SELF CALIBRATION IN CLUSTER STUDIES OF DARK ENERGY: COMBINING THE CLUSTER REDSHIFT DISTRIBUTION, THE POWER SPECTRUM AND MASS MEASUREMENTS

Subhabrata Majumdar¹ and Joseph J Mohr^{1,2} submitted to ApJ May 16, 2003

ABSTRACT

We examine the prospects for measuring the dark energy equation of state parameter w within the context of any uncertain redshift evolution of galaxy cluster structure (building on Majumdar & Mohr 2003) and show that including the redshift averaged cluster power spectrum, (\bar{P}_{cl}) , and direct mass measurements of 100 clusters helps tremendously in reducing cosmological parameter uncertainties. Specifically, we show that when combining the redshift distribution and the power spectrum information for a particular X-ray survey (DUET) and two SZE surveys (SPT & Planck), the constraints on the dark energy equation of state w can be improved by roughly a factor of 4. Because surveys designed to study the redshift distribution of clusters will have all the information necessary to construct \bar{P}_{cl} , the benefit of adding \bar{P}_{cl} in reducing uncertainties comes at no additional observational cost. Combining detailed mass studies of 100 clusters with the redshift distribution improves the parameter uncertainties by a factor of 3-5. The data required for these detailed mass measurements—assumed to have 1σ uncertainties of 30%are accumulating in the the XMM-Newton and Chandra archives. The best constraints are obtained when one combines both the power spectrum constraints and mass measurements with the cluster redshift distribution; when using the survey to extract the parameters and evolution of the mass-observable relations, we estimate the uncertainties on w of $\sim 4\%$ to 6%. These parameter constraints are obtained from self-calibrating cluster surveys alone. In combination with CMB or distance measurements that have different parameter degeneracies, cluster studies of dark energy will provide enhanced constraints and allow for cross-checks of systematics.

1. INTRODUCTION

Galaxy clusters have been used extensively to determine the cosmological matter density parameter and the amplitude of density fluctuations. The number density of massive clusters is exponentially sensitive to the amplitude of initial Gaussian fluctuations [whose normalization we describe using σ_8 , the *rms* fluctuations of overdensity within spheres of $8h^{-1}$ Mpc radius] (Eke et al. 1996; Henry 1997; Bahcall & Fan 1998; Viana & Liddle 1999; Reiprich & Böhringer 2002; Lin & Mohr 2003). In principle, clusters contain information about many aspects of the evolution of the universe. Wang & Steinhardt (1998) argued that a measurement of the changes of cluster number density or abundance with redshift would provide constraints on the dark energy equation of state parameter $w \equiv p/\rho$. Haiman et al. (2001) showed that with future large survevs it should be possible to obtain precise measurements of the amount Ω_E and nature w of the dark energy. Since then, a series of papers has focused on the prospects of high yield cluster surveys as probes of dark energy (Holder et al. 2001; Weller et al. 2001; Levine et al. 2002; Hu & Kravtsov 2003; Majumdar & Mohr 2003; Hu 2003). These papers also show that constraints from cluster surveys will be complimentary to those from cosmic microwave background (CMB) anisotropy and SNe Ia distance measurements.

The potential of using cluster surveys can only be realized fully if we not only know the cluster redshifts but

also have some estimate of the cluster masses (Haiman et al. 2001). However, this total mass has to be inferred indirectly through use of cluster scaling relations and observables like the X-ray flux, SZE flux, galaxy light and weak lensing shear. Recently, Levine et al. (2002) examined an X-ray cluster survey, showing that a sufficiently large survey allows one to measure cosmological parameters and constrain the cluster mass-observable relation simultaneously if one assumes perfect knowledge of the redshift evolution of galaxy cluster structure. If one allows for an imperfect understanding of galaxy cluster evolution, then the constraints on w are seriously weakened (Majumdar & Mohr 2003, hereafter MM03). To overcome this important limitation, MM03 examined the impact of follow-up of a fraction of the survey cluster sample and showed that even a 1% follow-up helps in improving the w constraints by a factor 2 to 3. These calculations underscore the importance of incorporating information from multiple observables into future cluster surveys, and they demonstrate that cluster surveys are essentially selfcalibrating—containing enough information to solve for the mass-observable relation at every redshift and constrain cosmological parameters. As another solution to overcome the evolution-cosmology degeneracy, Hu (2003) has shown that there is potential for internal calibration by using the shape of the mass function of clusters in redshift slices. In the case of tight mass-observable relations and accurate redshifts, this approach essentially enables one to solve for the mass observable relation independently in each redshift

¹Department of Astronomy, University Of Illinois, 1002 West Green St., Urbana, IL 61801

²Department of Physics, University Of Illinois, 1002 West Green St., Urbana, IL 61801

slice of the survey. Additional calculations are needed to examine how well this very promising approach will work in future cluster surveys.

Here we look at another way to improve constraints on the equation of state of dark energy. We show how one may use the redshift averaged cluster power spectrum $P_{cl}(k)$, derived from the correlated positions of galaxy clusters in the survey, to tighten the constraints on cosmological parameters. Because the sky position and the redshift (already needed to measure the redshift distribution) for each cluster gives us enough information to construct \bar{P}_{cl} , one essentially gets the cluster power spectrum without further observational effort. The amplitude and shape of the cluster power spectrum depends on the underlying dark matter power spectrum and the bias of the tracers, which is related to the mass of the halo (Mo & White 1996; Sheth & Tormen 1999) in the same way as the mass function of the halos. Thus, a measure of biased cluster power spectrum essentially provides an indirect measurement of the mass of the cluster tracers. This additional information is essential in constraining the evolution of the mass-observable relation, which is key to obtaining tight cosmological constraints from the cluster redshift distribution. In addition, the shape of the cluster power spectrum provides an additional constraint on the matter density because of its effect on the transfer function.

