad (\text{B102})$$

We bound $\left| \hat{P}_{ij}^{(d)} - P_{ij} \right|$ on the test set \mathbb{S}^c . Let $i \in S_p$ and $j \in S_q$ for some $1 \leq p < q \leq s$. Then from Theorem B5, there exist $W_p, W_q \in \mathcal{O}_d$ such that

$$\begin{aligned} \left| \hat{P}_{ij}^{(d)} - P_{ij} \right| &= \left| \left(W_p \hat{X}_{p,i} \right)^\top \left(W_q \hat{X}_{q,j} \right) - X_i^\top X_j \right| \\ &\leq \left| \left(W_p \hat{X}_{p,i} - X_i \right)^\top \left(W_q \hat{X}_{q,j} - X_j \right) \right| \\ &\quad + \left| X_i^\top \left(W_q \hat{X}_{q,j} - X_j \right) \right| + \left| \left(W_p \hat{X}_{p,i} - X_i \right)^\top X_j \right| \\ &\leq \left\| W_p \hat{X}_{p,i} - X_i \right\| \left\| W_q \hat{X}_{q,j} - X_j \right\| \\ &\quad + \|X_i\| \left\| W_q \hat{X}_{q,j} - X_j \right\| + \left\| W_p \hat{X}_{p,i} - X_i \right\| \|X_j\| \\ &= O_p \left(\frac{\sqrt{\rho_n} \log^2(o+m)}{\sqrt{(o+m)\rho_n}} \right) \quad (\text{From Theorem B5 and (B101)}) \\ &= O_p \left(\frac{\log^2(o+m)}{\sqrt{(o+m)}} \right). \quad (\text{B103}) \end{aligned}$$

Since $1 \leq p < q \leq s$ are arbitrary and the bound in Theorem B5 is uniform over all subsets S_{0q} , we have

$$\max_{(i,j) \in \mathbb{S}^c} \left| \hat{P}_{ij}^{(d)} - P_{ij} \right| = O_p \left(\frac{\log^2(o+m)}{\sqrt{o+m}} \right). \quad (\text{B104})$$

Continuing from (B102), we have

$$\left| L(A, \hat{P}^{(d)}) - L(A) \right| = O_p \left(|\mathbb{S}^c| \rho_n \frac{\log^2(o+m)}{\sqrt{o+m}} \right) = O_p \left(s(s-1)m^2 \rho_n \frac{\log^2(o+m)}{\sqrt{o+m}} \right). \quad (\text{B105})$$

Case 2: ($\tilde{d} = d-1$) Recall that $P^{(\tilde{d})}$ is the rank \tilde{d} truncated version of P , defined as

$$P^{(\tilde{d})} = U_{\cdot[\tilde{d}]} \Lambda_{[\tilde{d}]} U_{\cdot[\tilde{d}]}^\top = X_{\cdot[\tilde{d}]} X_{\cdot[\tilde{d}]}^\top,$$

where $P = U \Lambda U^\top$ is the eigen decomposition of P and $\Lambda = \rho_n \Lambda^0$. Then we have

$$\begin{aligned} \left| \hat{P}_{ij}^{(d-1)} - P_{ij} \right| &= \left| \hat{P}_{ij}^{(d-1)} - P_{ij}^{(d-1)} + P_{ij}^{(d-1)} - P_{ij} \right| \\ &\geq \left| P_{ij} - P_{ij}^{(d-1)} \right| - \left| \hat{P}_{ij}^{(d-1)} - P_{ij}^{(d-1)} \right| \\ &= I - II, \quad (\text{say}). \end{aligned} \quad (\text{B106})$$

From Lemma B7, there exists Δ_{d-1}

$$I = \left| P_{ij} - P_{ij}^{(d-1)} \right| = \rho_n \left| P_{ij}^0 - P_{ij}^{0(d-1)} \right| \geq \phi' \rho_n \quad \text{for all } (i, j) \in \Delta_{d-1} \cap \mathbb{S}^c. \quad (\text{B107})$$

