Spatial fluctuations of guanine and cytosine base content (GC%) are studied by spectral analysis for the complete set of human genomic DNA sequences. We find that (i) the  $1/f^{\alpha}$  decay is universally observed in the power spectra of all twenty-four chromosomes, and that (ii) the exponent  $\alpha \approx 1$ extends to about  $10^7$  bases, one order of magnitude longer than what has previously been observed. We further find that (iii) almost all human chromosomes exhibit a cross-over from  $\alpha_1 \approx 1$  ( $1/f^{\alpha_1}$ ) at lower frequency to  $\alpha_2 < 1$  ( $1/f^{\alpha_2}$ ) at higher frequency, typically occurring at around 30,000–100,000 bases, while (iv) the cross-over in this frequency range is virtually absent in human chromosome 22. In addition to the universal  $1/f^{\alpha}$  noise in power spectra, we find (v) several lines of evidence for chromosome-specific correlation structures, including a 500,000 bases long oscillation in human chromosome 21. The universal  $1/f^{\alpha}$  spectrum in human genome is further substantiated by a resistance to variance reduction in guanine and cytosine content when the window size is increased.

## I. INTRODUCTION

By measuring the proportion of a signal's power S(f)falling into a range of frequency components f, a power spectrum of the form  $S(f) \sim 1/f^{\alpha}$  distinguishes between two prototypes of noise: white noise  $(\alpha = 0)$ and Brownian noise  $(\alpha = 2)$ . The intermittent range, termed "1/f noise", can practically be defined as  $1/f^{\alpha}$  $(0.5 \leq \alpha \leq 1.5)$ . 1/f noise was experimentally observed first in electric current fluctuations of the thermionic tube at the beginning of the nineteenth century [1]. Since then, 1/f noise has been found repeatedly in many other conducting materials [2]. More generally, it has also been observed in wide ranges of natural as well as human-related phenomena, including traffic flow, star light, speech, music and human coordination [3, 4]. For biological sequences, such as DNA, the concept of slowvarying, multiple-length variations in the power of frequency components can be translated to long-ranging correlations in the spatial arrangement of the four bases adenine (A), cytosine (C), guanine (G) and thymine (T). One can categorize chemically A, C, G, and T as strong (G or C) or weak (A or T) bonding. It has been shown that fluctuations of the GC base content along a DNA sequence are typically stronger correlated when compared to other possible binary classifications [5, 6]. Initial studies of 1/f noise in DNA sequences were motivated by a model of spatial 1/f noise of symbolic sequence evolution [7]. Subsequently, empirical 1/f spectra were indeed observed in non-protein-coding DNA sequences [8], and

their generality in DNA sequences was further illustrated in [9].

1/f noise has been detected in a variety of different species and taxonomic classes, including bacteria [10], yeasts [11], insects [12], and other higher eukaryotic genomes. Integrating this and several other lines of evidence, a consensus on 1/f noise in DNA sequences has emerged: (1) for DNA sequences of the order of  $10^6$  bases (1 Mb),  $1/f^{\alpha}$  spectrum ( $\alpha \approx 1$ ) is consistently observed; (2) for isochores, which are DNA sequences of relatively homogeneous base concentration at least  $300 \cdot 10^3$  bases (300 kb) long [13, 14, 15],  $1/f^{\alpha}$  spectrum is also observed, but typically shows a smaller exponent  $\alpha < 0.7$ [14, 16, 17]; (3) for DNA sequences of the order of several kb, the decay of S(f) is non-trivial and may depend on whether the sequence is protein-coding [8]. The viral DNA sequence of the  $\lambda$ -phage, e.g., shows a single step in its GC base concentration and its spectrum is  $S(f) \sim 1/f^2$ , which is characteristic of random block sequences [18]. We note that the universal scaling of  $S(f) \sim 1/f^{\alpha} \ (\alpha \approx 1)$  across all species discussed in [9] has apparently been restricted to a length scale of 1 kb, by averaging the spectrum over many N = 2 kb DNA segments.

With the availability of the first completed version of the DNA sequence of human genome [19], several studies have been able to demonstrate that the base-base correlation function  $\Gamma(d)$  (*d* distance between bases) of several DNA sequences follows a power-law decay,  $\Gamma(d) \sim 1/d^{\gamma}$ . For instance, the DNA sequence of human chromosome 22 shows statistically significant power-law correlations up to d = 1 Mb, and correlations in the DNA sequence of chromosomes 21 are statistically significant up to several Mb (with the scaling exponent  $\gamma$  changing beyond a few kb) [6, 20]. While the DNA sequences of human

FIG. 1: Double-logarithmic representation of the human genome-wide length distribution of interspersed repeat sequences, non-repetitive sequences, and sequences of unknown base composition (gaps). The length distribution of interspersed repeats and non-repetitive sequences exhibits a power-law-like decay, while that of gap sequences is scattered across different sequence length. The peaks at  $\sim 300$  bases and several kb correspond to Alu and possibly LINE repeats.

chromosomes 21 and 22 are about 34 Mb long, in order to estimate the limit of the range of  $1/f^{\alpha}$  spectrum, longer sequences are necessary.

