Abstract.

We report measurements of the evolution of lines, planes, and volumes in an intensely turbulent laboratory flow using high-speed particle tracking. We find that the classical characteristic time scale of an eddy at the initial scale of the object considered is the natural time scale for the subsequent evolution. The initial separation may only be neglected if this time scale is much smaller than the largest turbulence time scale, implying extremely high turbulence levels.

The transport of material by a carrier fluid is ubiquitous in both the natural world and in engineering applications [1]. When the carrier flow is turbulent, the dispersion of the transported substance can be very rapid. Turbulent flows are also extremely efficient at mixing [2], since their nonequilibrium nature drives the production of small scales and sharp gradients where diffusion can occur rapidly. To study both transport and mixing, it is natural to work in the Lagrangian framework where the fundamental objects are the trajectories of individual fluid elements [3].

The trajectory of a single Lagrangian particle is, in general, not sufficient for characterizing turbulent transport. Instead, knowledge of the collective motion of groups of particles is required [1,4]. The simplest such multiparticle quantity is the growth of the relative distance between a pair of particles [5]. We have previously measured this relative dispersion [6,7], finding excellent agreement with Batchelor's theoretical predictions [8]. Geometrically, the two particles in relative dispersion define a line, and therefore a particle pair only gives one-dimensional information about turbulent dispersion. An even deeper understanding of turbulent transport requires the study of higher-dimensional structures: groups of three particles, which define a plane, and of four particles, which define a volume. While such structures have been considered before in models and numerical simulations [9–11] and in low-Reynolds-number experiments [12,13], they have not been investigated at the high Reynolds numbers that are common in nature.

Here, we present measurements of the shape dynamics of collections of Lagrangian particles in an intensely turbulent laboratory water flow. We consider lines (two particles), planes (three particles), and volumes (four particles). In all of these cases, the initial size of the object plays a strong role: the time scale determined by this initial size, which we denote by t_0 , characterizes the experimentally observed evolution [14]. We find that two particles separate superdiffusively, as is well-known in turbulence, but that t_0 divides two types of separation behavior. Triangles formed from three particles and volumes spanned by four particles also grow in time, but assume stationary shapes after t_0 , with triangles evolving to a preferred set of internal angles and volumes flattening into nearly planar structures.

Our measurements are made using optical particle tracking [15] in a swirling water flow between counter-rotating baffled disks, as described in detail elsewhere [7]. We characterize the strength of the turbulence with the Taylor-microscale Reynolds number $R_{\lambda} = \sqrt{15u'L}/\nu$, where u' is the root-mean-square velocity, L is the correlation length of the velocity field, and ν is the kinematic viscosity; here, we report measurements for R_{λ} as high as 815. Our polystyrene tracer particles are smaller than or comparable to the smallest scale of the turbulence, the Kolmogorov length scale $\eta = (\nu^3/\epsilon)^{1/4}$, where ϵ is the mean rate of energy dissipation per unit mass, for all Reynolds numbers studied, and faithfully follow the flow [16]. By modifying our tracking algorithms, we have been able to increase the lengths of measured trajectories significantly, allowing for the study of longer-time statistics [17].

Let us first consider one-dimensional shape changes by measuring the growth of

Figure 1. (a) The separation of two particles in time, compared with a modified Richardson-Obukhov law, for different initial separations, ranging from 1 mm to 5 mm. The Reynolds number is fixed at $R_{\lambda}=690$, with a Kolmogorov scale of $\eta=30$ μ m. We observe similar behavior at other Reynolds numbers. (b) The change of C_R with T_L/t_0 , shown for three Reynolds numbers.

the separation $\mathbf{R}(t)$ between two particles. For this case, the well-known Richardson-Obukhov law [5, 18] predicts that

$$\langle R^2(t) \rangle = g\epsilon t^3 \tag{1}$$

in the inertial range, i.e., $\eta \ll R \ll L$ and $\tau_{\eta} \ll t \ll T_L$, where $T_L = (L^2/\epsilon)^{1/3}$ is the large-eddy turnover time. In Eq. (1) the dimensionless coefficient g, known as the Richardson constant, is expected to be universal and independent of initial separation R_0 . It has been notoriously difficult, however, to observe conclusive evidence of this t^3 scaling experimentally [5]. In our previous measurements of relative dispersion [6,7], we instead found that the initial separation of the pair R_0 plays an important role, as first suggested by Batchelor [8]. He predicted that

$$\langle \delta R_i \delta R_i \rangle = (11/3) C_2 (\epsilon R_0)^{2/3} t^2, \tag{2}$$

where $\delta \mathbf{R}(t) \equiv \mathbf{R}(t) - \mathbf{R}_0$ and $C_2 = 2.13 \pm 0.22$ is the scaling constant for the second-order Eulerian velocity structure function [19]. Batchelor additionally predicted that this scaling law should hold for $t \ll t_0$, where

$$t_0 \equiv (R_0^2/\epsilon)^{1/3},\tag{3}$$

may be regarded as the lifetime of an eddy of scale R_0 .