Moreover, an advantage of \bar{P}_{cl} over any spatial correlation, $\xi(r)$, studies is in the respective uncertainty analysis. For \bar{P}_{cl} , one can assume, for an initial Gaussian field, the statistical fluctuation to be mainly uncorrelated (Feldman et al. 1994). However, \bar{P}_{cl} is similar to $\xi(r)$ in the sense that both exhibit different parameter degeneracies than those from using dN/dz and hence combining power spectrum constraints with the cluster redshift distribution helps in tightening parameter constraints. The aim of this paper is to examine the complementarity of the redshift distribution and cluster power spectrum that can be obtained in any high yield cluster surveys. We show that by combining these two analyses, dramatic improvement on w-constraints can be realized even in the face of uncertain evolution of the cluster mass—observable relation.

The paper is arranged in the following way. In §2 we describe the basic formalism and then in §3 we describe three representative surveys and our method of estimating parameter constraints. In §4 we present our results and finally conclusions are drawn in §5.

2. PRELIMINARIES

2.1. Cluster Redshift Distribution

To begin, we estimate the redshift distribution of detectable clusters within a survey solid angle $\Delta\Omega_M$,

$$\frac{dN}{dz} = \Delta \Omega \frac{dV}{dz d\Omega}(z) \int_{0}^{\infty} f(M, z) \frac{dn(M, z)}{dM} dM \qquad (1)$$

where $dV/dzd\Omega$ is the comoving volume element, (dn/dM)dM is the comoving density of clusters of mass M, and f(M,z) is the redshift dependent cluster selection function for the survey. In this analysis we take f(M,z) to be a step function at some limiting mass M_{lim} , which corresponds to the mass of a cluster that lies at the survey detection threshold. In a real survey the selection function will depart from a step function, and this has

been examined elsewhere (Holder et al. 2000; Lin & Mohr 2003). We use the cluster mass function dn/dM determined from structure formation simulations (Jenkins et al. 2001). Sample dn/dz plots can be found in MM03.

For an X-Ray survey, the mass-observable relation takes the form of bolometric flux - mass relations and we use

$$f_x(z)4\pi d_L^2 = A_x M_{200}^{\beta_x} E^2(z) (1+z)^{\gamma_x}$$
 (2)

where f_x is the observed flux in units of $\operatorname{erg} \operatorname{s}^{-1} \operatorname{cm}^{-2}$, d_L is in units of Mpc, M_{200} in units of $10^{15} M_{\odot}$ is the mass enclosed within a radius r_{200} having a overdensity of 200 with respect to critical and $H(z) = H_0 E(z)$. where $E^2(z) = \Omega_M (1+z)^3 + \Omega_k (1+z)^2 + \Omega_E^{3(1+w)}$. We convert M_{200} to M(z), the halo mass appropriate for our mass function at redshift z using a halo model (Navarro et al. 1997, hereafter, NFW). Following MM03, the possibility of non-standard evolution of the mass-observable relation is included through the parameter γ_x . In our fiducial model we take $\gamma_x = 0$ to be consistent with the observed weak evolution in the luminosity-temperature relation (Vikhlinin et al. 2002), and we choose $\beta_x = 1.807$ and $\log A_x = -3.926$ (Reiprich & Böhringer 2002).

For an SZE survey, the corresponding SZE flux-mass relation is given by

$$f_{sz}(z,\nu)d_A^2 = f(\nu)f_{ICM}A_{sz}M_{200}^{\beta_{sz}}E^{3/2}(z)(1+z)^{\gamma_{sz}}$$
 (3)

where $f(\nu)$ is the frequency dependence of the SZE distortion, f_{sz} is the observed flux in mJy, M_{200} is in units of $10^{15}M_{\odot}$, $f_{ICM}=0.12$ (e.g Mohr et al. 1999) and d_A is in units of Mpc (see Diego et al. 2001). For our fiducial model, we use the mass - temperature relation for clusters having $T>3{\rm KeV}$ (Finoguenov et al. 2001), to get $\log A_{sz}=16.47,\ \beta_{sz}=1.68$ and $\gamma_{sz}=0$ to model standard structure evolution. Note that in determining the estimated uncertainties on cosmological parameters, we allow the normalization of these mass—observable relations to be free to vary. Finally, we impose a minimum cluster mass of $10^{14}h^{-1}$ ${\rm M}_{\odot}$ on all surveys.

2.2. The Cluster Power Spectrum

The power spectrum of future high yield surveys provides a different probe of the background cosmological model. Taken alone, the constraints from cluster power spectrum are far weaker than those from dN/dz alone. However, when combined with other measures of cosmological parameters, the power spectrum studies can give very powerful constraints. While in most cases, people have studied the power spectrum for galaxy surveys, the cluster power spectrum holds similar promise because clusters are highly biased when compared to galaxies, making it possible to obtain similar statistical uncertainties with far smaller samples. Another important issue that contrasts the cluster power spectrum, $P_{cl}(k)$, from that of galaxies is the fact that the bias, b(M, z), for clusters can be determined from large scale N-body simulations and theoretical calculations (Mo & White 1996; Sheth & Tormen 1999). In addition, cluster masses are related to simple observables, making it possible to directly connect the bias of the cluster power spectrum to these same observables. The same physics of gravitational collapse of dark matter dominated halos underlies the theoretical and numerical predictions of the bias-mass relation and the mass function of collapsed haloes (Mo & White 1996; Sheth & Tormen 1999; Jenkins et al. 2001; Sheth et al. 2001).

