(Dated: October 25, 2018)

We study a dynamical Ising model of agents' opinions (buy or sell) with coupling coefficients reassessed continuously in time according to how past external news (magnetic field) have explained realized market returns. By combining herding, the impact of external news and private information, we test within the same model the hypothesis that agents are rational versus irrational. We find that the stylized facts of financial markets are reproduced only when agents are over-confident and mis-attribute the success of news to predict return to herding effects, thereby providing positive feedbacks leading to the model functioning close to the critical point.

PACS numbers: 64.60.Ht; 89.65.Gh; 87.23.Ge

Social systems offer a fascinating field for the application of recent concepts and methods developed in Physics to tackle complex N-body systems with nonlinear feedbacks, and many competing states. A long tradition started with the application of Ising models and its extensions to social interactions and organization [1, 2, 3, 4]. A large set of economic models can be mapped to various versions of the Ising model to account for social influence in individual decisions (see [5] and references therein). Other recent works using the Ising model include models of bubbles and crashes [6, 7], a version with stochastic coupling coefficients which leads to volatility clustering and a power law distribution of returns at a single fixed time scale [8], and models of opinion polarization [9, 10]. The dynamical updating rules of the Ising model can be shown to describe the formation of decisions of boundedly rational agents [11] or to result from optimizing agents whose utilities incorporate a social component [5]. The Ising model is one of the simplest models describing the competition between the ordering force of imitation or contagion and the disordering impact of private information or idiosyncratic noise, which leads already to the crucial concept of spontaneously symmetry breaking and phase transitions [12].

However, human beings are not spins, they can learn, that is, adapt the nature and strength of their interactions with others, based on past experience. In the language of the Ising model, this amounts to generalize to time-dependent coupling coefficients which reflect past experience. Here, we study a generalized Ising model of interacting agents buying and selling a single financial asset who base their decisions on a combination of mutual influences or imitation, external news and idiosyncratic judgements. The novel ingredient is that they update their willingness to extract information from the other agents' behavior based on their assessment of how past news have explained market returns. Agents update their propensity to herding according to how the news have been successful in predicting returns. We distinguish between two possible updating rules: rational and irrational. In the rational version, agents decrease their propensity to imitate if news have been good predictors of returns in the recent past. In the irrational version, agents mis-attribute the recent predictive power of news to their collective action, leading to positive selfreinforcement of imitation. We show that the model can reproduce the major empirical stylized facts of financial stock markets only when the updating of the strength of imitation is irrational, providing a direct test and the evidence for the importance of misjudgement of agents biased toward herding. This model also offers a dynamical derivation of the multifractal properties of the structure functions of the absolute values of returns and their consequences in the characteristic power law relaxations of the volatility after bursts of endogenous versus exogenous origins.

Consider  $n^2$  agents interacting within a  $n \times n$  2D square lattice network  $\mathcal{N}$  (we have verified that the properties described below are not sensitive to n in the range 20 – 100 that we tested). At each time step t, agent i places a buy  $(s_i(t) = +1)$  or sell  $(s_i(t) = -1)$  order according to the following process

$$s_i(t) = \operatorname{sign}\left[\sum_{j \in \mathcal{N}} K_{ij}(t) \operatorname{E}[s_j](t) + \sigma_i(t)G(t) + \epsilon_i(t)\right],$$
(1)

where  $E[s_j](t)$  is the expectation formed by agent *i* on what will be the decision of agent *j* at the same time *t*. An agent *i* imitates only her friends, that is  $K_{ij} = 0$  if i = j or *j* is not a friend of (connected to) *i*. Expression (1) embodies three contributions: (i) Imitation in which  $K_{ij}$  is the relative propensity of the trader *i* to be contaminated by the sentiment of her friend j; (ii) The impact G(t) of external news (positive resp. negative for favorable resp. unfavorable news) and  $\sigma_i(t)$  is the relative sensitivity of agent's sentiment to the news, uniformly distributed in the interval  $(0, \sigma_{\text{max}})$  and frozen to represent the heterogeneity of the agents; (iii) Idiosyncratic judgement  $\epsilon_i(t)$  associated with private information, assumed to be normally distributed around zero with an agent-dependent standard deviation  $s_{\epsilon,i}$  equal to the sum of a common constant CV and of a uniform random variable in the interval [0, 0.1] again to capture the heterogeneity of agents. We have tested several implementation of the formation of expectations  $E[s_i](t)$  in (1), such as backward looking  $(E_i[s_j](t) = s_j(t-1))$  for all i and j's) or information cascades along specific chains within the network [13], which give similar results.