It has been suggested that the failure to observe the Richardson-Obukhov law is due to the influence of particle pairs that separate anomalously slowly or quickly, so that they bring in non-inertial-range effects [20,21]. This will occur unless the inertial range is sufficiently wide and the effects of both the dissipation and integral scales are negligible, requiring very large Reynolds numbers. In addition, the finite measurement volume in experiments may introduce a bias against quickly separating particle pairs [22]. We

Figure 2. (a) Change of the energy of relative motion $\delta u^2(t) - \delta u^2(0)$ following the pairs, normalized by $(11/3)(\epsilon R_0)^{2/3}$, the theoretical average relative energy at the initial separation between the pairs, where δu is the relative velocity between the pairs. (b) The rate of energy change dE/dt normalized by the turbulence dissipation rate, where $E = (\delta u^2)/2$. Both (a) and (b) are from the $R_{\lambda} = 690$ experiment, with a Kolmogorov scale of $\eta = 30~\mu\text{m}$. The legends give the initial separations in mm. We observed similar behavior at other Reynolds numbers.

have therefore also measured $\langle R^{2/3}(t)\rangle - R_0^{2/3}$, which is less affected by the finite-volume bias and may display scaling behavior at Reynolds numbers accessible in current experiments [6]. If the Richardson-Obukhov law holds, then

$$(\langle R^{2/3}(t)\rangle - R_0^{2/3})/R_0^{2/3} = C_R(t/t_0), \quad (t_0 \ll t \ll T_L, R_0 \ll R \ll L)$$
 (4)

where C_R should be a constant related to the Richardson constant g. The compensated plot $(\langle R^{2/3}(t) \rangle - R_0^{2/3})/R_0^{2/3}/(t/t_0)$ should collapse to a plateau in the inertial range, independent of initial separation R_0 . As shown in Fig. 1(a), plateaus, though short, do exist for $t \gg t_0$. We find, however, that the initial separation R_0 again plays a role: t_0 is the time scale of the transition to the $\langle R^{2/3} \rangle \sim t$ scaling and the plateau values depend on R_0 . These observations support our earlier argument that a very large separation between T_L and t_0 (corresponding to a very large Reynolds number) is required to observe R_0 -independent Richardson-Obukhov scaling [6], which is also supported by recent work using a stochastic model [22]. To quantify the effect, we plot in Fig. 1(b) the change of C_R with T_L/t_0 at three different Reynolds numbers, where C_R is measured from the peak value in the plateau region of the compensated curves. The largest T_L/t_0 in this plot are taken from $R_0 \approx 30\eta$, the lower bound of the inertial range [23]. It can be seen that the measurements from three different Reynolds numbers collapse very well, and that the R_0 -independent region is not reached even at $R_\lambda = 815$.

The absence of Richardson universal scaling law even at $R_{\lambda} \sim 10^3$ may be better understood from the evolution of δu , the relative velocity between fluid particles pairs. Figure 2(a) shows the change of the energy of relative motion, $\delta u^2(t) - \delta u^2(0)$, following the pairs. Figure 2(b) shows the rate of the change, dE/dt, following the pairs, where

Figure 3. The evolution of Lagrangian triangles at $R_{\lambda}=815$ ($\eta=23~\mu\mathrm{m}$), characterized by (a) the mean-squared lengths of the triangle edges and (b) the mean triangle angles. R_0 , the initial edge length, varies from 4 mm to 6 mm. As in the two-particle case, the data for different initial sizes collapse when time is scaled by t_0 .

 $E \equiv \delta u^2/2$. Clearly, the energy of relative motion decreases initially before the final increase. As initial separation increases, the return to dE/dt > 0 takes longer time. These observations are in good agreement with results Numerical simulations [24], where the same change of the energy of relative motion was found for a "cloud" of tracer particles. This initial decrease of relative motion energy can be linked to the large correlation length of forcing in three-dimensional turbulence [4]. In light of Figure 2, the relative motion between a pair of particles is first slowed down and it takes a time comparable to t_0 for the relative motion to accelerate again. The further apart the particles the longer the relative period of slow down is. Only after the initial decreasing period, the Richardson regime can possibly be observed.