FIG. 1.— The upper panel shows redshift averaged cluster power spectrum, \bar{P}_{cl} , for the SPT survey, for the three redshift bins, z=0-0.42 (short-dashed line), z=0.42-0.72 (long-dashed) and z=0.72-3 (dotted line), each bin having ~ 9700 clusters. The solid line shows the results for one single redshift bin from z=0-3. The lower panel shows the fractional uncertainties in estimating the power spectrum, $\sigma_{\bar{P}_{cl}}(k)/\bar{P}_{cl}(k)$, using the method detailed in Feldman et al. (1994).

To calculate the parameter sensitivity of $P_{cl}(k)$ we follow the method described in a number of papers dealing with galaxy power spectrum (Tegmark 1997; Eisenstein & Hu 1999), keeping in mind that clusters are biased with respect to the underlying matter distribution. We use the bias model in Sheth & Tormen (1999). In the limit where the survey volume is much larger than the scale of any features in the power spectrum (Hamilton 1997), the uncertainties can be well estimated with the method given by Feldman et al. (1994, hereafter FKP). The cluster power spectrum is constructed as $P_{cl}(k,z) = b_{eff}^2(z)P(k,z)$ where P(k,z) is the matter power spectrum and b_{eff} at a particular redshift is the cluster mass function averaged linear bias, b(M,z) (Suto et al. 2000; Moscardini et al. 2000). The effective bias is, then, given by

$$b_{eff}(z) = \frac{\int dM \frac{dn}{dM} b(M, z)}{\int dM \frac{dn}{dM}}$$
(4)

where dn/dM is the cluster mass function obtained from N-body simulations (Sheth & Tormen 1999; Jenkins et al. 2001). This is valid for a small redshift interval δz at a particular z. It is useful to measure the power spectrum over a wide redshift range. In this case, the light cone averaged cluster power spectrum, \bar{P}_{cl} , in the redshift range of interest between z_{min} and z_{max} is obtained as

of interest between
$$z_{min}$$
 and z_{max} is obtained as
$$\bar{P}_{cl}(k) = \frac{\int_{z_{min}}^{z_{max}} dz \frac{dV}{dz} n^2(z) P_{cl}(k, z)}{\int_{z_{min}}^{z_{max}} dz \frac{dV}{dz} n^2(z)}$$
(5)

where the comoving number density of clusters in the flux limited surveys is computed by integrating Eqn 1. Thus,

 \bar{P}_{cl} not only depends on cosmology but also on the specific survey that determines the redshift dependence of observed clusters.

We assess the sensitivity of \bar{P}_{cl} to different parameters through the Fisher matrix formalism detailed in the next section. Note that the evolution of b(M, z) follows the growth of structures in hierarchical models of structure formation (Mo & White 1996; Sheth & Tormen 1999; Sheth et al. 2001). Also note that the amplitude of the power spectrum evaluated on the light cone for a given flux limit increases with z; the increasing bias at higher redshift offsets the reduction in amplitude of the underlying power spectrum of dark matter fluctuations. For all the surveys, the power spectrum is calculated in the k-range $0.0014h^{-1}{\rm Mpc}^{-1}$ to $1.4h^{-1}{\rm Mpc}^{-1}$. The uncertainty in the estimation of \bar{P}_{cl} increases rapidly as we decrease k, and effectively cuts off the contribution to the Fisher matrix for wavenumbers less than k_{min} . At higher k, non-linear effects become important and increase \bar{P}_{cl} . Although, the power spectrum in the non-linear regime remains a well defined quantity, it is unwise to to use the Fisher matrix approach (see below) to estimate constraints on parameters as the density field becomes nonlinear and non-Gaussian; in this regime Equation 7 could give incorrect estimates of the parameter constraints. One needs to use Monte-Carlo methods to accurately study processes having non-Gaussianities. We ask the reader to keep these considerations in mind when assessing our results. Finally, we neglect redshift space distortion and non-linear contributions to P_{cl} , which produce a small change in the power spectrum amplitude (Suto et al. 2000).

2.3. Follow-up of Large Solid Angle Surveys

Finally, MM03 introduced the idea of follow-up of a fraction of the cluster sample to calibrate the mass-observable relation and highlighted the resulting improvement in parameter constraints. Followup requires detailed X-ray, SZE or galaxy spectroscopic observations that allow one to measure the mass-like quantity $M_f(\theta) = M(\theta)/d_A$, which we will refer to as the follow-up mass, where the $M(\theta)$ can be calculated using a NFW profile for the matter distribution. We assume a concentration c = 5. At fixed redshift, this follow-up produces an M_f - f_x of M_f - f_{sz} relation which would provide direct constraints on the structural evolution of the clusters. The parameter sensitivity of these scaling relation observations can exhibit quite different degeneracies than for the cluster redshift distribution. making the scaling relations and the cluster redshift distribution complementary (see MM03). We emphasize that a large number of clusters are now being studied in great detail with Chandra, XMM and deep optical weak lensing data. This growing ensemble of well studied clusters will be available for mass calibration in all future surveys. We model this additional information by placing 100 clusters uniformly over a range of redshifts from $0.3 \le z \le 1.2$ and masses from $10^{14}h^{-1}M_{\odot}$ to $10^{15}h^{-1}M_{\odot}$.