We account for the adaptive nature of agents and their learning abilities by updating the coefficient of influence of agent j on agent i according to the following rule:

$$K_{ij}(t) = K_i(t) = b_i + \alpha K_i(t-1) + \beta r(t-1)G(t-1) .$$
(2)

The idiosyncratic imitation tendency  $b_i$  of agent i is uniformly distributed in  $(0, b_{\text{max}})$  and frozen. The coefficient  $\alpha$  quantifies the persistence of past influences on the present (the case  $\alpha = 0$  has been studied in part in Ref. [13]). It captures the fact that social connections evolve slowly and exhibit significant persistence, as documented in numerous studies [14]. Networks of investors communicating their opinions and sentiment on the stock market are similarly persistent. The last term with  $\beta \neq 0$ quantifies how agent i updates her propensity for imitation based on the role of the exogenous news G(t) in determining the sign and amplitude of the observed return in the preceding time period. Note that, by construction, the model is non-variational as  $K_{ji}(t) \neq K_{ij}(t)$  in general if the  $b_i$ 's are different, but this is not crucial for our results. Finally, the market price is updated according to  $p(t) = p(t-1) \exp[r(t)]$  where the return r(t) obeys  $r(t) = \frac{\sum_{i \in \mathcal{N}} s_i(t)}{\lambda N}$ , where  $\lambda$  measures the market depth or liquidity. The return is thus proportional to the "magnetization" or aggregated decisions of the agents.

The sign of the coefficient  $\beta$  is crucial. For  $\beta < 0$ , agent i is less and less influenced by other agents, the better has been the success of the news in determining the direction and amplitude of the market return. This process is self-reinforcing since, as  $K_{ij}$  decreases, the dominant term becomes  $\sigma_i(t)G(t)$ , which further ensures that the news correctly predict the decision of agents and therefore the direction of the market move, thus decreasing further the coefficient of influence  $K_{ij}$ . Reciprocally, agents tends to be more influenced by others when the news seems to incorrectly predict the direction of the market. The news being not reliable, the agents turn to other agents, believing that others may have useful information. This is in agreement with standard economics which views

the stock market as an efficient machine transforming all news into prices.

For  $\beta > 0$ , the more the news predict the direction of the market, the more the agents imitate other agents. This is the "irrational" case where agents either misattribute the origin of the market moves to herding rather than to the impact of news, or misinterpret the exogenous character of news in terms of endogenous herding or infer that other agents will be following more eagerly as a group the direction given by the news. This may occur due to mutually-reinforcing optimism [15] and overconfidence [16].

In our simulations, we fix  $\lambda = 40$  to obtain returns with amplitudes comparable to that of empirical observations and  $\alpha = 0.2$ . Similar results are obtained for  $\alpha = 0.4, 0.6$ , and 0.8. We have explored the properties of the model in the parameter space of  $b_{\max}$ ,  $\sigma_{\max}$  and CV. There is no loss of generality in fixing  $|\beta| = 1$  to explore the relative importance of the term  $\beta r(t-1)G(t-1)$ , since the typical scale of the  $K_i$ 's is set by  $b_{\max}$  whose amplitude is varied in our numerical exploration.

For  $\beta = -1$ , it is easy to show that the attractor of the dynamics is characterized by negligible imitation and only the news and private information terms are important for the dynamics. Indeed, starting from large  $K_i(t)$ 's such that the system is above its critical value  $K_c$  and the agents behave collectively (ferromagnetic phase), the news G(t) acts as a "magnetic" field which orders the agents' decision accordingly, leading to the news correctly predicting the returns. Since  $\beta = -1$ , the coupling coefficients  $K_i$ 's will be decreased by the amount |r(t)|. This will continue until the  $K_i$ 's are in majority much smaller than  $K_c$ , at which point the dynamics becomes stable in the "paramagnetic" phase because the collective decision  $\sum_{i} s_i$  and therefore the market return have little or no relationship with the external news. Hence, the term  $\beta r(t+1)G(t)$  takes random signs from one time step to the next, leading to an effective random forcing added to the autoregressive equation  $K_i(t) = b_i + \alpha K_i(t-1)$ . We thus expect Gaussian distributions of returns when  $b_i/(1-\alpha)$  is smaller than  $K_c$  and bimodal distributions when  $b_i/(1-\alpha) > K_c$  reflecting the slaving of the global opinion to the sign of the news. Our simulations, which have scanned 480 different models for  $b_{\rm max}$  from 0.1 to 0.5 with spacing 0.1,  $\sigma_{\rm max}$  from 0.005 to 0.08 with spacing 0.005, and CV from 0.1 to 1.1 with spacing 0.2, confirm this prediction. Consider the distribution of returns  $r_{\tau}(t) = \ln[p(t)/p(t-\tau)]$  at different time scales  $\tau$ . For large idiosyncratic noise (large CV) and not too large  $b_{\rm max}$ , the distribution of returns is Gaussian for all time scales  $\tau$ . For smaller CV's and larger  $b_{\max}$ , we observe multimodal return distributions. In the parameter space that we have explored and notwithstanding our best attempts, we have not been able to find a set of parameters leading to distributions of returns exhibiting a monomodal shape with fat tails for small time scales,

