(Dated: October 31, 2018)

We consider a linear model of optical pulse transmission through fiber with birefringent disorder in the presence of amplifier noise. Both disorder and noise are assumed to be weak, i.e. the average bit-error rate (BER) is small. The probability of rare violent events leading to the values of BER much larger than its typical value is estimated. We show that the probability distribution has a long algebraic tail.

PACS numbers: 42.81.Gs, 78.55.Qr, 05.40.-a

Optical fibers are widely used for transmission of information. In an ideal case, information carried by pulses would be transmitted non-damaged. In reality, however, various impairments lead to the information loss. Noise generated by optical amplifiers and fiber birefringence are the two major impairments in high-speed fiber communications. The amplifier noise is short-correlated in time, while the birefringence varies significantly along the optical line and is practically frozen in time, since the characteristic temporal scale of such variations is long compared to the signal propagation time through the entire fiber line. Coexistence of two different sources of randomness characterized by two well-separated time scales is pretty common in statistical physics of disordered systems. A classical example would be the glassy behavior driven by short-correlated thermal noise in a system with frozen structural disorder (see, e.g., [1] for review). An extremely non-Gaussian statistics of the observables is an important feature of the disordered/glassy system. In this letter we demonstrate that strong deviation from Gaussianity is also typical for optical fiber telecommunication systems.

Birefringent disorder is caused by weak random ellipticity of the fiber cross section. Birefringence splits the pulse into two polarization components and it also leads to pulse broadening [2, 3, 4]. This effect known as polarization mode dispersion (PMD) have been extensively studied experimentally [5, 6, 7, 8, 9, 10] and theoretically [11, 12, 13]. PMD is usually characterized by the so-called PMD vector that was found to obey Gaussian statistics [11, 12, 13]. It was also shown, e.g. in [14], that first order PMD compensation corresponding to cancellation of the PMD vector on the carrier frequency is experimentally implementable. Higher-order generalizations of the PMD vector (introduced to resolve complex frequency dependence of the PMD phenomenon with higher accuracy) as well as a suggestion on how to compensate for PMD in the higher orders have been also discussed [16] and implemented experimentally, e.g. in [15]. This works were focused on separating effects caused by PMD

from other potential impairments. Common wisdom hiding behind this strategy says that one should start with evaluating the two impairments separately and then estimate the joint effect on the optical telecommunication system performance taking them on equal footing. In this letter we challenge this equal-footing approach. We show that the effects of temporal noise and structural disorder on the overall system performance may not be separated since the bit-error-rate (BER) strongly depends on a realization of birefringent disorder. Thus, the probability distribution function (PDF) of BER and especially its tail corresponding to large values of BER are the objects of prime interest and practical importance for describing the probability of the system outage.

Our letter is organized as follows. We start with discussing the dynamical equations for an optical pulse evolution in a birefringent fiber also influenced by the amplifier noise. BER produced by the amplifier noise for a given realization of the birefringent disorder is analyzed first. Then we describe the PDF of BER, found by averaging over many realizations of disorder. Some general remarks conclude the letter.

The envelope of the electromagnetic field propagating through optical fiber in the linear regime (i.e. at relatively low pulse intensity), which is subject to PMD distortion and amplifier noise, satisfies the following equation [2, 3, 17]

$$\partial_z \Psi - i\hat{\Delta}(z)\Psi - \hat{m}(z)\partial_t \Psi - id(z)\partial_t^2 \Psi = \xi(z, t), \quad (1)$$

where z is the position along the fiber, t is the retarded time (measured in the reference frame moving with the optical signal), ξ is the amplifier noise, and d is the chromatic dispersion coefficient. The envelope Ψ is a two-component complex field where the components stand for two polarization states of the optical signal. Birefringent disorder is characterized by two random Hermitian 2×2 traceless matrices $\hat{\Delta}$ and \hat{m} measuring fiber birefringence in the first- and second-order and corresponding to the first two terms of the expansion in $\omega - \omega_0$ with ω and ω_0 being the signal and carrier frequencies