3. COSMOLOGICAL SENSITIVITY OF A SURVEY

3.1. Fisher Matrix Technique

We employ the Fisher matrix technique to probe the relative sensitivities of cluster surveys to different cosmological and cluster structural parameters. The Fisher matrix information for a data set (see Tegmark et al. 1997; Eisenstein et al. 1998) is defined as $F_{ij} \equiv - \langle \frac{\partial^2 \ln \mathcal{L}}{\partial p_i \partial p_j} \rangle$, where \mathcal{L} is the likelihood for an observable (proportional to $\frac{dN}{dz}$ for the redshift distribution, \bar{P}_{cl} for the power spectrum and M_f for the follow-up) and p_i describes our parameter set. The inverse F_{ij}^{-1} describes the best attainable covariance matrix $[C_{ij}]$ for measurement of the parameters considered. The diagonal terms in $[C_{ij}]$ then give the uncertainties on each of our parameters. To estimate the full potential for cluster surveys, we calculate the final Fisher matrix is the sum of the Fisher matrices for the cluster redshift distribution (F_{ij}^s) , the cluster power spectrum (F_{ij}^p) , the follow up observations (F_{ij}^f) and the priors.

We construct the survey Fisher matrix F_{ij}^s following Holder et al. (2001) as

$$F_{ij}^{s} = \sum_{n} \frac{\partial N_{n}}{\partial p_{i}} \frac{\partial N_{n}}{\partial p_{j}} \frac{1}{N_{n}}, \tag{6}$$

where we sum over n redshift bins of size $\Delta z = 0.01$ to $z_{max} = 3.0$ and N_n represents the number of surveyed clusters in each redshift bin n. The Fisher matrix for the power spectrum is given by

$$F_{ij}^{p} = \Sigma_{m} \frac{\partial \bar{P}_{cl}(k)}{\partial p_{i}} \frac{\partial \bar{P}_{cl}(k)}{\partial p_{j}} \frac{\Delta k_{m}}{\sigma^{2}_{FKP}}$$
 (7)

where we sum over m logarithmic bins in k-space between k_{min} and k_{max} (see, for example Tegmark (1997)). The variance in each k-bin is calculated using the formulation given in Feldman et al. (1994) with optimal weighting for each survey.

The Fisher matrix for the follow-up is constructed as

$$F_{ij}^{f} = \Sigma_n \left(\frac{\partial M_f}{\partial p_i} \frac{\partial M_f}{\partial p_j} \frac{1}{\sigma_{M_f}^2} \right)$$
 (8)

where M_f is a function of halo mass M and angular radius θ at a particular redshift z. As noted above, we model the available followup information from deep X-ray studies of clusters by summing over 100 clusters that uniformly span a range of redshifts $(0.3 \le z \le 1.2)$ and a range of masses $(10^{14}h^{-1}M_{\odot})$ to $10^{15}h^{-1}M_{\odot}$. In this way we attempt to model the information provided by all the detailed cluster analyses that accumulate in the literature. Any followup of clusters in a particular survey would result in additional constraints on cluster structural evolution. In this analysis we take $\sigma_{M_f} = 0.3M_f$ to be the characteristic uncertainty in the follow-up mass measurements. For more details on cluster follow-up specifications, please refer to MM03.

3.2. Future Surveys, Fiducial Cosmology and External Priors

For our study, we adopt three representative surveys, two in SZE and one in X-Ray. For the X-Ray survey we examine the $10^4~\rm deg^2$ flux limited X–ray survey proposed as part of the DUET mission to the NASA Mediumclass Explorer Program. For the SZE surveys, we consider the 4,000 $\rm deg^2$ SZE survey to be carried out with an 8m telescope being constructed for the South Pole (SPT) and the Planck full sky SZE cluster survey. We model the DUET X-ray survey as having a bolometric flux limit of $f_x > 1.25 \times 10^{-13}~\rm erg/s/cm^2$ (corresponding

to $f_x > 5 \times 10^{-14}$ erg/s/cm² in the 0.5:2 keV band). For our fiducial cosmological model,this survey yields ~22,000 detected clusters, consistent with the known X-ray log N–log S relation for clusters (e.g. Gioia et al. 2001). We model the SPT SZE survey as a flux limited survey with $f_{SZ} > 5$ mJy at 150 GHz. Within our fiducial cosmological model this survey would yield ~ 29,000 clusters with measured fluxes. And finally for the Planck survey, we take a flux limit of $f_{SZ} > 50$ mJy at 353 GHz (at which the angular resolution of Planck would reach 5 arc min) (Diego et al. 2002) which for 70% of the sky yields ~21,000 clusters.

The fiducial cosmological parameters (and priors) of our model are adopted from the first year WMAP result (Bennett et al. 2003) and are h = 0.71, $\Omega_M = 0.27$, n = 0.93, $\Omega_B = 0.044, \, \sigma_8 = 0.84 \text{ and } w = -1. \text{ From WMAP results}$ we know that the curvature is very close to zero, and hence we assume a flat universe, taking $\Omega_{tot} = \Omega_M + \Omega_E = 1$. We also neglect any variation in w with redshift. The priors used for our calculations are $\sigma_h = 0.035, \sigma_{\Omega_b} = 0.004$ and $\sigma_n = 0.03$. We do not use any priors on Ω_M , σ_8 or w for the main results of this paper as summarized in Table 1. However, to show the effect of strong CMB priors on Ω_M , σ_8 and w (shown within parentheses in Table 1), we use $\sigma_{\Omega_M} = 0.04, \sigma_{\sigma_8} = 0.04 \text{ and } \sigma_w = 0.11$. Note that this provides a crude estimate of the complementarity with CMB constraints, because we have not used the parameter covariance appropriate for CMB power spectrum analyses.

