Abstract

Understanding the aging process of aerosol particles is important for assessing their chemical reactivity, cloud condensation nuclei activity, radiative properties and health impacts. In this study we investigate the aging of black carbon containing particles in an idealized urban plume using a new approach, the particleresolved aerosol model PartMC-MOSAIC. We present a method to estimate aging time-scales using an aging criterion based on cloud condensation nuclei activation. The results show a separation into a daytime regime where condensation dominates and a nighttime regime where coagulation dominates. For the chosen urban plume scenario, depending on the supersaturation threshold, the values for the aging timescales vary between 0.06 hours and 10 hours during the day, and between 6 hours and 20 hours during the night.

Key words: black carbon, aerosol aging, mixing state, CCN

1 1 Introduction

² Black carbon containing particles, or "soot" particles, are ubiquitous in the
³ atmosphere and their role for regional and global climate has been widely rec-

⁴ ognized (IPCC, 2007). Since black carbon absorbs light (Horvath and Trier,

 $_{\tt 5}$ $\,$ 1993), it contributes to the aerosol radiative forcing, potentially partially off-

⁶ setting the cooling effect of scattering aerosol particles such as sulfates (Menon

Black carbon containing particles originate from the incomplete combustion of 8 carbon containing material, hence emissions from traffic are an important conç tributor (Bond et al., 2004). Other important sources for black carbon include 10 biomass burning and the combustion of coal by industrial processes. In this 11 paper we focus on black carbon from traffic emissions. Measurements of vehi-12 cle emissions from gasoline and diesel cars show that the emitted particles are 13 a complex mixture of many chemical species with the main constituents being 14 black carbon and organic carbon (Medalia and Rivin, 1982; Toner et al., 2006). 15 Trace concentrations of ionic and metallic species are also present (Kleeman 16 et al., 2000). The exact composition depends on several factors, including the 17 fuel type, the operating conditions and the condition of the individual vehicles. 18

During their transport in the atmosphere, the composition of these particle 19 emissions are further modified. Coagulation, condensation and photochemistry 20 are contributing processes, collectively known as aging (Weingartner et al., 21 1997). During this aging process the composition of the individual particles 22 or, in other words, their mixing states change (Furutani et al., 2008). This 23 impacts the particles' physico-chemical properties including their chemical 24 reactivity, radiative properties and health impacts. In particular, the aging 25 process can change the particles' hygroscopicity from initially hydrophobic to 26 more hydrophylic, and hence change their ability to become cloud condensa-27 tion nuclei (McFiggans et al., 2006; McMurry and Stolzenburg, 1989; Moffet 28 et al., 2008; Cubison et al., 2008). 29

This is important as models and observations suggest that wet deposition 30 represents 70-85% of the tropospheric sink for carbonaceous aerosol mass 31 (Pöschl, 2005). As a consequence, to assess the budget and impact of black 32 carbon, models need to capture the aging process adequately. Many global 33 models have simulated both (fresh) hydrophobic black carbon and (aged) hy-34 drophilic black carbon, which can be considered a minimal representation of 35 the black carbon mixing state (Cooke et al., 1999; Lohmann et al., 1999; Koch, 36 2001: Croft et al., 2005). In such a framework only the hydrophilic black car-37 bon is subject to in-cloud scavenging. The conversion from hydrophobic to 38 hydrophilic is frequently modeled as a first-order system with the single pa-39 rameter of aging rate or its inverse, the aging time-scale τ which represents the 40 time-scale on which a population of black carbon containing particles transfers 41 from the "fresh" category to the "aged" category. 42

⁴³ While conceptually simple, the actual value of the aging time-scale τ is not ⁴⁴ well constrained. Koch (2001) and Croft et al. (2005) compared different ag-⁴⁵ ing parameterizations in global models and concluded that the model results

⁷ et al., 2002).

critically depended on the respective formulation. Riemer et al. (2004) used 46 mesoscale simulations to determine τ . They derived the aging time-scale for 47 black carbon particles as a function of height and time of the day, which sug-48 gested that assuming a single parameter for the black carbon aging time-scale 49 is an oversimplification that will incorrectly estimate the black carbon burden. 50 However, even though this treatment allowed more detailed insight into the 51 aging process, it was still based on ad hoc aging rules inherent to the modal 52 model framework that was used (Riemer et al., 2003). 53

Recently, Riemer et al. (2009) developed a particle-resolved aerosol model, PartMC-MOSAIC, which explicitly resolves the composition of individual particles in a given population of different types of aerosol particles, so that no ad hoc aging criteria needs to be invoked. They applied PartMC-MOSAIC in a Lagrangian box-model framework to an idealized urban plume scenario to study the evolution of urban aerosols due to coagulation and condensation over the course of 24 hours.