While studying the two-particle case tells us how particles separate along lines in turbulence, groups of three particles can show richer dynamics since they form two-dimensional objects. We therefore measured the shape statistics of triangles formed from three particles. Here we report only the statistics of triangles that were initially nearly equilateral. We then measured the growth of the sides the triangles, analogous to the evolution of the mean-squared separation of two particles considered above, and the distortion of the triangles, information that is unavailable from pair separation measurements.

Figure 3(a) shows the evolution of the mean-squared lengths of the triangles $\langle \Lambda_i^2 \rangle$ (with $\Lambda_1 \geq \Lambda_2 \geq \Lambda_3$) for three different initial triangle sizes. When time is scaled by t_0 , defined now with the side length of the initially equilateral triangles, the data collapse for different initial sizes. Additionally, scaling in this fashion collapses data taken at different Reynolds numbers (not shown). We note that unlike the monotonic increase of $\langle \Lambda_1^2 \rangle$ and $\langle \Lambda_2^2 \rangle$, there is initially a slight decrease in $\langle \Lambda_3^2 \rangle$, an effect that is absent in the statistics of particle pairs. This result shows the importance of studying higher-

Figure 4. The evolution of Lagrangian tetrads at $R_{\lambda}=690~(\eta=30~\mu\text{m})$, characterized by (a) the mean eigenvalues of the inertia tensor scaled by the initial tetrad size and (b) the mean normalized eigenvalues for initial sizes ranging from 10 mm to 20 mm. Once again, the data for different initial sizes collapse when time is scaled by t_0 .

dimensional structures in three-dimensional turbulence. We shall discuss this initial decrease in more detail when considering four-particle statistics below.

In addition to a mean growth, three particles can assume nontrivial 2D configurations. To quantify these shapes, we show the evolution of the means of the three triangle angles $\langle \theta_i \rangle$ in Fig. 3(b). Just as for the edge lengths, the angle data collapse when time is scaled by t_0 . We also observe that our initially equilateral triangles become distorted over a time of order t_0 to stationary, obtuse shapes, with angles of 0.56π , 0.27π , and 0.17π . These values appear to be independent of Reynolds number: indeed, our observations are in agreement with earlier results from 3D numerical simulations [10] and 2D experiments [12], even though they were performed at significantly lower Reynolds number.

The evolution of triangles has given us more insight into transport than the twoparticle case, but for 3D turbulence, we must consider volumes for a full characterization. We therefore consider groups of four particles, the minimum number of points required to define a volume. Such groups form "tetrads," which have previously been used to construct a stochastic model of the coarse-grained velocity gradient tensor [9]. Following Chertkov et al. [9], we characterize the spatial arrangement of the particles with the eigenvalues g_i (with $g_1 \geq g_2 \geq g_3$) of the "inertia" tensor $g_{ij} \equiv X_{ik}X_{kj}$. The column vectors of the tensor X_{ij} are defined based on the relative separation between the four points:

$$\mathbf{X}_{1} = (\mathbf{x}_{2} - \mathbf{x}_{1}) / \sqrt{2},$$

$$\mathbf{X}_{2} = (2\mathbf{x}_{3} - \mathbf{x}_{2} - \mathbf{x}_{1}) / \sqrt{6},$$

$$\mathbf{X}_{3} = (3\mathbf{x}_{4} - \mathbf{x}_{3} - \mathbf{x}_{2} - \mathbf{x}_{1}) / \sqrt{12},$$

$$(5)$$

Figure 5. The evolution of PDF of the shape factor $\langle I_3 \rangle$ following Lagrangian tetrads with initial size $R_0 = 20$ mm in turbulence. The legends show the time (in units of τ_{η}) at which the PDFs are measured. Similar changes are observed for tetrads with initial size of 10 and 15mm. (a) $R_{\lambda} = 690 \ (\eta = 30 \ \mu\text{m})$; (b) $R_{\lambda} = 815 \ (\eta = 23 \ \mu\text{m})$.

where \mathbf{x}_n (n=1,2,3,4) is the position of the n^{th} Lagrangian particle. The volume of the tetrad is given by $V = (\sqrt{g_1g_2g_3})/3$, and its radius of gyration is $R_g^2 = g_1 + g_2 + g_3$ [10,11]. We also define normalized eigenvalues $I_i = g_i/R_g^2$ to describe the tetrad shape: $I_1 = I_2 = I_3 = 1/3$ defines an isotropic tetrad, $I_3 = 0$ means that the four points are coplanar, and $I_2 = I_3 = 0$ means that they are collinear. As with the triangles studied above, we considered only tetrads that were initially nearly isotropic, with the length of all edges within 10% of a nominal size R_0 .