For power spectrum calculations, each survey is divided into three redshift bins such that each bin has an approximately equal number of clusters. For example, for the SPT survey which has the most clusters at high redshift, the redshift binnings are z=0.0-0.42, 0.42-0.72 and 0.72-3.0. For the fiducial cosmology and SPT survey, \bar{P}_{cl} and the the fractional uncertainty, $\sigma_{FKP}/\bar{P}(k)$, for the three redshift bins are shown in Figure 1 using short-dashed, long-dashed and dotted lines respectively. The solid line is for the case of a single redshift bin from z=0.0-3.0.

4. COSMOLOGICAL PARAMETER CONSTRAINTS

Our main results are summarized in Table 1 and highlighted in the following three figures, one for each survey. The table contains the 1- σ parameter uncertainty for each survey for Ω_M , σ_8 and w and addresses the main focus of this paper, which is to examine the degree to which one can tighten cosmological from the redshift distribution dn/dzby adding the cluster power spectrum P_{cl} and detailed followup of 100 clusters. With the exception of Majumdar & Mohr (2003) and Hu (2003), previous studies of cluster surveys have implicitly assumed full knowledge of cluster structure evolution and only addressed the sensitivity of cluster surveys to cosmological parameters. Constraints from such considerations are grouped under the heading 'Only Cosmology' in Table 1. However, if one does not assume perfect knowledge of cluster structure and lets the survey solve for both cosmology and cluster scaling parameters, then the cosmological constraints are weakened. This is illustrated in the next column labeled 'Std Evol.'. This approach, however, still assumes that there is no unexpected evolution in scaling relation with redshift and ignores any uncertainty due to it. A cautious approach

ESTIMATED PARAMETER CONSTRAINTS

would be to try to solve for any evolution from the survey itself (see Eqn 2 and 3). The estimated uncertainties for this self-calibrating case are shown in column labeled 'Self-Cal'. The next column shows constraints when one combines information from both dn/dz and \bar{P}_{cl} , both calculated for the self-calibration case. The second last column shows the constraints if one does a mass follow-up of 100 clusters from the survey sample and the final column shows the cosmological constraints when one uses information from dn/dz, \bar{P}_{cl} and also follow-up. The constraints are using cluster surveys only. However, in the last column, within parentheses, we show an estimate of how the constraints change if one includes strong priors of Ω_M , σ_8 and w.

From the table, one is able to draw two general conclusions:

- Assuming complete knowledge of cluster structure can give overly optimistic constraints on cosmological parameters. A complete lack of knowledge of cluster structure can drastically degrade our ability to constrain such parameters (especially w) from future cluster surveys. This is illustrated in columns 2-4.
- The last three columns show that one can greatly improve the constraints if one uses information from power spectrum studies or mass follow-up of 100 clusters. Using all available information from dn/dz, \bar{P}_{cl} and follow-up can deliver uncertainties comparable to the case of using the redshift distribution alone and assuming perfect knowledge of cluster structure and evolution. This, indeed, is very encouraging.

4.1. Self-calibration and degradation of constraints

For the case with perfect knowledge of cluster structure, all the three surveys compare favourably, yielding 1- σ uncertainty on w of 0.0371, 0.0397 and 0.0505 for the SPT, Planck and DUET surveys respectively. The marginally better uncertainty on w from SPT over Planck is due to the higher sensitivity of the SPT survey, which delivers higher redshift clusters that are more sensitive to change in w (for example, see Figure 4 in MM03). Planck, which essentially detects only high mass clusters over the entire extragalactic sky, constrains Ω_M most effectively. Note, that

when we have no uncertainties entering from any imprecise knowledge of cluster structure, SPT having the maximum number of clusters and the deepest redshift range best constrains σ_8 . However, with the addition of extra information from the cluster power spectrum and mass follow-up, the shallower but largest solid angle Planck survey provides the the best constraints on σ_8 . The joint 1- σ constraints for this case on w and Ω_M are shown in Figure 2 and on σ_8 and Ω_M in Figure 3 using dotted lines.

When one solves for both the normalization and the slope of cluster scaling relations, along with cosmology, from cluster surveys, the uncertainties degrade by factors of upto 2-5 depending on the survey and the parameter concerned. The fact that one still obtains uncertainties on w of 0.0663 and 0.0806, for SPT and DUET respectively, shows that it is possible to constrain both cosmology and cluster physics reasonable well from future cluster surveys (see also Levine et al. 2002). The weakening of parameter constraints is most significant for *Planck* for which the peak of dN/dz falls at $z \sim 0.14$ which is much below the modal redshift in SPT or DUET. This is due to fact that lower sensitivity surveys that are picking out only the few, most massive clusters can less effectively constrain the cluster mass-observable relation normalization and slope (i.e its more costly to solve for cluster structure) and these larger uncertainties lead to weakened cosmological parameter constraints (for example, Planck can constrain the slope of the mass-observable relation to $\sim 27\%$ compared to $\sim 17\%$ and 9% from DUET and SPT).

The crux of the problem arises when one takes into account the possibility of non-standard evolution. When one requires that the survey also solve for the evolution of the mass-observable relation, the constraints on w weaken further by a factor of $\sim 2-2.5$ for the two SZE surveys (i.e $\sigma_w \sim 0.1745$ for SPT and ~ 0.3930 for Planck) and a factor ~ 4.5 for DUET. Because this uncertain evolution affects the mass estimates for high redshift clusters, it affects the constraint from DUET more than those from Planck, even though both have similar total number of clusters. Constraints on Ω_M and σ_8 also weaken significantly. The reason for this weakening of constraints is the fact that constraints on the evolution parameters (γ_X/γ_{SZ}) are very weak and this large uncertainty in the evolution of the mass-observable relation makes it harder

to know the masses of high redshift clusters; this drives the weakened sensitivity to other cosmological parameters (for additional discussion, see MM03). The interplay between redshift depth and total number of clusters is complex, though, for SPT, though deeper than DUET, has slightly less degradation in errors due to it having $\sim 30\%$ more clusters than DUET. In Figures 2 and 3, we have shown constraints on $w-\Omega_M$ and $\sigma_8-\Omega_M$ for 'Self-Cal' using long–dashed lines.