After the release of the draft of the human genome sequence in February 2001, about three years later in 2004, a dozen (out of 24) human chromosomes have been completed with a sequence accuracy to following the standard of less than one error per 10,000 DNA bases (99.99% accuracy) [21]. Building upon the release of updated, high-quality sequence data, in the era of genomics we can now conduct a systematic analysis of several issues of 1/f noise in the DNA sequences of our own species *Homo sapiens*, which have been pursued over the last decade in a fragmentary manner.

In this paper, we use the DNA sequences of the complete set of twenty-two autosomes and two sex chromosomes to address the following issues: Is 1/f noise universally present across the entire set of human genome sequences? Does 1/f noise extend to lower frequency ranges in longer DNA sequences? Is the decay of S(f)characterized by a single exponent  $\alpha$ , or does it exhibit cross-overs (multiple scaling exponents)? Given the presence of universal variations at multiple scales, do these co-exist with variations at chromosome-specific scales?

# **II. DATA AND METHODS**

In this section, we introduce the data for human genome sequences, as well as the notation and definitions used throughout this study. Twenty-four chromosomes are assembled in build 34 of the NCBI (human genome hg16 release). Sequence data were downloaded from the UCSC human genome repository (available at

FIG. 2: Distribution of genome-wide GC content (GC%) of the human genome for interspersed repeat sequences, nonrepetitive sequences, and all ("overall") sequences with sequence segments of 20 kb. The mode (peak location) of nonrepetitive sequences is at ~35%, while the mode of repetitive sequences shifted to a higher GC% (~42%). The fraction of non-repetitive sequences with GC% > 50% is markedly larger as compared to the repetitive sequences.

http://genome.ucsc.edu/). Unsequenced bases are kept to preserve spacing between bases. Human chromosomes (Chr) 13, 14, 15, 21, and 22 contain large amount of unsequenced bases in the left end of their DNA sequences, consisting of about 15%, 17%, 18%, 21%, and 29% of the individual chromosome size, respectively; 51% of chromosome Y are unsequenced.

Our analysis on human DNA sequences is conducted using coarse-grained data. Each original sequence was transformed into a spatial series of GC content (GC%) values. To this end, we evenly partition a DNA sequence into N non-overlapping windows of length w bases, compute  $\rho_i(w) = \text{GC}\%_i$  for each window i, to obtain a spatial GC% series:

$$\{\rho_i\} \equiv \{\rho_i(w)\} \equiv \{GC\%_i\} \ i=1, 2, \dots, N$$
 (1)

Table 1 lists the corresponding window sizes for each human chromosome. Since different human chromosomes have different sizes, whereas the number of partitions (N)is the same, the window lengths vary.

Human DNA sequences contain a large fraction of interspersed repeats, i.e., copies of an ancestral sequence fragment that possess a high similarity between the duplicated and the ancestral sequence. One can detect interspersed repeats by using the program Repeat-Masker [22]. "Soft-masked" annotations of interspersed repeats are taken from the DNA sequences of the UCSC human genome repository (http://genome.ucsc.edu/), where repetitive (non-repetitive) bases are annotated in small (capital) letters. Figure 1 shows the length distribution of the three sequences classes of uninterrupted non-repetitive, interspersed repeat, and gap sequences. Figure 2 shows the corresponding distribution of the genome-wide GC% for these three sequences classes.

To investigate the effect of interspersed repeats, we

TABLE I: Average GC content  $(\overline{\text{GC\%}} \text{ or } \overline{\rho})$ , the window size (w) for partitions using  $N = 2^{17}$  non-overlapping windows for twenty-four human chromosomes. Low-frequency scaling exponents  $\alpha_1$  are estimated from  $S(f; s = 3) \sim 1/f^{\alpha_1}$  in the range of  $10^{-7} < f < 10^{-5}$  base<sup>-1</sup>, and high-frequency scaling exponents  $\alpha_2$  are estimated in the range of  $10^{-5} < f < 2 \times 10^{-4}$  base<sup>-1</sup>. The difference between the two scaling exponents,  $\Delta \alpha \equiv \alpha_2 - \alpha_1$ , are listed in the fifth column. Low- and high-frequency exponents for S(f) with substituted interspersed repeats are indicated by  $\alpha'_1$  and  $\alpha'_2$ , and their difference by  $\Delta \alpha' \equiv \alpha'_2 - \alpha'_1$ .