In this study, we build upon Riemer et al. (2009) and present a method for es-61 timating aging time-scales of black carbon containing particles using PartMC-62 MOSAIC, based on the idealized urban plume scenario. We take the particle 63 population simulated in Riemer et al. (2009) and use a CCN-based aging cri-64 teria to determine whether each individual particle is fresh or aged at every 65 timestep, and how many particles transfer between the fresh and aged cate-66 gories during each timestep. By fitting these results to a first-order bulk model 67 of aerosol aging we are able to determine the aging timescale without mak-68 ing any a priori assumptions about the aging process. To our knowledge it 69 is the first time that a method is presented for explicitly calculating aging 70 time-scales. 71

Section 2 introduces the model system. In Section 3 we describe the idealized
plume scenario that served as a basis for the time-scale estimation. Section 4
presents our method for deriving time-scales from our model and Section 5
shows the results. We summarize our findings in Section 6.

76 2 Model description

PartMC-MOSAIC is a particle-resolved model that simulates the evolution of individual aerosol particles and trace gases in a single parcel (or volume) of air moving along a specified trajectory. For each particle the mass of each constituent species is tracked, but the particle position in space is not simulated, making this a zero-dimensional or box model. In addition to coagulation and aerosol- and gas-phase chemistry, the model includes prescribed emissions of aerosols and gases, and mixing of the parcel with background air. The simulation results shown here use around 100,000 particles in a volume of around
16 cm³ (the precise values vary over the course of the simulation). We regard
this volume as being representative of a much larger air parcel. The model
accurately predicts both number and mass size distributions and is therefore
suited for applications where either quantity is required. Details of PartMCMOSAIC and the urban plume scenario are described in Riemer et al. (2009).
Here we give a brief summary.

The simulation of the aerosol state proceeds by two mechanisms. First, the composition of each particle can change as species condense from the gas phase and evaporate to it. Second, the aerosol population can have particles added and removed, either by coagulation events between particles, by emissions, or by dilution. While condensation/evaporation is handled deterministically, emission, dilution and coagulation are treated with a stochastic approach.

⁹⁷ Coagulation between aerosol particles is simulated in PartMC by generating ⁹⁸ a realization of a Poisson process with a Brownian coagulation kernel. For ⁹⁹ the large number of particles used here it is necessary to employ an efficient ¹⁰⁰ approximate simulation method. We developed a binned sampling method ¹⁰¹ to efficiently sample from the highly multi-scale coagulation kernel (in our ¹⁰² case the Brownian kernel) in the presence of a very non-uniform particle size ¹⁰³ distribution, which is described in detail in Riemer et al. (2009).

Particle emissions and dilution with background air are also implemented 104 in a stochastic manner. Because we are using a finite number of particles to 105 approximate the current aerosol population, we need to add a finite number of 106 emitted particles to the volume at each timestep. Over time these finite particle 107 samplings should approximate the continuum emission distribution, so the 108 samplings at each timestep must be different. As for coagulation, we assume 109 that emissions are memoryless, so that emission of each particle is uncorrelated 110 with emission of any other particle. Under this assumption the appropriate 111 statistics are Poisson distributed, whereby the distribution of finite particles 112 is parametrized by the mean emission rate and distribution. 113

Lastly, we must also obtain a finite sampling of background particles that have diluted into our computational volume during each timestep. In addition, some of the particles in our current sample will dilute out of our volume and will be lost, so this must be sampled as well. Again, we assume that dilution is memoryless, so that dilution of each particle is uncorrelated with the dilution of any other particle or itself at other times, and that once a particle dilutes out it is lost.