Next, we consider

$$\begin{aligned} \left| \hat{P}_{ij}^{(d-1)} - P_{ij}^{(d-1)} \right| &= \left| \left(W_p \hat{X}_{p,i} \right)_{[d-1]}^\top \left(W_q \hat{X}_{q,j} \right)_{[d-1]} - X_{i[d-1]}^\top X_{j[d-1]} \right| \\ &\leq \left\| \left(W_p \hat{X}_{p,i} \right)_{[d-1]} - X_{i[d-1]} \right\| \left\| \left(W_q \hat{X}_{q,j} \right)_{[d-1]} - X_{j[d-1]} \right\| \\ &\quad + \left\| X_{i[d-1]} \right\| \left\| \left(W_q \hat{X}_{q,j} \right)_{[d-1]} - X_{j[d-1]} \right\| + \left\| \left(W_p \hat{X}_{p,i} \right)_{[d-1]} - X_{i[d-1]} \right\| \left\| X_{j[d-1]} \right\| \\ &\leq \left\| W_p \hat{X}_{p,i} - X_i \right\| \left\| W_q \hat{X}_{q,j} - X_j \right\| \\ &\quad + \left\| X_i \right\| \left\| W_q \hat{X}_{q,j} - X_j \right\| + \left\| W_p \hat{X}_{p,i} - X_i \right\| \left\| X_j \right\| \\ &= O_p \left(\frac{\log^2(o+m)}{\sqrt{o+m}} \right). \quad (\text{from (B103)}) \end{aligned} \quad (\text{B108})$$

Thus,

$$\min_{(i,j) \in \Delta_{d-1} \cap \mathbb{S}^c} \left| \hat{P}_{ij}^{(d-1)} - P_{ij} \right| = \Omega_p(\rho_n) - O_p\left(\frac{\log^2(o+m)}{\sqrt{o+m}}\right) = \Omega_p(\rho_n), \quad (\text{B109})$$

as $\rho_n = \Omega\left(\frac{\log^{2+a_0/2}(n)}{\sqrt{n}}\right)$ and $o+m \asymp n$.

Using Bernstein's inequality, the following holds with very high probability, where the expectation is over the test entries

$$\begin{aligned} L(A, \hat{P}^{(d-1)}) - L(A) &\geq \frac{1}{2} E_{\mathbb{S}^c} \left[L\left(A, \hat{P}^{(d-1)}\right) - L(A) \right] \\ &= \frac{1}{2} \sum_{(i,j) \in \mathbb{S}^c} E_{\mathbb{S}^c} \left[\left(A_{ij} - \hat{P}_{ij}^{(d-1)} \right)^2 - \left(A_{ij} - P_{ij} \right)^2 \right] \\ &= \frac{1}{2} \sum_{(i,j) \in \mathbb{S}^c} E_{\mathbb{S}^c} \left[A_{ij}^2 - 2A_{ij}\hat{P}_{ij}^{(d-1)} + \left(\hat{P}_{ij}^{(d-1)} \right)^2 - A_{ij}^2 + 2A_{ij}P_{ij} - P_{ij}^2 \right] \\ &= \frac{1}{2} \sum_{(i,j) \in \mathbb{S}^c} \left[-2P_{ij}\hat{P}_{ij}^{(d-1)} + \left(\hat{P}_{ij}^{(d-1)} \right)^2 + 2P_{ij}^2 - P_{ij}^2 \right] \\ &= \frac{1}{2} \sum_{(i,j) \in \mathbb{S}^c} \left(\hat{P}_{ij}^{(d-1)} - P_{ij} \right)^2 \\ &\geq \frac{1}{2} \sum_{(i,j) \in \Delta_{d-1} \cap \mathbb{S}^c} \left(\hat{P}_{ij}^{(d-1)} - P_{ij} \right)^2 \\ &= \Omega_p\left(s(s-1)m^2\rho_n^2\right). \end{aligned} \quad (\text{B110})$$

Case 3: ($\tilde{d} \leq d-2$) For $\tilde{d} \leq d-2$, a similar argument can be used as in the $\tilde{d} = d-1$ case, the only difference being the bounds in (B107), (B108) and the subsequent terms differing by a factor of d . Since d is fixed in terms of n , the asymptotic bounds for this case are the same as $\tilde{d} = d-1$ case.