$\operatorname{Chr}$	$\overline{GC\%}$	w (kb)	$\alpha_1 \ \alpha_2$	$\Delta \alpha$	$\alpha_1'  \alpha_2'$	$\Delta \alpha'$

substitute them by random bases according to the chromosomal level of GC%. Transformed, repeat-substituted DNA sequences of original human chromosomes are distinguished from original sequences. On the coarsegrained level, it is equivalent to the replacement in the  $\{\rho_i\}$   $(i = 1, 2, \dots, N)$  series of any values calculated from the interspersed repeats by a random value which is sampled from a Gaussian distribution; the mean and variance of this Gaussian distribution is the same as those of GC% in the original sequence. Another possibility consists in substituting repetitive sequences by by a constant value (e.g., the averaged GC% value of the original sequence). This method introduces additional correlations (and less variance) in the  $\{\rho_i\}$  series, and is not adopted in this paper.

Three different, albeit functionally related, measures are applied to the  $\{\rho_i\}$  series: the power spectrum as a function of the frequency S(f), the correlation function  $\Gamma(d)$  as a function of the distance d between windows, and variance  $\sigma^2(w)$  of GC% series as a function of the window size w. First, we conduct spectral analyses by calculating the power spectrum, the absolute squared-average of the Fourier transform, defined as:

$$S(f) \equiv \frac{1}{N} \left| \sum_{k=1}^{N} \rho_k \cdot e^{-i2\pi k f/N} \right|^2.$$
 (2)

where N is the total number of windows, and f is measured in units of cycle/window, which can be converted to units of cycle/base by the window size (cf. Table 1).

Coarse-graining "hides" base-base correlations at scales smaller than w bases. The choice of  $N = 2^{17}$  windows was made such that it is (i) sufficiently large to cover small-scale fluctuations, while (ii) at the same time sufficiently small so that the spectral analysis is computationally feasible. As different chromosomes have difference lengths, equal number of partitions leads to different window sizes w.

The unsmoothed S(f), or periodogram, contains N/2independent spectral components. One can filter periodograms to obtain a "smoothed" spectrum S(f;s), where s is the span-size parameter. Since filtering with a relatively large s-value possibly distorts the shape of S(f;s) at lower frequency components, different spansizes are applied for different frequency ranges.

The second measure applied to the  $\{\rho_i\}$  series is the correlation function,  $\Gamma(d)$ , which is computed from two truncated series of  $\{\rho_i\}$ ,  $\rho' = \{\rho_k\}$  (k = 1, 2, ..., N - d) and  $\rho'' = \{\rho_k\}$  (k = d + 1, d + 2, ..., N):

$$\Gamma(d) \equiv \frac{\operatorname{Cov}(\rho', \rho'')}{\sqrt{\operatorname{Var}(\rho')}\sqrt{\operatorname{Var}(\rho'')}}$$
(3)

where  $\operatorname{Cov}(\rho', \rho'') = \langle \rho' \rho'' \rangle - \langle \rho' \rangle \langle \rho'' \rangle$  and  $\operatorname{Var}(\rho') = \langle \rho'^2 \rangle - \langle \rho' \rangle^2$  (or  $\operatorname{Var}(\rho'') = \langle \rho''^2 \rangle - \langle \rho'' \rangle^2$ ) are the covariance and variance. Note that the  $\Gamma(d)$  defined in Eq.(3) is slightly different from that defined using a periodic boundary condition.

The third and final measure applied to the  $\{\rho_i\}$  series is the variance  $\sigma^2(w)$ :

$$\sigma^2(w) \equiv \langle \rho(w)^2 \rangle - \langle \rho(w) \rangle^2 \tag{4}$$

as a function of the window size w. The power spectrum, the correlation function, and the window-size-dependent variance are interrelated quantities [16]:

$$\sigma^{2}(w) \sim \frac{\Gamma(0)}{w} \cdot \left\{ 1 + \frac{2}{w} \sum_{d=1}^{w-1} (w-d) \Gamma(d) \right\}.$$
 (5)

If  $S(f) \sim 1/f^{\alpha}$ ,  $\Gamma(d) \sim 1/d^{\gamma}$ ,  $\sigma^2(w) \sim 1/w^{\beta}$  are powerlaw functions, then their scaling exponents are related by  $\alpha = 1 - \gamma$  and  $\gamma = \beta$  [16].

The calculation of S(f) and  $\Gamma(d)$  was carried out by the statistical package *S-PLUS* (Version 3.4, MathSoft, Inc.), and the type of filter implemented for S(f) is the Daniell-filter [23].