¹²¹ We coupled the stochastic PartMC particle-resolved aerosol model to the de-¹²² terministic MOSAIC gas- and aerosol-chemistry code (Zaveri et al., 2008) ¹²³ in a time- or operator-splitting fashion (Press et al., 2007, Section 20.3.3). MOSAIC treats all the globally important aerosol species including sulfate, nitrate, chloride, carbonate, ammonium, sodium, calcium, primary organic aerosol (POA), secondary organic aerosol (SOA), black carbon (BC), and inert inorganic mass.

MOSAIC consists of four computationally efficient modules: 1) the gas-phase 128 photochemical mechanism CBM-Z (Zaveri and Peters, 1999); 2) the Multicom-129 ponent Taylor Expansion Method (MTEM) for estimating activity coefficients 130 of electrolytes and ions in aqueous solutions (Zaveri et al., 2005b); 3) the Mul-131 ticomponent Equilibrium Solver for Aerosols (MESA) for intra-particle solid-132 liquid partitioning (Zaveri et al., 2005a); and 4) the Adaptive Step Time-split 133 Euler Method (ASTEM) for dynamic gas-particle partitioning over size- and 134 composition-resolved aerosol (Zaveri et al., 2008). The version of MOSAIC 135 implemented here also includes a treatment for SOA based on the SORGAM 136 scheme (Schell et al., 2001). 137

¹³⁸ 3 Idealized urban plume scenario

For our urban plume scenario, we tracked the evolution of gas phase species 139 and aerosol particles in a Lagrangian air parcel that initially contained back-140 ground air and was advected over and beyond a large urban area, as described 141 in Riemer et al. (2009). The simulation started at 06:00 local standard time 142 (LST), and during the advection process, primary trace gases and aerosol par-143 ticles from different sources were emitted into the air parcel for the duration 144 of 12 hours. After 18:00 LST, all emissions were switched off, and the evo-145 lution of the air parcel was tracked for another 12 hours. The time series of 146 temperature, relative humidity and mixing height are shown in Figure 1. 147

Initial gas-phase and aerosol particle concentrations as well as gas phase and
particle emissions were the same as in Riemer et al. (2009). The gas phase
emissions varied throughout the emission time interval according to a typical
diurnal cycle found in polluted urban areas.

The initial particle distribution, which was identical to the background aerosol 152 distribution, was bimodal with Aitken and accumulation modes (Jaenicke, 153 1993). We assumed that it consisted of $(NH_4)_2SO_4$ and POA, as shown in Ta-154 ble 1. We considered three different types of carbonaceous aerosol emissions: 155 1) meat cooking aerosol, 2) diesel vehicle emissions, and 3) gasoline vehicle 156 emissions. The parameters for the distributions of these three emission cate-157 gories were based on Eldering and Cass (1996), Kittelson et al. (2006a), and 158 Kittelson et al. (2006b), respectively. For simplicity in this idealized study, the 159 particle emissions strength and their size distribution and composition were 160 kept constant with time during the time period of emission. 161

Furthermore, we assumed that every particle from a given source had the same composition, with the species listed in Table 1, since to date the mixing state of particle emissions is still not well quantified. In particular, we assume that the diesel and gasoline exhaust particles consist exclusively of POA and BC, which is very nearly the case (Andreae and Gelencśer, 2006; Medalia and Rivin, 1982; Kleeman et al., 2000).

Figure 2 shows time series of the bulk aerosol mass concentrations as they 168 result from this urban plume scenario. We observed a pronounced production 169 of ammonium nitrate, reaching nitrate mass concentration of up to $26 \,\mu \mathrm{g \, m^{-3}}$ 170 and ammonium mass concentration of $10 \,\mu \text{g m}^{-3}$ in the late afternoon. Sulfate 171 mass concentrations increased from $4.1 \,\mu \mathrm{g} \,\mathrm{m}^{-3}$ to $6.0 \,\mu \mathrm{g} \,\mathrm{m}^{-3}$ due to conden-172 sation of photochemically produced sulfuric acid. POA and BC were directly 173 emitted (with a temporally constant rate) and accumulated to $11 \,\mu g \, m^{-3}$ and 174 $4.3 \,\mu \mathrm{g} \,\mathrm{m}^{-3}$, respectively, until 18:00 LST when the emissions stopped. After 175 18:00 LST the mass concentrations declined due to dilution, especially nitrate 176 and BC for which the background mass concentration were zero. 177

178 3.1 Characterizing mixing state

To characterize the mixing state and to discuss the composition of a particle, we refer to the BC mass fractions as

$$w_{\rm BC,dry} = \frac{\mu_{\rm BC}}{\mu_{\rm dry}} \tag{1}$$

where μ_{BC} is the mass of BC in a given particle and μ_{dry} is the total dry mass.