respectively. The disorder is frozen at least on all the propagation related time scales, i.e. the two matrices can be considered to be t -independent. The random matrix, $\hat{\Delta}(z)$, can be excluded from the consideration by means of the transformation to the coordinate system rotating together with polarization state of the signal at the carrier frequency: $\Psi \rightarrow \hat{V}\Psi$, $\xi \rightarrow \hat{V}\xi$ and $\hat{m} \rightarrow \hat{V}\hat{m}\hat{V}^{-1}$. Here, the unitary matrix $\hat{V}(z)$ is the ordered exponential, $T \exp[i \int_0^z dz' \hat{\Delta}(z')]$ defined as the solution of the equation, $\partial_z \hat{V} = i \hat{\Delta} \hat{V}$, with $\hat{V}(0) = \hat{1}$. Hereafter we use the notations \hat{m} , ξ and Ψ for the renormalized objects whereas the original objects will be no more referred to. With this notation the equation for Ψ has the same form as Eq. (1) if we set $\hat{\Delta} = 0$. The solution of the renormalized equation can be partitioned into a sum of a homogeneous contribution, insensitive to the additive noise and the inhomogeneous one, ϕ and φ , respectively:

$$\varphi = \hat{W}(z)\Psi_0(t), \quad \phi = \int_0^z dz' \hat{W}(z)\hat{W}^{-1}(z')\xi(z', t), \quad (2)$$

$$\hat{W}(z) = \exp \left[i \int_0^z dz' d(z') \partial_t^2 \right] T \exp \left[\int_0^z dz' \hat{m}(z') \partial_t \right], \quad (3)$$

where Ψ_0 describes the input pulse shape (at $z = 0$).

We assume the optical system length Z is much larger than the distance between the next-nearest amplifier stations. (The stations are set to compensate for losses in the pulse intensity.) Coarse-graining on the inter-amplifier scale allows treating amplification in the continuous limit. Zero in average additive noise, ξ , is the amplification leftover. The amplifier noise has Gaussian statistics [18] and its correlation time (set by quantum excitation processes in amplifiers) is much shorter than the pulse width. Therefore, ξ -statistics is fully determined by its pair correlation function

$$\langle \xi_\alpha(z_1, t_1) \xi_\beta^*(z_2, t_2) \rangle = D_\xi \delta_{\alpha\beta} \delta(z_1 - z_2) \delta(t_1 - t_2), \quad (4)$$

where the coefficient D_ξ characterizes the noise strength.

Averaging over birefringent disorder is of different nature: statistics here is collected over different fibers or, alternatively, over different states of the same fiber collected over time. (Birefringence is known to vary on a time scale essentially exceeding the pulse propagation time.) The matrix \hat{m} can be expanded in the Pauli matrices, $\hat{m}(z) = h_j(z)\hat{\sigma}_j$, where h_j is a real three-component field. The field is zero in average and short-correlated in z . It enters the observables described by Eqs. (2,3) in an integral form and, according to the central limit theorem (see, e.g., [19]), can be treated as a Gaussian random field described by the following pair correlation function

$$\langle h_i(z_1) h_j(z_2) \rangle = D_m \delta_{ij} \delta(z_1 - z_2), \quad (5)$$

where D_m characterizes the disorder strength. Note that even though the original \hat{m} entering Eq. (1) is anisotropic the isotropy of h_j [implied in Eq. (5)] is restored as a result of the $\hat{m} \rightarrow \hat{V}\hat{m}\hat{V}^{-1}$ transformation.

We discuss here the case of the so-called return-to-zero (RZ) modulation format when pulses in a given frequency channel are well separated in t . Detection of a pulse at the fiber output corresponding to $z = Z$ requires a measurement of the pulse intensity, I ,

$$I = \int dt G(t) |\mathcal{K}\Psi(Z, t)|^2, \quad (6)$$

where the function $G(t)$ is a convolution of the electrical (current) filter function with the sampling window function (limiting the information slot). The linear operator \mathcal{K} in Eq. (6) stands for an optical filter and may also incorporate a variety of engineering “tricks” applied to the output signal $\Psi(Z, t)$. Ideally, I takes a distinct value if the bit is “1” and is negligible if the bit is “0”. Both the noise and the disorder enforce I to deviate from its ideal value. One declares the output signal to code 0 or 1 if the value of I is less or larger than the decision threshold I_0 . The information is lost if the output value of the bit differs from the input one. The probability of such event should be small (this is a mandatory condition for a successful fiber line performance) i.e. both impairments typically cause only small distortion to a pulse. Formally, this means: $D_\xi Z \ll 1$, $D_m Z \ll 1$, where both the initial signal width and its amplitude are rescaled to unity.