## III. 1/f NOISE IS A UNIVERSAL FEATURE OF HUMAN DNA SEQUENCES

In this section, we use the power spectrum S(f) to study GC% of human genome sequences, with the goals of testing the universality of 1/f noise, quantifying different decay ranges for  $S(f) \sim 1/f^{\alpha}$ , and comparing S(f)across DNA sequences of different human chromosomes.

Figure 3 shows for  $N = 2^{17}$  GC% values the power spectra S(f) across all human chromosomes. We find that S(f) exhibits no clear plateau at low frequency  $(< 10^{-6}$  cycle/base) and increases steadily with decreasing frequency. The decay can be mathematically approximated by a power-law of the form  $S(f) \sim 1/f^{\alpha}$ with  $\alpha \approx 1$ . Table 1 lists for the frequency range f = 10 Mb<sup>-1</sup>-100 kb<sup>-1</sup> the estimated scaling exponent  $\alpha_1$  for all chromosomes, using a best-fit regression of  $\log_{10} S(f; s = 3) = a + \alpha_1 \log_{10}(f)$ . We find that  $\alpha_1$  is typically close to  $\alpha_1 \approx 1$  with practically little variation across chromosomes.

A closer inspection of Fig. 3 shows that the majority of 1/f spectra undergo a cross-over from  $\alpha_1 \approx 1$  to  $\alpha_2 < 1$  at high frequency. The deviation from  $\alpha_1 \approx 1$ starts about 30–100 kb and continues at smaller distances. Figure 4 illustrates this feature for S(f; s = 31)of the DNA sequences of Chr15, Chr21, and Chr22 in more detail. We find that chromosomes 15 and 21 exhibit clear cross-overs at about 100 kb, while chromosome 22 exhibits no apparent break-point. Table 1 contains for the frequency range of  $f = 100 \text{ kb}^{-1}-5 \text{ kb}^{-1}$  the corresponding scaling exponents  $\alpha_2$ , obtained from the regression  $\log_{10} S(f; s = 3) = a + \alpha_2 \log_{10}(f)$ . We find a pronounced difference in absolute values between  $\alpha_1 \approx 1$ and  $\alpha_2 < 1$ , indicating a transition from the universal  $1/f^{\alpha_1}~(\alpha_1~\approx~1)$  spectrum at low frequency to a more flattened  $1/f^{\alpha_2}$  ( $\alpha_2 < 1$ ) spectrum at higher frequency.

Figure 5(a) shows for all human chromosomes  $\alpha_1$  and  $\alpha_2$  as a function of chromosome-specific GC%. The majority of human chromosomes have a specific GC content ranging between 38–43%, whereas chromosomes 16, 17, 19, 20, and 22 have higher GC% up to 49%. While the low-frequency scaling exponent  $\alpha_1$  remains approximately independent of GC%, Fig. 5(a) shows that  $\alpha_2$  increases with increasing GC% and gives rise to a positive correlation between  $\alpha_2$  and GC%.

The three chromosomes illustrated in Fig. 4 exhibit different degrees of transition from the  $1/f^{\alpha_1}$  ( $\alpha_1 \approx 1$ ) to the flattened  $1/f^{\alpha_2}$  ( $\alpha_2 < 1$ ) spectrum, with chromosome 21 (22) undergoing the sharpest (smoothest) transition. This observation can be further quantitized by the change in scaling exponents  $\alpha_1$  and  $\alpha_2$ . Table 1 lists for all chromosomes  $\Delta \alpha = \alpha_2 - \alpha_1$ . Chromosome 22 is distinct from all other human chromosomes as the most scale-invariant one (same or similar scaling exponent at different length scales). The same observation that human chromosome 22 was perhaps different from the remaining human chromosomes was made using limited sequence data in [14, 20].

#### IV. INTERSPERSED REPEATS ARE NOT RESPONSIBLE FOR 1/f SPECTRUM

About 45% of human genomic DNA sequences are interspersed repeats [19]. Interspersed repeats consist of copies of the same sequence segment that are inserted in the human genome, possess a high similarity between the duplicated and ancestral sequence, and have been implicated in a variety of biological functions, including genome organization, human chromosome segregation, or regulation of gene expression [24]. Large copy numbers increase the sequence redundancy and it has been shown, e.g., that about 10% interspersed Alu repeats significantly increase base-base correlations in the range up to 300 bases [6].