evolving slowly towards Gaussian distributions at large time scales, as can be observed in empirical data [17]. In addition, the correlation function of returns  $(C_{\tau}(r, r))$ and of volatilities  $(C_{\tau}(|r|, |r|))$  have similar amplitudes and decay with the same characteristic time scale as a function of time lag. This is very different from the observed correlations of financial markets, with very short memory for returns and long-memory for the volatility.

For  $\beta = 1$ , we obtained the following main stylized facts of financial stock markets: (i) distributions of returns at different time scales  $\tau$  (Fig. 1); (ii) correlation function of returns and of the absolute value of the returns (Fig. 2); (iii) scaling of the moments of increasing orders of the absolute values of the returns (testing multifractality); (iv) the existence of a hierarchy of exponents controlling the relaxation of the volatility after an endogenous shock, another hallmark of multifractality (Fig. 3); (v) the existence of bubbles and crashes. We have explored 160 models with  $b_{\text{max}}$  from 0.1 to 0.5 with spacing 0.1,  $\sigma_{\rm max}$  from 0.01 to 0.08 with spacing 0.01, and CV from 0.1 to 0.7 with spacing 0.2. For each model, we generate time series of length equal to  $10^5$ time steps. We have found several parameter combinations which lead to realistic stylized facts, for instance,  $(b_{\max}, \sigma_{\max}, CV)$  equal respectively to (0.3, 0.03, 0.1),(0.4, 0.04, 0.1), (0.4, 0.05, 0.1), (0.5, 0.06, 0.1), (0.1, 0.01),(0.3), (0.1, 0.02, 0.3), (0.2, 0.02, 0.3), (0.2, 0.03, 0.3), (0.(0.04, 0.3), (0.5, 0.05, 0.3), (0.5, 0.07, 0.3), (0.3, 0.03, 0.5), (0.4, 0.3), (0.5, 0.05, 0.3), (0.5, 0.07, 0.3), (0.5, 0.03, 0.5), (0.5, 0.03),and (0.5, 0.05, 0.5). The results presented here are for  $(b_{\text{max}} = 0.3, \sigma_{\text{max}} = 0.03, CV = 0.1)$  which is typical.

FIG. 1: (Color online) Probability distribution density (in logarithmic scales) of log-returns at different time scales  $\tau$  of a price time series obtained with  $\lambda = 40$ ,  $\alpha = 0.2$ ,  $b_{\text{max}} = 0.3$ ,  $\sigma_{\text{max}} = 0.03$ , and CV = 0.1. The log-returns  $r_{\tau}$  are normalized by their corresponding standard deviations  $\sigma_{\tau}$ . The pdf curves are translated vertically for clarity. The thick dashed line is the Gaussian pdf. The other dashed lines have been obtained by  $\tau$ -fold convolutions of the pdf of the one-time step return  $r_1(t) = \ln p(t)/p(t-1)$ .

Figure 1 shows the evolution of the pdf's of returns from stretched exponential or power laws at short time scales that cross over smoothly to a Gaussian law at the largest shown time scale, in excellent agreement with empirical facts [17]. Note the difference between the continuous and dashed lines for  $\tau = 4$ , 16, and 64, which expresses the existence of significant dependence in the time series of returns. Such behavior is very similar to what is observed in real data.

FIG. 2: (Color online) Impact of  $\alpha$  on the auto-correlation of the absolute values of the returns.