Below we focus our analysis on the initially “1” (unitary) bit. We do not consider the evolution of a zero bit since it does not contribute to the anomalously large values of BER, which we are mainly interested to describe. The probability to loose the unitary bit is $B = \int_0^{I_0} dI P(I)$. Here $P(I)$ is the PDF of the signal intensity (6) (that fluctuates due to the noise ξ) for the initial signal Ψ_0 corresponding to the bit “1”. In engineering practice BER is measured collecting the statistics over many initially identical pulses. (As different pulses sense different realizations of the noise, this averaging over different pulses is actually equivalent to the noise averaging.) Repeating the measurement of B many times (each separated from the previous one by a time interval larger than the characteristic time of the disorder variations or, alternatively, making measurements on different fibers) one constructs the PDF of B , $\mathcal{S}(B)$. The PDF achieves its maximum at B_0 , a typical value of B . Even though the average distortion of a pulse caused by the noise and disorder is weak, rare but violent events may substantially affect the optical system performance. The probability of such rare events is determined by $\mathcal{S}(B)$ taken at $B \gg B_0$. Our further analysis is focused on this PDF tail.

Mentioning the importance of accounting for an appropriate form of the linear operator \mathcal{K} , we restrict our discussion to two possibilities, when the optical filtering is accompanied by an overall time shift (this operation is usually called “setting the clock”) or by a compensation achieved by insertion of an additional piece of fiber with adjustable birefringence. Optical filter is re-

quired to separate different frequency channels. In addition the filter smoothes out an otherwise strong impact on the pulse caused by amplifier noise temporal ultra-locality. “Setting the clock” procedure is formalized as, $\mathcal{K}_{cl}\Psi = \Psi(t - t_{cl})$, where t_{cl} is an optimal time delay. The so-called first-order compensation means

$$\mathcal{K}_1\Psi = \exp\left[-\int_0^Z dz \hat{m}(z)\partial_t\right]\Psi, \quad (7)$$

where the usual exponent (instead of the ordered one) enters Eq. (3). In the engineering practice or laboratory experiments all the three strategies (along with some additional others) can be applied simultaneously. Below we imply that the optical filter is always inserted. As far as the “setting the clock” and the first-order compensation procedures are concerned we intend to compare those effects with the pure (no compensation) case.

The first step in our calculations is to find the value of B for a given realization of disorder. In this case the φ -part of the envelope Ψ is a constant (dependent on the disorder) while the ϕ -contribution fluctuates. One obtains from Eqs. (2,4) that ϕ is a zero mean Gaussian variable, with the pair correlation function $\langle\phi_\alpha(z, t_1)\phi_\beta^*(z, t_2)\rangle = D_\xi z\delta_{\alpha\beta}\delta(t_1 - t_2)$. Note that statistics of ϕ is sensitive neither to the chromatic dispersion coefficient d nor to the birefringence matrix \hat{m} . Thus, averaging over the noise statistics is reduced to a Gaussian path integral over ϕ . The inequality $D_\xi Z \ll 1$ justifies the saddle-point evaluation of the integral and also allows to estimate $\ln B$ as $\ln P(I_0)$. Thus, one finds that the product $D_\xi Z \ln B$ is a negative quantity of order one, insensitive to the noise characteristics. This quantity depends on the initial signal profile Ψ_0 , disorder h_j , integral chromatic dispersion $\int_0^Z d(z)dz$, and also on the details of the measurement and compensation procedures.