Figure6 shows the power spectrum S(f) for the original human chromosome 1 and for the transformed sequence in which interspersed repeats are substituted. We find in the low-frequency range of  $10^{-7} < f < 10^{-5}$  cycle/base that S(f) decays in the original sequence with  $\alpha_1 \approx 0.88$ and in the transformed sequence with  $\alpha'_1 \approx 0.80$ , indicating only marginal differences in the decay properties of S(f) due to repetitive sequences. In contrast, in the high frequency range of  $10^{-5} < f < 2 \times 10^{-4}$  we find  $\alpha_2 \approx 0.46$ and  $\alpha'_1 \approx 0.29$ , and thus interspersed repeats contributes to the decay properties of S(f) for high-frequency components by flattening the power spectrum.

The scaling exponents  $\alpha'_1$  and  $\alpha'_2$  for repeat-substituted DNA sequences of all 24 human chromosomes are shown in Table 1. The difference between low- and highfrequency ranges for DNA sequences of original chromosomes,  $\Delta \alpha = \alpha_2 - \alpha_1$ , is smaller than the difference between low- and high-frequency ranges for transformed sequences,  $\Delta \alpha' = \alpha'_2 - \alpha'_1$ . When we compare  $\alpha_1$  and  $\alpha'_1$ , as well as  $\alpha_2$  and  $\alpha'_2$ , we find that the magnitude of  $\alpha'_1$  ( $\alpha'_2$ ) is always smaller than that of  $\alpha_1$  ( $\alpha_2$ ), which means a flattened spectrum due to the substitution of interspersed repeats. The average change of low-frequency scaling exponents,  $\alpha_1 - \alpha'_1$ , is about 0.07, whereas the average change of high-frequency scaling exponents,  $\alpha_2 - \alpha'_2$ , is about 0.14. This confirms that the universal presence of 1/f spectrum at low frequency is not caused by interspersed repeats, but that interspersed repeats affect S(f)predominantly at high frequencies. A similar conclusion that the decay rate of base-base correlations in DNA sequences of human chromosomes 20, Chr21, and Chr22 is not markedly affected by the substitution of interspersed repeats was reached in [6].

We note that the extent of deviation,  $|\alpha' - \alpha|$ , depends on how the replacement of interspersed repeats is conducted. Possible substitutions of interspersed repeats include the substitution by a constant value or a randomly sampled value. In general, the substitution of GC% values calculated from the repetitive sequences by random values enhances the deviation and flattens the spectrum S(f) more than the substitution by a constant value (e.g., average GC%).

FIG. 3: Double-logarithmic representation of power spectra S(f) of GC% of all twenty-four human chromosomes. Each plot shows S(f) of six chromosomes (shifted on the *y*-axis for clearer representation): chromosomes (a) 1–6; (b) 7–12; (c) 13–18; (d) 19–22, X, and Y. The *x*-axis (in logarithmic scale) is converted from cycle/window to cycle/base by using the window sizes listed in Table 1. S(f) is filtered at different levels for different frequency ranges: S(f; s = 1) for the first ten spectral components, S(f; s = 3) for the components 11–30, S(f; s = 31) for the components 31–400, and S(f; s = 501) for the components 400–65536 (=2<sup>16</sup>).

FIG. 4: Cross-over from  $S(f) \sim 1/f^{\alpha_1}$  to  $S(f) \sim 1/f^{\alpha_2}$ illustrated for human chromosomes 15, 21, and 22 (smoothed with the span size of 31, and shown in double-logarithmic scale). The scaling exponents  $\alpha_1$  and  $\alpha_2$  are shown for the frequency ranges 10 Mb<sup>-1</sup>-100 kb<sup>-1</sup> and 100 kb<sup>-1</sup>-5k<sup>-1</sup>.

# V. RESISTANCE TO VARIANCE REDUCTION AT LARGER WINDOW SIZES

In this section, we study the decay properties of the variance  $(\sigma^2)$  of spatial GC% series as a function of difference window sizes w, and we compare the scaling of  $\sigma^2$  with the scaling of the power spectrum S(f).

Early experimental measurement of the GC% distribution by using cesium chloride (CsCl) profile [25] showed

FIG. 5: (a) Scaling exponents  $\alpha_1$  and  $\alpha_2$  for fitting the power spectrum  $S(f) \sim 1/f^{\alpha_i}$  (i = 1, 2) at the frequency range of 10 Mb<sup>-1</sup>–100 kb<sup>-1</sup>, and 100 kb<sup>-1</sup>–5 kb<sup>-1</sup>, respectively, versus the chromosome-specific GC content of all 24 human chromosomes. (b) Scaling exponents  $\alpha'_1$  and  $\alpha'_2$  for S(f) with substituted interspersed repeats.

for mouse *Mus musculus* genomic DNA sequences that the variance of GC% values does not markedly decreases with the DNA segment size [26]. This experimental observation is directly related to the presence of 1/f spectra in DNA sequences [14, 27]. If the variance of the