Fig. 2.— Constraints on w and Ω_M for an SZE SPT survey (top), SZE Planck survey (middle) and an X-ray DUET survey (bottom). Contours denote joint $1-\sigma$ constraints in five scenarios: constraints from dN/dz for 'Only Cosmology' case (i–dotted) ; constraints from dN/dz for 'Non-Std Evol' case (ii–long–dashed); constraints from $dN/dz+\bar{P}_{cl}$, (iii–dot–dashed); dN/dz+100 cluster follow-up (iv–short–dashed) and the finally constraints from $dN/dz+\bar{P}_{cl}+$ follow-up (v–solid). Note, that for the Planck survey, for the 'Non-Std Evol' scenario (i.e long–dashed), the constraint ellipse is too large and lies outside the range for the two axes. A flat universe is assumed for all the cases. The different terms are described in the text.

4.2. Including the Cluster Power Spectrum

The addition of constraints from \bar{P}_{cl} from the survey sample to that from dn/dz provides us with a rather neat and effective option to dramatically improve the cosmological constraints. The fact that parameter degeneracies on cosmological parameters from the redshift distribution and the spatial two point correlation function $\xi(r)$ are quite different has been demonstrated for future surveys (Refregier et al. 2002). Because P(k) and $\xi(r)$ are Fourier transform pairs, this also holds for dn/dz and \bar{P}_{cl} as well. Includ-

ing the cluster power spectrum helps in two ways. First, because the amplitude of the cluster power spectrum depends on the cluster bias, a measure of the power spectrum essentially provides a handle on the masses of the tracers used to measure the power spectrum. This information provides an indirect measurement of of masses of the clusters for any particular survey and mass-observable relation. Secondly, the shape of the power spectrum reflects the transfer function for density perturbations, which is very sensitive to the epoch of matter–radiation equality; thus, the cluster power spectrum places strong constraints on cosmological parameters, mainly Ω_M . Because of the complex parameter degeneracies, improved constraints on Ω_M are reflected by tighter constraints on other parameters.

We emphasize that any survey that delivers the redshift distribution naturally gives the spatial position and the redshift of the tracers; hence the cluster power spectrum comes without any extra observational effort. Although serendipitous cluster surveys may be adequate for measuring the cluster redshift distribution, it will require contiguous coverage to keep survey window functions sufficiently simple to make robust estimates of the cluster power spectrum.

It is clear from Table 1 that adding the \bar{P}_{cl} constraint reduces uncertainties on w for the two larger area surveys by factor of $\sim 2-4$ to make the uncertainty closer to ones obtained from the redshift distribution in the 'Only Cosmology' scenario. Using the cluster power spectrum tightens the constraint on w most for Planck, followed by DUET and SPT. This is expected because of the large physical scales probed by the all sky *Planck* survey. This is more evident when one compares DUET with Planck, both of which have similar total number of clusters. Thus, when one combines \bar{P}_{cl} information to that from dN/dz, one obtains 1- σ constraint of $\sim 10\%$ on w from Planck which is a factor of ~ 4 improvement on the $\sim 39\%$ constraint on w obtained in the 'Self-Cal' scenario. Notice that addition of the power spectrum also very effectively tightens the constraint on Ω_M , especially for Planck, which is reduced by a factor of ~ 4.5 from $\sigma_{\Omega_M} = 0.082$ to 0.0188. For SPT and DUET, the Ω_M constraint also improves by factor of $\sim 2-3$.

A point to note is that the amplitude of the power spectrum, which depends on the bias of the tracers and the underlying amplitude of the dark matter power spectrum- σ_{8} is a key component which helps in tightening the constraints. The effective bias, for a particular survey, depends on the number distribution of the clusters and their masses, which—in turn—depends on the cosmological parameters (mainly σ_8) and the cluster structure. Hence, constraints on σ_8 and cluster structure from using the power spectrum are very degenerate. Finally, we should also keep in mind that σ_{FKP} depends not only on volume but also on number density. Hence, the area and the depth of the surveys affect the uncertainty estimation in a non-trivial manner. Constraints from adding the power spectrum to the cluster redshift distribution are shown by dot-dashed lines in Figures 2 and 3. The fact that parameter degeneracies from the redshift distribution and P_{cl} are quite different is evident from the rotation of the elliptical joint parameter constraints when one adds \bar{P}_{cl} constraints to that from dn/dz.