We next analyze the dependence of B on the birefringent disorder. The smallness of $D_\xi Z$ means that even weak disorder can produce large deviations in B from its typical value B_0 , $\ln B_0 \sim -(D_\xi Z)^{-1}$, corresponding to $h_j = 0$. Therefore $\ln(B/B_0)$ can be represented as a series in h_j . The leading contribution is found upon expanding the ordered exponential (3) [entering φ in accordance with Eq. (2)] in a series in \mathbf{h} , followed by substituting the result for φ into Eq. (6), and performing the saddle-point calculations, aiming to find $P(I_0)$. The smallness of $D_\xi Z$ enables us to substitute $\ln B$ by $\ln P(I_0)$. Then, in the second-order in h , one obtains

$$\begin{aligned} \ln(B/B_0) &= \Gamma/(D_\xi Z), \quad \Gamma = \mu_1 H_3 + \mu_2 H_j^2 \quad (8) \\ &+ \mu'_2 \int_0^Z dz_1 \int_0^{z_1} dz_2 [h_1(z_1)h_2(z_2) - h_2(z_1)h_1(z_2)], \end{aligned}$$

where $H_j = \int_0^Z dz h_j(z)$ and the initial pulse Ψ_0 is assumed to be linearly polarized. The coefficients μ entering Eq. (8) are sensitive to the initial signal profile Ψ_0 ,

chromatic dispersion and to the measurement procedure. The coefficients can be calculated only numerically, however, some conclusions based on the general form of Eq. (8) can be drawn without this detailed calculations.

If no correction procedure is applied to the output signal then $\mu_2 \sim 1$, whereas μ_1 and μ'_2 are corrections related to the temporal asymmetry of the pulse (produced by the optical filter) and to the so-called the pulse chirp (generated by the dispersion term), respectively. If no compensation is applied the leading role is played by the first term in Eq. (8), and one arrives at $\ln \mathcal{P} \approx -\Gamma^2/(2\mu_1^2 D_m Z)$. If the “setting the clock” procedure applies (with t_{cl} dependent on \mathbf{h} : $t_{cl} = t_0 - H_3$, with t_0 being the optimal time shift without disorder), the first-order term in the right-hand side of Eq. (8) cancels out and the second-order term is dominated by $\mu_2(H_1^2 + H_2^2)$. According to Eqs. (2,3) the statistics of B depends on the integral dispersion $\int_0^Z dz d(z)$. In practice some special technical efforts (dispersion compensation) are made to reduce it, so that usually this quantity is small. If the initial pulse is real (there is no chirp) and if the integral dispersion is small, then μ'_2 is negligible. In this case Eq. (5) leads to the following PDF of Γ

$$\mathcal{P}(\Gamma) = \frac{1}{2\mu_2 D_m Z} \exp\left(-\frac{\Gamma}{2\mu_2 D_m Z}\right). \quad (9)$$

If the first-order compensation scheme described by Eq. (7) is used the first two terms in the right-hand side of Eq. (8) cancel out, $\mu_1 = \mu_2 = 0$, and if in addition $\mu'_2 \neq 0$ one arrives at

$$\mathcal{P}(\Gamma) = (2D_m Z \mu'_2)^{-1} \cosh^{-1}\left(\frac{\pi\Gamma}{2\mu'_2 D_m Z}\right), \quad (10)$$

replacing Eq. (9). Comparing Eqs. (9,10) with the result for the no-compensation case we conclude that the compensations lead to much narrower PDF. If μ'_2 is also 0 (i.e. if the first order compensation is applied and the output signal is not chirped) then higher-order terms in the expansion of Γ in h_j should be accounted for. This case will be discussed elsewhere.

Finally, we are in a position to analyze the PDF of B , $\mathcal{S}(B)$. Expressing Γ via B according to (8) followed by substituting the result into Eq. (9) for the PDF of Γ leads to the following expression for the remote ($\mathcal{B} \gg \mathcal{B}_0$) tail of the PDF of \mathcal{B}

$$\mathcal{S}(B) dB \sim \frac{B_0^\alpha dB}{B^{1+\alpha}}, \quad \alpha = \frac{D_\xi}{2\mu_2 D_m}. \quad (11)$$