FIG. 6: Power spectra S(f) of GC% for the original and the transformed (interspersed repeats substituted) DNA sequence of human chromosome 1. The scaling exponent for low-frequency (10 Mb–100 kb) and high-frequency (100 kb– 5 kb) ranges are obtained by a best-fit regression of  $\log_{10} S(f)$ over  $\log_{10} f$ .

spatial GC% series calculated at the window size w is  $\sigma^2(w)$ , then a scaling of  $\sigma^2(w) \sim 1/w^{\beta}$  implies a corresponding scaling in the power spectrum  $S(f) \sim 1/f^{1-\beta}$  [14, 28]. If GC% is obtained from w uncorrelated bases, it follows a binomial distribution. Consequently,  $\sigma^2(w) \sim \langle \rho \rangle (1 - \langle \rho \rangle) / w \sim 1/w$  with  $\beta = 1$ . The corresponding scaling exponent of the power spectrum is  $\alpha = 1 - \beta = 0$ , and thus the  $S(f) \sim \text{cons.}$  is equivalent to the white noise.

Figure 7 shows  $\sigma^2(w)$  as a function of window size w for all human chromosomes. In a double-logarithmic representation, we find that  $\log(\sigma^2(w))$  decays approximately linearly with  $\log(w)$ . A decay according to  $\sigma^2(w) \sim 1/w^{\beta}$ with  $\beta = 1$  leads to white noise. This situation is indicated in Fig. 7 by the straight line. An inspection of Fig. 7 shows, however, that the variance decays at a much slower rate than what would be for white noise. The variance of the DNA sequence of human chromosome 1, e.g., gives rise to  $\beta \approx 0.12$ , and the corresponding scaling exponent  $\alpha_1 \approx 1 - \beta = 0.88$  is indeed close to the estimated exponent listed in Table 1. The scaling of the variance with the exponent  $\beta << 1$  is in accord with the low-frequency 1/f noise.

The scaling of  $\sigma^2(w)$  shown in Fig. 7 differs from one human chromosome to another. For instance, in the range of w = 1 kb–5 Mb, for example, human chromosome 13 exhibit a clear transition from  $\beta_2 \approx 0.27$ (w < 50 kb) to  $\beta_1 \approx 0.10$  (w > 50 kb), corresponding to  $S(f) \sim 1/f^{0.63}$  and  $S(f) \sim 1/f^{0.9}$ , respectively, at highand low-frequency ranges. Other human chromosomes, although generally exhibiting a power-law scaling form of  $\sigma^2(w)$ , show deviations from  $\sigma^2(l) \sim 1/l^{\beta}$  line for the largest window sizes tested.

The investigation of  $\sigma^2(w)$  as a function of different window sizes w requires careful examination [29, 30].

FIG. 7: Double-logarithmic representation of the variance  $\sigma^2(w)$  of the spatial GC% series for all human chromosomes (Chr) as a function of the window size w: (a)  $\bigcirc$  Chr1,  $\triangle$  Chr2, + Chr3, × Chr4,  $\diamondsuit$  Chr5,  $\bigtriangledown$  Chr6; (b)  $\bigcirc$  Chr7,  $\triangle$  Chr8, + Chr9, × Chr10,  $\diamondsuit$  Chr11,  $\bigtriangledown$  Chr12; (c)  $\bigcirc$  Chr13,  $\triangle$  Chr14, + Chr15, × Chr16,  $\diamondsuit$  Chr17,  $\bigtriangledown$  Chr18; (d)  $\bigcirc$  Chr19,  $\triangle$  Chr20, + Chr21, × Chr22,  $\diamondsuit$  ChX,  $\bigtriangledown$  ChrY. Straight lines indicate  $\sigma^2(w) \sim 1/w$  (corresponding to white noise). One regression line for Chr1 ( $\beta \approx 0.12$ ) and a piece-wise regression for Chr13 ( $\beta \approx 0.27$  and  $\beta \approx 0.10$ ) are drawn. The 95% confidence interval for the  $\sigma^2(w)$  estimation of Chr1 at each point of w is marked by a vertical dashed line.

First, since we partition each human chromosome in  $2^k$  (k = 17, 16, ...) windows, the variance of GC% series  $\{\rho_i\}$  could be accidentally large when windows reside on the isochore borders, and small by chance if they start/end within an isochore.