Based on this quantity, we then define a two-dimensional number concen-180 tration that is a function of both particle composition and diameter. The 181 two-dimensional cumulative number distribution $N_{\rm BC,dry}(w,D)$ is the number 182 of particles per volume that have a diameter less than D and a BC mass 183 fraction of less than w. The top panels in Figure 3 show the corresponding 184 two-dimensional distributions, normalized with the respective total number 185 concentrations, after 1 hour and after 24 hours of simulation time. Since even 186 at the time of emission no particles were pure BC, particles were not present 187 at $w_{\rm BC,dry} = 100\%$. Fresh emissions from diesel vehicles ($w_{\rm BC,dry} = 70\%$) and 188 gasoline vehicles ($w_{\rm BC,drv} = 20\%$) appear as horizontal lines since particles 189 in one emission category were all emitted with the same composition. At 190 $w_{\rm BC,dry} = 0\%$ all the particles appear that do not contain any BC (i.e. back-191 ground particles and particles from meat cooking emissions that have not un-192 dergone coagulation with particles containing BC). After 1 hour (07:00 LST) 193 a small number of particles between these three classes indicate the occur-194 rence of coagulation. Comparing this result to the result for the end of the 195

¹⁹⁶ simulation, we note that at the end of the simulation particles with diameter ¹⁹⁷ below $D = 0.03 \,\mu\text{m}$ were heavily depleted due to coagulation. A continuum of ¹⁹⁸ mixing states formed between the extreme mixing states of $w_{\text{BC,dry}} = 0\%$ and ¹⁹⁹ $w_{\text{BC,dry}} = 70\%$.

200 3.2 Calculating CCN activity

Given that we track the composition evolution of each individual particle 201 throughout the simulation, we can calculate the critical supersaturation $S_{\rm c}$ 202 that the particle needs in order to activate. We use the concept of a dimen-203 sionless hygroscopicity parameter suggested by Ghan et al. (2001) or Petters 204 and Kreidenweis (2007). In Petters and Kreidenweis (2007) this parameter is 205 denoted by κ , and we adopt their notation for the remainder of the paper. 206 This concept has the advantage that results from laboratory measurements 207 can be used to quantify the hygroscopicity of complex compounds for which 208 κ values cannot be calculated in a straightforward manner. The overall κ for 209 a particle is the volume-weighted average of the κ values of the constituent 210 species. This requires the assignment of individual κ values for each aerosol 211 component in MOSAIC. 212

Petters and Kreidenweis (2007) compiled a table (Table 1 in their paper) with κ values for a variety of inorganic and organic species based on recent laboratory measurements or on thermodynamic model calculations. For $(NH_4)_2SO_4$ and NH_4NO_3 they report κ values of 0.61 and 0.67, based on calculations by Clegg et al. (1998) and measurements by Svenningsson et al. (2006), respectively. Based on this we assume $\kappa = 0.65$ for all salts formed from the NH_4^+ -SO₄²⁻-NO₃⁻ system. For all MOSAIC model species that represent SOA we assume $\kappa = 0.1$, based on measurements by Prenni et al. (2007). Following Petters et al. (2006) we assume $\kappa = 0.001$ for POA and $\kappa = 0$ for BC. The critical supersaturation S_c for a particle of diameter D and volume-weighted hygroscopicity parameter κ is then given by

$$S_{\rm c} = \frac{C}{\sqrt{\kappa D^3}},\tag{2}$$

where

$$C = \sqrt{\frac{4A^3}{27}} \quad \text{and} \quad A = \frac{4\sigma_w m_w}{R^* T \rho_w},\tag{3}$$

with σ_w being the surface tension of water, m_w the molecular weight of water, R^* the universal gas constant, ρ_w the water density, and T the temperature.