The temporal correlation of the log returns  $r_1$  as a function of the time lag  $\ell$  exhibits a very short correlation time, of duration smaller than one time step (not shown). In contrast, the temporal correlation of the absolute value of log returns  $r_1$  ("volatility"), taken as a proxy for the volatility, exhibits long-range dependence up to approximately 1000 time steps. The linear-log relationship suggested by the plots in Fig. 2 are predicted by the multifractal random walk (MRW) [18], which provides an excellent model of many properties of financial time series [19]. The MRW depends only on three parameters: the multifractal parameter  $\lambda^2 \approx 0.02 - 0.04$ , the integral time scale  $T \approx 1$  year and the standard deviation of returns. Comparing the dependence properties of the returns and of the volatility suggests that one trading day corresponds roughly to 5 time steps of the model. This correspondence translates into a integral time scale T of about 200 days, which is compatible with empirical estimates for the MRW [20]. The MRW also predicts (and this is well-verified by empirical data) that the auto correlation functions of  $|r_{\tau}(t)|$  for different  $\tau$  should superimpose for time lags larger than their respective  $\tau$ [18]. This prediction is also approximately observed in our model (not shown).

Another important stylized facts is the multifractal structure of the absolute values of log-returns [20, 21]. We verify the existence of a strong multifractality in our time series (not shown) expressed by the scaling of the structure function  $M_q(\tau) \equiv \langle |r_\tau|^q \rangle \sim \tau^{\xi_q}$ , with exponents  $\xi_q$  exhibiting a clear nonlinear dependence as a function of the order q of the structure function. Rather than showing this standard looking multifractal spectrum, we show in Fig. 3 another striking signature of multifractality discovered first in empirical data [22]: the MRW predicts a continuous spectrum of exponents  $\eta(s)$  for the relaxation of the volatility  $E[\sigma^2(t)|s] \sim t^{-\eta(s)}$  from a local peak as a function of its amplitude  $\propto e^s$  given by

$$\eta(s) = \frac{2s}{3/2 + \ln(T/\tau)} .$$
 (3)

FIG. 3: (Color online) For a given relative log-amplitude s of a local burst of volatility occurring at some time  $t_s$ , we translate and superimpose all time series starting at those times of local bursts of the same amplitude s. Averaging over these time series of volatility obtains the average conditional relaxation function of the volatility  $E[\sigma^2(t)|s] \sim t^{-\eta(s)}$  following a local burst of volatility of amplitude  $\propto e^s$ . The inset shows the average normalized conditional volatility  $E[\sigma^2|s]/E[\sigma^2]$  as a function of the time after the local burst of volatility for different log-amplitudes s. The figure shows the exponents  $\eta(s)$ measured as the slopes of the curves in the inset for  $\tau = 1, 2, 4$ , and 8.

We have outlined an Ising model with imitation between agents, their influence by external news and the impact of their private information, which describes the "digestion" of external news by the collective behavior of the population of traders to create time series of returns presenting long-range memory in the volatility and multifractal properties, in agreement with empirical data. This formulation has allowed us to test within the same model the hypothesis that agents are rational versus irrational. The empirical stylized facts of financial stock markets have been found only when agents misinterpret, or mis-attribute the source of the prediction of returns or are over-confident ( $\beta > 0$ ). We can interpret our results by saving that, conditioned on their role of reflecting the stock market, the news serve as the substrate for fostering social interactions and reinforcing herding. Technically, the stylized facts in this regime result from the fact that the model operates around the critical point of the corresponding Ising model, with coupling coefficients which are time-dependent and endowed with a memory of past

realizations. The critical point of the Ising model is associated with a critical value  $K_c$  for the average coupling coefficient. Close to this value, agents organize spontaneously within clusters of similar opinions, which become very susceptible to small external influences, such as a change of news. This may explain the occurrence of crashes as argued previously[23]. Intuitively, the critical slowing down well-known to characterize the proximity to the critical Ising point can explain the long-term memory of the volatility while the almost absence of correlation of the returns themselves is ensured by the impact of the news and the random idiosyncratic decisions.

As a bonus, we have discovered that this simple model exhibits a rich multifractal structure, diagnosed not only by the standard convexity of the exponents of the structure functions but also by a continuous spectrum of power law response functions to endogenous shocks [22, 24]. To our knowledge, this is the first nonlinear model in which such clear distinction is documented quantitatively, based on a bottom-up self-organization. In contrast, the multifractal random walk which has provided the theoretical predictions used here is a descriptive phenomenological model.