4.3. Including Limited Mass Follow-up

Yet another way to reduce the cost of forcing the survey to self-calibrate (i.e. solve for cluster structure and its evolution in addition to cosmology), is to add information from a mass follow-up of 100 clusters between the redshifts of 0.3 and 1.2, with 10 clusters followed-up at redshift intervals of 0.1. At each redshift, the 10 clusters are equally divided in mass between $10^{14}h^{-1}M_{\odot}$ and $10^{15}h^{-1}M_{\odot}$. This is equivalent to following up less than 1% of the cluster sample in each survey, and we envision this followup as mostly being available through deep, archival X-ray observations that are being accumulated by XMM-Newton and Chandra even now. We see that followup significantly reduces the uncertainties for all the three surveys. The constraints for w goes down to $\sim 0.06, 0.115$ and 0.077 for SPT, *Planck* and DUET respectively. There are also major improvements in Ω_M (by a factor of 1.3-2.6) and σ_8 (by a factor of 2-4.5) uncertainties. Essentially, follow-up helps is tightening the constraints on the unknown cluster structure and its evolution; this translates into more accurate mass estimates for the clusters, and that reduces the uncertainties on the cosmological parameters. Because SPT probes to higher redshift, follow-up is most valuable for this survey which contains the most high redshift clusters, whose masses are most uncertain without the follow-up information. Short-dashed lines in Figures 2 and 3 show joint constraints when one added information from a follow-up of 100 clusters to that from dN/dz. MM02 demonstrated that although there is some further improvement in constraints as one follows up a larger fraction of the clusters, the difference between following up 10\% and 100\% of the cluster population is minimal. We remind the reader that follow-up does not explicitly depend on σ_8 , n, h and Ω_B and hence cannot constrain these parameters by itself and contains no cross-correlation of other cluster structure or cosmological parameters with these four parameters.

4.4. Combining dn/dz, \bar{P}_{cl} and Follow-up

It is interesting at this point to compare and combine parameter constraints obtained by the two options at hand; follow-up mass measurements versus addition of \bar{P}_{cl} constraints. Other than the Planck survey, having mass follow-up helps in tightening constraints on w more than adding power spectrum information. Planck, which surveys the maximum solid angle, delivers power spectrum constraints that are slightly more powerful than follow-up. However, for Ω_M and σ_8 , the addition of \bar{P}_{cl} constraints fares better than addition of follow-up constraints (for example, for SPT survey addition of \bar{P}_{cl} improves the constraint of Ω_M by a factor of ~ 2 compared to ~ 1.3 when one adds the follow-up Fisher matrix).

As a simple extension, one can add both power spectrum and follow-up constraints to that from dN/dz. This, then, gives us the best possible constraints on all the cosmological parameters. One ends up having 3.76%, 4.04% and 6.25% constraints on w from SPT, Planck and DUET respectively. This can be compared to the overly optimistic 3.71%, 5.05% and 3.97% constraints one obtains in the 'Only Cosmology' case. For the DUET and Planck sur-

veys, which are more sensitive to the massive clusters compared to SPT, the final constraints on Ω_M and σ_8 are even better than the 'Only Cosmology' case. Thus, one not only regains any cosmological sensitivity lost due to uncertain knowledge of cluster structure and evolution, but infact does marginally better. The best case scenario for parameter constraints estimated by adding constraints from dN/dz, power spectrum and follow-up are shown by solid lines in Figures 2 and 3. In Table 1, numbers in parentheses show the result of adding CMB constraints to that from cluster surveys. In adding constraints from CMB observations to those from cluster surveys, one should add the full covariance matrix in order to get uncertainties on individual parameters as well as parameter degeneracies. Our estimate of the uncertainties in parentheses (in Table 1) uses the CMB priors on the individual parameters and does not include information on their cross-correlations; thus, these numbers should be viewed as rough estimates.

Fig. 3.— Constraints on σ_8 and Ω_M for an SZE SPT survey (top), SZE Planck survey (middle) and an X-ray DUET survey (bottom). Contours denote joint 1σ constraints in four scenarios: constraints from dN/dz for 'Only Cosmology' case (i–dotted) ; constraints from dN/dz for 'Non-Std Evol' case (ii–long–dashed); constraints from $dN/dz+\bar{P}_{cl}$, (iii–dot–dashed); dN/dz+100 cluster follow-up, (iv–short–dashed)and finally constraints from $dN/dz+\bar{P}_{cl}+$ fo llow-up (v–solid). A flat universe is assumed for all the cases. The different terms are described in the text.

4.5. Combining CMB with \bar{P}_{cl}

Cosmological parameter constraints can, of course, be derived using only the cluster power spectrum \bar{P}_{cl} ; how-

ever, taken by itself, the cluster power spectrum constraints are quite weak due to large parameter degeneracies. Because the shape of the power spectrum depends on combinations of Ω_M , h and Ω_B , the best constraints are on these parameters and other parameters like σ_8 and ware quite weak. This trend has already been noted in related works using correlation functions (see Refregier et al. 2002). The cluster power spectrum, by itself, is unable to constrain the cluster structure and evolution parameters. Of the three surveys, *Planck* constrains the cluster parameters a few orders of magnitude better than the other surveys (although still extremely weakly; for example they are about a factor ~ 5 weaker than those from dN/dzalone). One can break these degeneracies by adding CMB anisotropy constraints and cross-correlations. Infact, if one puts in WMAP CMB priors on Ω_M , σ_8 and w, then one can get constraints on w of $\sim 10\%$, although this is not much better than the CMB prior on w of 11%. Note that in contrast, once dn/dz and \bar{P}_{cl} constraints are combined, any further addition of strong external CMB priors on Ω_M , σ_8 and w has little effecton the constraints (see numbers within parentheses in Table 1). In fact, it's important to stress that future, self-calibrating cluster surveys by themselves can give roughly a factor of 2.5 (e.g 4%for SPT) improvement on w constraints when compared to those obtained using present CMB data (Spergel et al. 2003).

Fig. 4.— Constraints on Ω_E and Ω_M for the three surveys; SPT (short–dashed lines), Planck (long–dashed lines) and DUET (solid lines). The thin lines are for freely varying w and the thick lines are for fixed w=-1.