Similarly to the use of $w_{BC,dry}$ above, we can use S_c to define a two-dimensional cumulative number distribution $N_S(D, S_c)$ in terms of size and critical supersaturation. The bottom panels in Figure 3 show examples of the corresponding

two-dimensional distributions after 1 hour (left) and after 24 hours (right) of 218 simulation. While freshly emitted diesel, gasoline and meat cooking particles 219 differ in their BC and POA mass fractions, they are very similar in their hy-220 groscopicity with initial κ values close to zero. After 1 hour they are visible 221 as the dark band of high number concentrations at high S_c values. Separated 222 from this we see another dark band representing the most hygroscopic parti-223 cles, consisting of wet background particles. They contain the largest fraction 224 of inorganic mass (ammonium, sulfate, and nitrate), hence their critical su-225 persaturation is lowest at a given size compared to the other particle classes. 226

Directly slightly above the most hygroscopic band at 1 hour is a weaker band, 227 which represents the dry background particles. Because they are dry and the 228 vapor pressure of HNO_3 is still low, nitrate formation does not occur on these 229 particles. The coexistence of wet and dry particles can be explained by the 230 fact that the relative humidity falls below 85% at 06:42 LST, which is the del-231 iquescence point of the inorganic mixture of ammonium, sulfate, and nitrate. 232 Particles that exist before that time contain water and take up nitrate. They 233 stay wet throughout the whole day as a result of the hysteresis of particle 234 deliquescence and crystallization. Particles that are emitted after 06:42 LST 235 do not contain water and take up nitrate only much later. Hence after 1 hour 236 of simulation, at a given size the fraction of highly hygroscopic inorganics is 237 higher for the wet particles, which results in a higher κ value and lower critical 238 supersaturation S_c . 239

The individual bands are not completely separated at 1 hour, but the regions in between have started to fill out. The reason for this is the occurance of coagulation, which produces particles of intermediate composition and hence corresponding intermediate S_c values. After 24 hours the population as a whole has moved to lower critical supersaturations, and the distribution with respect to S_c has become more continuous. Given a certain size, the critical supersaturation ranges over about one order of magnitude.

Figure 4 shows CCN properties as more traditional CCN spectra. This repre-247 sentation is the one-dimensional projection of the bottom panels of Figure 3 248 onto the critical supersaturation axis, plotted as a cumulative distribution. 249 The change in CCN properties over the course of 24 hours is obvious. After 250 1 hour a supersaturation of S = 1.5% is necessary to activate 50% of the 251 particles by number. This required supersaturation decreases to S = 0.1%252 after 24 hours. In the following section we use the results of this urban plume 253 scenario as a basis for estimating the aging time-scales. 254

²⁵⁵ 4 First-order Models of Aging

In this section we describe the first-order model of black carbon aging to which 256 we fit the particle-resolved data simulated with PartMC-MOSAIC, in order 257 to determine the aging time-scale. We emphasize that we do not actually 258 simulate using the first-order models presented in this section. Such first-259 order systems are frequently used, however, to model the conversion from 260 hydrophobic to hydrophilic black carbon with the single parameter of aging 261 rate or its inverse, the aging time-scale τ (Croft et al., 2005). More specifically, 262 the aging time-scale represents the time-scale on which particles that would 263 initially not activate turn into particles that can be activated, given a certain 264 chosen supersaturation threshold. Budget equations for the fresh and aged 265 populations can be formulated in terms of either number or mass. A number 266 based aging time-scale is relevant for aerosol indirect forcing as the cloud 267 optical properties depend on the cloud droplet number distribution. On the 268 other hand, a mass aging time-scale is relevant for in-cloud scavenging and wet 269 removal of BC mass. In the following we will present results for both number-270 and mass-based aging time-scales. 271

At time t, the total number concentration $N_{\rm BC}(t)$ of BC-particles is the sum 272 of the number concentration of BC-containing fresh particles $N_{\rm f}(t)$ and the 273 number concentration of BC-containing aged particles $N_{\rm a}(t)$. We define anal-274 ogously the total BC mass concentration $M_{\rm BC}(t)$, the BC mass concentration 275 in fresh BC-containing particles $M_f(t)$, and the BC mass concentration in aged 276 BC-containing particles $M_{\rm a}(t)$. The aged and fresh populations are separated 277 by applying an aging criterion, in our case activation at a certain supersat-278 uration threshold $S_{\rm c}$. Fresh particles are those with critical supersaturation 279 above the threshold value, while aged particles have critical supersaturations 280 below the threshold. 281