In Fig. 4(a), we show the evolution of the tetrad eigenvalues scaled by the initial tetrad size. Data for different initial sizes collapse when time is scaled by t_0 , as it would for different Reynolds numbers. Here, it is clear that while the two larger eigenvalues increase monotonically, the smallest eigenvalue decreases. This observation provides direct experimental evidence for earlier theoretical and numerical work [9] that in 3D turbulence the large-scale, coarse grained strain-rate tensor has, on average, two positive eigenvalues and one negative eigenvalue. The negative eigenvalue causes the initial compression in one direction, and consequently the decrease in $\langle g_3 \rangle$. The normalized eigenvalues, shown in Fig. 4(b), also collapse for different sizes when scaled by t_0 . We also find that the tetrads develop towards a nearly planar configuration after a time of order t_0 . Within the experimental resolution, we determine the stationary values of the normalized eigenvalues to be $\langle I_2 \rangle = 0.25$ and $\langle I_3 \rangle = 0.06$ (note that $\langle I_1 \rangle = 1 - \langle I_2 \rangle - \langle I_3 \rangle$), similar to our earlier results where we did not select only the initially nearly isotropic tetrads [25]. We note that we did not observe a Richardson-like $g_i \sim t^3$ for any Reynolds number or initial size accessible.

Our results are qualitatively similar to the recent numerical simulations of Lagrangian tetrads in Ref. [11], performed at $R_{\lambda} = 280$, where stationary values of $\langle I_2 \rangle = 0.16$ and $\langle I_3 \rangle = 0.02$ were reported, indicating an even stronger tendency towards

Figure 6. The evolution of the averaged tetrad volume $\langle V \rangle$, normalized by R_0^3 , following Lagrangian tetrads with inertial range sizes in turbulence. (a) $R_{\lambda} = 690$ $(\eta = 30 \ \mu\text{m})$; (b) $R_{\lambda} = 815$ $(\eta = 23 \ \mu\text{m})$.

planar tetrads than in our data. In Fig. 5, we show the evolution of the probability density function (PDF) of the smallest shape factor $\langle I_3 \rangle$ following Lagrangian tetrads. Again, the evolution of the PDFs are consistent with simulation results in Ref. [11] for tetrads with initial separation in the dissipative range. It can be seen that after $60 \sim 70\tau_{\eta}$ (or approximately t_0), the PDFs are still slowly evolving. Beyond that time, the tetrads, on average, have been swept away from their initial positions by half of the size of the measurement volume and disappear from our observation. Therefore, our measurement of $\langle I_i \rangle$ might be affected by the finite measurement volume. In addition, it is more probable for a vertex of an extremely deformed tetrad to move out of the finite measurement volume. There is hence a potential bias towards smaller deformation in our experiments.

A possible reason for the slight difference between the simulation and experimental results could be the higher potentiality for a vertex of an extremely deformed tetrad to move out of the finite measurement volume of our experiments, at which point the tetrad would no longer be detectable. There is therefore a potential bias towards smaller deformation in our experiments.

The initial size of the tetrads studied in Ref. [11] are in the dissipation range $(R_0 \sim \eta)$, whereas our smallest initial separation was $R_0 \sim 300\eta$, well into the inertial range. In Ref. [11], the initial decrease in g_3 , similar to that shown in Fig. 4(a), was attributed to dissipative effects, which were also presumed to be responsible for the lack of observed Richardson scaling. Since we observed very similar behavior with R_0 well in the inertial range, however, we attribute the lack of t^3 scaling to a small separation between t_0 and T_L , just as for the case of pair separation. The correspondence between our inertial-range results and the smaller-scale numerical results suggests additionally that the statistics of the coarse-grained velocity gradient tensor [9] may be very similar to those of the true velocity gradient. Further study of these similarities will be an excellent

opportunity to bring together complementary experiments and numerical simulations.

Figure 6 shows the change of averaged volume following the tetrads with different sizes. The tetrads volume remains constant initially for time $t < 0.1t_0$. Then decreases in volume before the final increase. This decrease was not observed in previous numerical work [10] and experimental measurements [13]. A possible reason is that the tetrad sizes are large enough to feel the effect of the mean strain.

In summary, we have measured multiparticle Lagrangian statistics in an intensely turbulent laboratory flow. We studied the evolution of lines, planes, and volumes, each parameterized by the minimum number of Lagrangian points. We find that, in three-dimensional turbulence, material volumes tend to flatten into planar shapes, in agreement with previous numerical and experimental studies at much lower Reynolds numbers. Our results clearly indicate that the initial particle separation is an important parameter in each of these cases and must be included in models. Only when the ratio of the largest turbulence time scale and the time scale based on the initial size of the object is very large, implying a very large Reynolds number, may the initial size be safely neglected.