Second, when the number of windows is small (e.g. the last point of  $\sigma^2(w)$  for each chromosome in Fig. 7 is calculated with the largest window size that gives rise to 32 windows), the standard error of the sample variance is large. The 95% confidence interval for  $\sigma^2(w)$  of Chr1 is shown in Fig. 7(a), using the interval:  $[(w-1)\sigma^2/t_{0.025}, (w-1)\sigma^2/t_{0.975}]$ , where  $t_x$  is defined by  $\int_{-\infty}^{t_x} \chi^2(df = w-1)dt = x$  (where  $\chi^2(df)$  is the chi-square distribution with df degrees of freedom) [31]. Figure 7(a) shows that for fewer windows (and larger window sizes), the 95% confidence interval of  $\sigma^2(w)$  could be large such that the estimated value of  $\beta$  may change from sample to sample.

Finally, the relationship between scaling exponents  $\alpha + \beta = 1$  [14, 28], is based on the assumption that both S(f) and  $\sigma^2(w)$  are theoretical power-law functions. If S(f) is a piece-wise power-law function, as in the case of GC% fluctuation of human chromosomes, a correction term to the relationship  $\alpha + \beta = 1$  is expected.

FIG. 8: Correlation function  $\Gamma(d)$  for 24 human chromosomes (Chr) as a function of the window distance d (converted to bases by the window size listed in Table 1). The distance is represented on a logarithmic scale. (a) Chr1–6; (b) Chr7–12; (c) Chr13–18; and (d) Chr19–22, ChrX, and ChrY.

FIG. 9: Correlation function  $\Gamma(d)$  for human chromosome 21 as a function of the window distance d (converted to bases by the window size given in Table 1). The oscillation in  $\Gamma(d)$  is highlighted by vertical lines, indicating the distances of d = 500 kb, 1 Mb, 1.5 Mb, and 2 Mb.

## VI. CHROMOSOME-SPECIFIC CORRELATION STRUCTURES

Apparently, 1/f noise in music and speech signals [32] does not prevent music and speech from sounding differently. Similarly, universal  $1/f^{\alpha}$  spectra in GC% fluctuations across human chromosomes do not imply that all chromosomes exhibit the same detailed correlation structure. The generic trend of S(f) spectra to increase at low frequency may "co-exist" with small peaks at higher frequency. Such chromosome-specific characteristic length scales can be more intuitively examined by correlation functions. In this section, we investigate the correlation function  $\Gamma(d)$  of coarse-grained DNA sequences of human chromosome-specific structures, such as characteristic 7

length scales and oscillation detected by  $\Gamma(d)$ .

Figure 8 shows for all human chromosomes the  $\Gamma(d)$ 's of GC% series  $\{\rho_i\}$  calculated for the window sizes given in Table 1, of all human chromosomes. For each chromosome, the minimum (maximum) distance is 80 (16,000) windows. Since each chromosome is partitioned into  $2^{17}$  windows, the maximum distance d at which the correlation is examined is about  $16,000/2^{17} \approx 12\%$  of the total sequence length.

An inspection of Fig. 8 shows that the magnitude of correlation at the distance of d = 1 Mb is clearly above the noise level. With the exceptions of Chr15, Chr22, and ChrY, the correlation function  $\Gamma(d) > 0.1$  at d = 1 Mb for all other chromosomes. The low correlation in ChrY is due to the fact that about half of the bases are unsequenced, and the substitution of gaps by random values lowers the correlation. At even longer distances such as d = 10 Mb, correlations  $\Gamma(d = 10$  Mb) for chromosomes 1 and 6 are still above the 0.1 level.

Given different windows (w) due to different chromosome sizes and provided that the covariance of GC% is approximately independent of w, a scaling of the variance according to  $1/w^{\beta}$  implies that the correlation function  $\Gamma(d)$  in Eq.(3) increases with the window size as  $\sim w^{\beta}$ . Test calculations of covariance for  $2^{15}$  and  $2^{17}$  windows show that the covariance differs by less than 1% (and hence is fairly independent in this range of window sizes). Consequently, for a detailed comparison of correlation functions calculated for different chromosomes one has to take into account different windows sizes.

Any deviation from the monotonic decrease of  $\Gamma(d)$  might be indicative of correlations at characteristic length scales (visible as "bumps"). For example, Fig. 8 shows for chromosome 1 such a bump at  $d \approx 21-23$  Mb. Bumps or sharper peaks in other chromosomes include  $d \approx 9.3$  Mb (Chr2), 7.2 Mb (Chr10), 3.2–3.8 Mb (Chr12), and 2.4–3.1 Mb (Chr19). One plausible explanation is that for chromosomes 2, 10, 12, and 19 one or few alterations of GC-rich/low isochores [13] with these length scales enhance the correlation.

Chromosome 21 stands out among all human chromosomes for having a comparatively higher correlations at distances of several Mb (despite having a smaller  $w^{\beta}$  factor than other chromosomes due to a smaller window size). A detailed inspection of Fig. 9 uncovers an oscillation of  $\Gamma(d)$  of about 500 kb, ranging from d = 500 kb to d = 2 Mb, which has not been reported before. It can be further shown that this oscillation is not due to the substitution of interspersed repeats [33], and it is localized to about one-eighth of the right distal end of chromosome 21 [33].