In the PartMC model we explicitly track a finite number of particles in a computational volume V. The number of fresh and aged BC-containing particles in the volume $V(t_k)$ at time t_k is denoted by $n_f(t_k)$ and $n_a(t_k)$, respectively. Similarly, $m_f(t_k)$ and $m_a(t_k)$ are respectively the total mass of BC in fresh and aged BC-containing particles in $V(t_k)$. The number and mass concentrations of fresh BC-containing particles in $V(t_k)$ are then given by

$$N_{\rm f}(t_k) = \frac{n_{\rm f}(t_k)}{V(t_k)} \qquad M_{\rm f}(t_k) = \frac{m_{\rm f}(t_k)}{V(t_k)} N_{\rm a}(t_k) = \frac{n_{\rm a}(t_k)}{V(t_k)} \qquad M_{\rm a}(t_k) = \frac{m_{\rm a}(t_k)}{V(t_k)}.$$
(4)

The fresh and aged number and mass concentrations can change due to emission and dilution, while condensation and coagulation can transfer number and mass concentration from the fresh to the aged population and vice versa. Changes in number and mass concentrations also occur due to temperature and pressure changes. In our model we neglect at present the impact of heterogeneous reactions on the surface of the particles, although studies have shown that these also contribute to the aging process (Rudich et al., 2007). The gain and loss terms for the fresh and aged BC-containing populations are given in Table 2.

To express changes in number and mass for coagulation we consider that all 291 constituent particles are lost during a coagulation event and the product of 292 coagulation is a gain of a new particle. Table 3 shows the overview of all 293 possible combinations and the resulting terms for each of those combinations. 294 For example, let us assume that there are four independent coagulation events 295 within a single timestep: one event between two fresh BC-containing particles 296 resulting in an aged particle, two events between fresh and aged BC-containing 297 particles each resulting in an aged particle, and one event between a fresh 298 BC-containing particle and a non-BC-containing particle resulting in a fresh 299 particle. Then we have losses $\Delta n_{f\to a}^{coag}(t_{k-1}, t_k) = 5$ and $\Delta n_{a\to a}^{coag}(t_{k-1}, t_k) = 2$, 300 and gains $\Delta n_{\rm f}^{\rm coag}(t_{k-1}, t_k) = 1$ and $\Delta n_{\rm a}^{\rm coag}(t_{k-1}, t_k) = 3$. 301

Note that for each particle pairing in Table 3 there can be two outcomes. For 302 example, coagulation of a small fresh and large aged particle generally pro-303 duces an aged particle, while coagulation of large fresh and small aged gener-304 ally produces a fresh particle. When S_c , as calculated in equations (2)–(3), is 305 used as the criterion for fresh versus aged, it can be shown that coagulation 306 of two aged particles never produces a fresh particle, and that the coagulation 307 of two fresh particles with S_c values close to the cutoff value can produce an 308 aged particle. 309

Coagulation can result in a net loss of number but must conserve mass. We thus have

$$\dot{N}_{a}^{coag}(t) \le \dot{N}_{f \to a}^{coag}(t) + \dot{N}_{a \to a}^{coag}(t)$$
(5)

$$\dot{M}_{\rm a}^{\rm coag}(t) = \dot{M}_{\rm f \to a}^{\rm coag}(t) + \dot{M}_{\rm a \to a}^{\rm coag}(t) \tag{6}$$

$$\Delta n_{\mathbf{a}}^{\mathrm{coag}}(t_{k-1}, t_k) \le \Delta n_{\mathbf{f} \to \mathbf{a}}^{\mathrm{coag}}(t_{k-1}, t_k) + \Delta n_{\mathbf{a} \to \mathbf{a}}^{\mathrm{coag}}(t_{k-1}, t_k) \tag{7}$$

$$\Delta m_{\mathbf{a}}^{\mathrm{coag}}(t_{k-1}, t_k) = \Delta m_{\mathbf{f} \to \mathbf{a}}^{\mathrm{coag}}(t_{k-1}, t_k) + \Delta m_{\mathbf{a} \to \mathbf{a}}^{\mathrm{coag}}(t_{k-1}, t_k) \tag{8}$$

and similarly for coagulation resulting in fresh particles.