The applicability range for Eq. (11) is given by $1 \gg \Gamma \gg D_m Z$ that transforms into $1/(D_\xi Z) \gg \ln(B/B_0) \gg D_m/D_\xi$. If the first-order compensation is applied Eq. (9) should be replaced by Eq. (10), thus leading to the same expression (11) for the tail with μ_2 replaced by μ'_2/π . The dependence of the PDF on BER is illustrated in Fig. 1. One also finds from Eq. (11) that the so-called

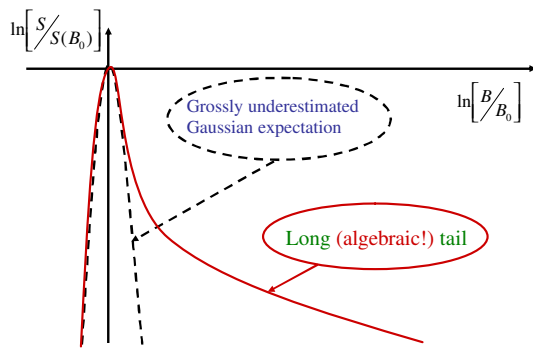

FIG. 1: Schematic log-log plot of the PDF of Bit-Error-Rate.

outage probability, $\mathcal{O} \equiv \int_{B_*}^1 dB \mathcal{S}(B)$, where B_* is some fixed value taken to be much larger than B_0 , is estimated as $\ln \mathcal{O} \sim (D_\xi/D_m) \ln(B_0/B_*)$.

There is also a universal remote tail of $\mathcal{S}(B)$ corresponding to huge fluctuations of the disorder when the signal is almost destroyed by the fluctuations. In this extreme case I is close to the threshold value I_0 already at $\xi = 0$. Then B is nothing but a probability of such an event (i.e. the noise configuration ξ) that the inhomogeneous contribution ϕ would fill the remaining small gap between I and I_0 . Thus one gets $\ln B \sim -\phi^2/(D_\xi Z)$. The value of ϕ is proportional to the deviation δh of the h -disorder term from such a special configuration, h_{sp} , which gives $I = I_0$ at $\xi = 0$. Therefore, one estimates, $\ln B \sim -(\delta h)^2 Z/D_\xi$. The logarithm of the probability for this disorder configuration to occur is a sum of two contributions: $\sim -1/(D_m Z)$, corresponding to the special configuration, h_{sp} , and the other one, $\sim \delta h/D_m$, corresponding to δh . One arrives at the following expression for the probability density

$$\ln \mathcal{S}(B) \approx -\frac{C_1}{D_m Z} + C_2 \sqrt{\frac{D_\xi}{D_m^2 Z}} \ln \frac{1}{B}, \quad (12)$$

where C_1 and C_2 are constants of order one. Eq. (12) holds when $(D_m Z)^2 \ll D_\xi Z |\ln B| \ll 1$. Note, that the remote tail (12) decays with B faster than the algebraic one (11).

Eq. (11) describes our major result: The PDF of BER has a long algebraic tail. The exponent α of the algebraic decay is proportional to the ratio of the amplifier noise variance, D_ξ , to the birefringent disorder variance, D_m . This statement clearly shows that effects of noise and disorder are, actually, inseparable. Another interesting feature of Eq. (11) is that the exponent α is Z -independent. The only Z -dependent factor in the final result (11) is the overall normalization factor B_0^α . Note also that even though an extensive experimental (laboratory and/or field trial) confirmation of this statement would be very welcome, some numerical results, consis-

tent with Eq. (11) are already available. Thus, Fig. 2a of [20] re-plotted in log-log variables shows a linear relation between $\ln S$ and $\ln B$, i.e. just the algebraic decay predicted by Eq. (11).

Summarizing, this letter is the first brief report on the new method/approach. We plan to discuss many related but more specific issues, e.g. more complex compensation strategies (periodic and higher-order compensation) in subsequent publications in specialized optical journals. However, it is important to stress that the major result of the paper that the PDF of BER is characterized by a long tail (algebraic or faster, but slower than exponential) is universal.

We are thankful to I. Gabitov for numerous extremely valuable discussions and G. Falkovich for useful comments. We also wish to acknowledge the support of LDRD ER on ‘‘Statistical Physics of Fiber Optics Communications’’ at LANL.