#### VII. DISCUSSIONS

We study correlation structures and spectral components in the set of human chromosomes, using power spectra, coarse-grained correlation functions, and the variance of different window sizes. All three measures are interrelated and highlight compositional structures at different feature levels. Our results firmly establish the presence of long-ranging correlations and  $1/f^{\alpha}$  spectra in the DNA sequences of the set of twenty-four human chromosomes.

Using updated and completed human sequence data, we find the presence of 1/f noise in the DNA sequences of all human chromosomes. We further find that, with the exception of chromosome 22, all chromosomes exhibit a cross over from  $1/f^{\alpha_1}$  at low-frequency to  $1/f^{\alpha_2}$ scaling at high-frequency ( $\alpha_1 > \alpha_2$ ). The result of two scaling ranges at low- and high-frequency are in accord with previous findings, obtained from sequence data of lower quality, and it refines break-point regions for each individual chromosome.

We also examined the effect of about 45% interspersed repeats in the human genome. Using a procedure in which masks and subsequently substitutes interspersed repeats with random GC% values, we find that interspersed repeats (i) only marginally affect the scaling exponent  $\alpha_1$  in the low-frequency range, but (ii) lower  $\alpha_2$ in the high-frequency range (cf. Fig.5(b)). This supports the general understanding that interspersed repeats only contribute to short-ranging (high-frequency) correlations [6].

We have shown elsewhere that  $1/f^{\alpha}$  spectra of GC% fluctuation are also universally present in the mouse *Mus musculus* genomic DNA sequences [34]. It is known that human and mouse genomes are separated by approximately 65–75 million years of evolution. Besides the similarity (or homology) between these two genomes on a local scale, there is in fact a large amount of reshuffling of the chromosome segments at a global scale when two current-day copies of the two genomes are compared side-by-side [35]. Since reshuffling of a sequence at global scales could potentially destroy long-range correlations, it is still to be resolved under what conditions a reshuffling of the human genome into the mouse genome, or vice versa, conserves 1/f noise.

One possible explanation of why  $1/f^{\alpha}$  spectra appear in both the human and the mouse genomes is that such long-range patterns were probably generated from ancestral DNA sequences by sequence evolutionary mechanisms. One sequence evolution model, termed expansionmodification (EM) model, is known to generate  $1/f^{\alpha}$ spectra [7]. The EM model incorporates duplications and mutations. Since the duplication process is an essential element in evolutionary genomics [36], whose role is perhaps as important as Darwin's natural selection [37], even a yet unsophisticated incorporation of duplications in the EM model may capture the essence of the evolutionary origin of long-range correlations in DNA sequences. In the EM model, only the duplication of segments with the same length scale is included, whereas in reality segments with a broad range of length scales are duplicated [19].

One frequently posed question concerns the "biological meaning" of  $1/f^{\alpha}$  spectra or long-range correlations in DNA sequences. In order to address this question, one may ask a couple of related questions beforehand. Does the compositional GC% have any biological effects? What biological functions of the DNA molecule are of relevance? From the functional genomics perspective, interesting biological processes related to DNA molecules include transcription, replication, and recombination, and their potential connection to GC% has been reviewed in [27, 38, 39]. Generally speaking, GC% has a statistical association with all three processes, though the cause-and-effect role has not yet been firmly established. Recent studies show that broadly expressed "housekeeping genes" tend to be located in GC-rich regions [40]. To understand the genome-wide organization of biological units that play a role in those processes (e.g., genes, origins and timing of replication, or recombination hotspots), at times it is more feasible to directly study the spatial distribution of functional units instead of using the GC% as a surrogate.

From the biophysics and cellular biology perspective, GC% is linked with bands from chromosome-staining [41], and in addition, possibly with the matrix/scaffold attachment/associated regions located at the end of DNA loops [42]. It has also been suggested that GC-rich chromosomes (or regions) tend to be located in the interior of the nuclear during interphase and are more "open" in their tertiary structure, whereas GC-poor segments are more likely to be close to the surface of the nuclear and more condensed [43].

Further exploration of the relationship between GC% fluctuations, as well as its large-scale patterns, and the above biological processes is beyond the scope of this paper. An attempt for bacterial genomes has been made to relate the scale-invariance feature in sequence statistics to the genome organization of transcription activities [29]. It is clear that more integrated computational and experimental analyses need be carried out along similar lines before one can give universal 1/f spectra in DNA sequences a satisfactory biological explanation.