4.6. Solving for Curvature and the Equation of State

We have also examined the effects of our flat universe prior by allowing Ω_{tot} to vary. This gives us an opportunity to examine the Ω_E constraints and the Ω_E - Ω_M degeneracy (shown in Figure 4). We look at both cases of a freely varying w and a fixed w=-1. We find the best constraint on Ω_E to be given by the SPT survey, and these are $\sigma_{\Omega_E}=0.0667(0.0185)$ when w is free (w fixed), followed by

Planck and then DUET. When we forego the assumption of a flat universe and also solve for the curvature along with the all the other parameters, we see only marginal degradation in the Ω_M or σ_8 constraints. As an example, for *Planck*, the respective constraints are 0.0102 and 0.0211 when curvature is free. On the other hand, the wconstraints are much affected, and they degrade by factors greater than 3 to $\sigma_w = 0.1353, 0.1092 \text{ and } 0.1955 \text{ for SPT},$ *Planck* and DUET, respectively. Note that Ω_E constraints from these surveys are better than the WMAP constraints, and although the w constraints have weakened, they are also comparable to or better than constraints the currently available tightest constraints that come from a combination of WMAP CMB measurements together with the galaxy power spectrum (Spergel et al. 2003). We note that the parameter degeneracies are potentially quite complementary to both CMB anisotropy and distance measurements, and thus one can obtain tighter constraints when one combines these different probes of dark energy.

5. DISCUSSION AND CONCLUSIONS

Any attempt to precisely measure cosmological parameters, especially w, from future cluster surveys will require an understanding of the mass-observable relations for clusters and the evolution of these relations. This is true whether clusters are found using X-rays, the SZE distortion, light from the galaxies or the weak lensing shear. Here we examine the effect of current uncertainties about cluster structural evolution for three future surveys and require that information from the surveys be used to calibration the structure and evolution of clusters in addition to solving for cosmology. We show that the process of self-calibration weakens cosmological constraints by a factors of 4-5, even for the deepest survey, in comparison to constraints derived by assuming perfect knowledge of cluster structure and evolution.

We have demonstrated that adding information from the redshift averaged cluster power spectrum to that from cluster counts would help in reducing the constraints up to factor ~ 4 . Measurement of cluster power spectrum helps us get a handle on the the masses of the tracer particles through the mass dependence of the effective bias b_{eff} . Moreover, the cluster power spectrum delivers an independent measure of the parameters important to the shape of the transfer function– primarily Ω_M , h and Ω_B , and the parameter degeneracies are also different to those from dN/dz. Estimation of power spectrum from a cluster survey designed to measure the redshift distribution of clusters would not require any additional observational effort and hence comes rather cheaply. However, to get the best power spectrum constraints, one needs to survey large, contiguous regions of the sky.

We have also examined the utility of detailed mass followup observations of 100 clusters, distributed in a redshift range of $0.3 \leq z \leq 1.2$. This followup information is being enabled by deep *Chandra* and *XMM-Newton* observations today, and this information will help determine the parameters of cluster mass–observable relations and their evolution.

The best constrains on the nature of dark energy and other cosmological and cluster parameters are obtained when the cluster redshift distribution is combined with the cluster power spectrum and the mass follow-up. One can achieve $\sim 4\%$ constraint on w for the two SZE surveys. This is a factor of 2.5 better than the best currently available constraints (Spergel et al. 2003). We emphasize that this constraint is from a self-calibrating cluster survey, where the cluster mass-observable relation and its evolution are pulled directly from the survey and followup. Recently, Hu (2003) has shown that by including the shape of the mass function within survey redshift bins one can essentially solve for the cluster mass-observable relation as a function of redshift—without including any information from the cluster power spectrum or follow-up mass measurements. Clearly, the best approach will include all the available information—the mass function, redshift distribution, cluster power spectrum and detailed mass measurements.

In constructing F_{ij}^p , we have subdivided each cluster sample into three redshift bins such that each bin has equal number of clusters. It is important to have thick redshift bins so as to avoid cross-correlation between adjacent bins. The final constraint would depend to a small degree on the binning of the cluster sample. For example, for SPT, if we subdivide the clusters in redshift bins z=0-0.3,0.3-0.7,0.7-3.0, then σ_w from $dN/dz+\bar{P}_{cl}$ is 0.1577 and very close to 0.1543 which was obtained when the clusters were divided to have equal number in each bin. Incidentally, if one has a single bin from z=0-3.0 rather than three redshift bins, one gets $\sigma_w=0.1568$. However, depending on the surveys, optimal redshift binning and the use of the full covariance matrix are important issues to consider in subsequent works.

To conclude, in the present paper we have demonstrated

the self-calibrating nature of cluster surveys and shown that the cluster survey is a powerful technique for studying the nature of the dark energy—as well as any other characteristic of the universe that affects the expansion history, growth of density perturbations or the nature of the transfer function. Constraints from cluster surveys tend to exhibit parameter degeneracies that are quite different from other techniques such as CMB anisotropy studies or distance measurements. By pursuing all these complementary means of studying the nature of dark energy and dark matter, we will produce independent constraints that will serve as cross checks of the different systematics underlying each technique. In addition, because the cluster survey is generating cosmological constraints from different physical properties of the universe than other techniques (i.e. surveys probe the growth of density perturbations whereas distance measurements only probe the expansion history), the pursuit of these different techniques makes it possible to precisely test the current framework for understanding our evolving universe. We look forward to the results of these precise, new tests with great anticipation.

We wish to thank Zoltan Haiman for many conversations that have positively impacted this study. SM wishes to thank Y-T Lin for technical help and Ben Wandelt for many useful discussions. JM wishes to thank the DUO collaboration for constructive comments during the later stages of this work. JM acknowledges financial support from NASA Long Term Space Astrophysics award NAG 5-11415 and an NSF Office of Polar Programs award OPP-0130612.
