Entropy Oriented Trading: A Trading Strategy Based on the Second Law of Thermodynamics

Yoichi Hirai*

March 1, 2022

Abstract

The author proposes a finance trading strategy named Entropy Oriented Trading and apply thermodynamics on the strategy. The state variables are chosen so that the strategy satisfies the second law of thermodynamics. Using the law, the author proves that the rate of investment (ROI) of the strategy is equal to or more than the rate of price change.

1 Definition of the Strategy

An Entropy Oriented Trading strategy has n target types of asset A_0, \dots, A_{n-1} . It has constant weights for the assets $(w_0, w_1, \dots, w_{n-1})$, where the weights are positive and the sum of them is one. The price and the held amount of the *i*th asset are written as p_i and h_i respectively. The value of the *i*th asset is

$$U_i = p_i h_i.$$

The total value of assets is

$$T = \sum_{i=0}^{n-1} U_i.$$

The prices p_i change according to time. On a point of time, a strategy can trade assets A_i and A_j . It can change the held amounts (h_i, h_j) to (h'_i, h'_j) only if the total asset is not changed. We define the traded amount of value $Q_{ij} = p_i h'_i - p_i h_i$ and express the trade condition

$$Q_{ij} + Q_{ji} = 0. (1)$$

Multiple trades may occur at the same time. In that case, the sum $Q_i = \sum_{j=0}^{n-1} Q_{ij}$ is the value of the bought amount of the asset A_i . The value of Q_i is negative if asset A_i is sold.

An Entropy Oriented Trading strategy tries to keep the distribution of asset equal to the weights, so in equilibrium, the equation (2) hold:

$$U_i = w_i T. (2)$$

When the price change is slow enough (or the strategy trades frequently enough), the equation (2) holds. Otherwise, $T_i = U_i/w_i$ can be different from T. In this case, the strategy trades to make all T_i 's equal.

We can assume that when $T_i > T_j$, an Entropy Oriented Trading strategy does not trade selling A_j and buying A_i . This means

$$\text{if} \quad T_i > T_j, \quad Q_{ij} \le 0.$$
 (3)

A trade involving A_i and A_j is reversible only if $T_i = T_j$.

2 Analysis of the Strategy

To analyse this strategy with thermodynamics, we have to choose the state variables and the equation of state. The state variables are p_i, h_i, T_i and the equation of state is

$$w_i T_i = p_i h_i \tag{4}$$

and we take the internal energy as $U_i = w_i T_i$. Note that the *T*-based trading restriction (3) is analogous to the second law of thermodynamics.

We first analyse the case in which the equation (2) always holds and then analyse the more general case. In both cases, we assume that we can consider a transformation of system as a continuous sequence of infinitesimal transformations.

2.1 On Reversible Transformations

When the equation (2) always holds, $T_i = T_j$ holds for any *i* and *j*, so that all trades are reversible. The equation of state becomes

$$w_i T = p_i h_i. \tag{5}$$

Taking the differential of (5), we have

$$w_i \mathrm{d}T = h_i \,\mathrm{d}p_i + p_i \,\mathrm{d}h_i.$$

The amount $p_i dh_i = d'Q_i$ is the change of U_i due to the trades occurring at the given point of time, whereas the amount $h_i dp_i = w_i T dp_i/p_i$ is the change of the value of U_i due to the price change.

Integrating this from the state C to the state D yields:

$$w_i \int_C^D \frac{\mathrm{d}T}{T} = w_i \int_C^D \frac{\mathrm{d}p}{p} + \int_C^D \frac{\mathrm{d}'Q_i}{T}.$$

Now we take the summation for *i*. For simplicity, we introduce weighted geometric average of prices $P = \prod_{i=0}^{n-1} p_i^{w_i}$. Since the trade condition (1) states $\sum_{i=0}^{n-1} d'Q_i/T = 0$, we can omit the term $\int_C^D d'Q_i/T$ and get

$$\ln\left(\frac{T(D)}{T(C)}\right) = \ln\left(\frac{P(D)}{P(C)}\right),\,$$

stating that the rate of investment is equal to the price change rate.

We take an arbitrary equilibrium state O and define the entropy $S_i(C)$ as

$$S_i(A) = \int_O^A \frac{\mathrm{d}'Q_i}{T_i},\tag{6}$$

where the integral is taken along a reversible transformation. We also define the total entropy $S(A) = \sum_{i=0}^{n-1} S_i(A)$. Note that the total entropy S is constant in reversible transformations.

2.2 On Irreversible Transformations

In irreversible transformations, the amount T_i can be different for different *i* because of delay of trades. Taking the differential of the equation of state (4) yields $w_i dT_i = p_i dh_i + h_i dp_i$. Dividing this by *T* and taking the integral from a state *C* to another state *D*, we get

$$w_i \ln\left(\frac{T_i(D)}{T_i(C)}\right) = w_i \ln\left(\frac{p_i(D)}{p_i(C)}\right) + \int_C^D \frac{\mathrm{d}'Q_i}{T_i}.$$

We assume that the states C and D are in equilibrium so that for any $i T_i(C) = T(C)$ and $T_i(D) = T(D)$. We take summation for i and see

$$\ln\left(\frac{T(D)}{T(C)}\right) = \ln\left(\frac{P(D)}{P(C)}\right) + (S(D) - S(C)).$$
(7)

The trading restriction (3) means $Q_{ij}/T_i + Q_{ji}/T_j \ge 0$. From this we can obtain $\Delta S = S(D) - S(C) \ge 0$. Especially, when a irreversible trade occurs between A_i and A_j , the entropy increases by $Q_{ij}/T_i + Q_{ji}/T_j > 0$.

The equation (7) states that the return of investment is the product of the rate of price change and $\exp(\Delta S)$, which is equal to or more than one:

$$\Delta(\ln T) = \Delta(\ln P) + \Delta S, \quad \text{where} \quad \Delta S \ge 0.$$