The following continuous equations describe the evolution of the number and

mass concentrations of fresh and aged BC-containing populations:

$$\frac{dN_{\rm f}(t)}{dt} = \dot{N}_{\rm f}^{\rm density}(t) + \dot{N}_{\rm f}^{\rm emit}(t) - \dot{N}_{\rm f}^{\rm dilution}(t) + \dot{N}_{\rm f}^{\rm coag}(t) - \dot{N}_{\rm f\to f}^{\rm coag}(t) - \underbrace{\left(\dot{N}_{\rm f\to a}^{\rm coad}(t) + \dot{N}_{\rm f\to a}^{\rm coag}(t)\right)}_{\dot{N}^{\rm aging}(t)} \tag{9}$$

$$\frac{dN_{a}(t)}{dt} = \dot{N}_{a}^{\text{density}}(t) + \dot{N}_{a}^{\text{emit}}(t) - \dot{N}_{a}^{\text{dilution}}(t) + \dot{N}_{f \to a}^{\text{coag}}(t) + \dot{N}_{a \to a}^{\text{coag}}(t) - \underbrace{\left(\dot{N}_{a \to f}^{\text{coad}}(t) + \dot{N}_{a \to f}^{\text{coag}}(t)\right)}_{\dot{N}^{\text{de-aging}}(t)} \tag{10}$$

$$\frac{dM_{\rm f}(t)}{dt} = \dot{M}_{\rm f}^{\rm density}(t) + \dot{M}_{\rm f}^{\rm emit}(t) - \dot{M}_{\rm f}^{\rm dilution}(t) \tag{11}$$

$$+ \underbrace{\left(\dot{M}_{\rm a \to f}^{\rm cond}(t) + \dot{M}_{\rm a \to f}^{\rm coag}(t)\right)}_{\dot{M}^{\rm de-aging}(t)} - \underbrace{\left(\dot{M}_{\rm f \to a}^{\rm cond}(t) + \dot{M}_{\rm f \to a}^{\rm coag}(t)\right)}_{\dot{M}^{\rm aging}(t)} \tag{12}$$

$$\frac{dM_{\rm a}(t)}{dt} = \dot{M}_{\rm a}^{\rm density}(t) + \dot{M}_{\rm a}^{\rm emit}(t) - \dot{M}_{\rm a}^{\rm dilution}(t) + \underbrace{\left(\dot{M}_{\rm f \to a}^{\rm coag}(t) + \dot{M}_{\rm f \to a}^{\rm coag}(t)\right)}_{\dot{M}^{\rm aging}(t)} - \underbrace{\left(\dot{M}_{\rm a \to f}^{\rm cond}(t) + \dot{M}_{\rm a \to f}^{\rm coag}(t)\right)}_{\dot{M}^{\rm de-aging}(t)} \tag{12}$$

Note that the mass equations (11)-(12) have been simplified from forms identical to the number equations (9)-(10) by using equation (6) for the conservation of mass during coagulation. Condensation (or rather evaporation) and coagulation can in principle also produce a transfer from aged to fresh particles. This is reflected by the terms denoted as $\dot{N}^{de-aging}(t)$ and $\dot{M}^{de-aging}(t)$ above.

The aging time-scales τ_N and τ_M for number and mass are then determined by the first-order models:

$$\dot{N}^{\text{aging}}(t) = \frac{1}{\tau_{\text{N}}(t)} N_{\text{f}}(t)$$
(13)

$$\dot{M}^{\text{aging}}(t) = \frac{1}{\tau_{\text{M}}(t)} M_{\text{f}}(t)$$
(14)

The discrete versions of the balance equations (9)-(12) are:

$$n_{\rm f}(t_k) - n_{\rm f}(t_{k-1}) = \Delta n_{\rm f}^{\rm emit}(t_{k-1}, t_k) - \Delta n_{\rm f}^{\rm dilution}(t_{k-1}, t_k)$$
(15)
+ $\Delta n_{\rm a \to f}^{\rm cond}(t_{k-1}, t_k) + \Delta n_{\rm f}^{\rm coag}(t_{k-1}, t_k) - \Delta n_{\rm f \to f}^{\rm coag}(t_{k-1}, t_k)$
- $\underbrace{\left(\Delta n_{\rm f \to a}^{\rm cond}(t_{k-1}, t_k) + \Delta n_{\rm f \to a}^{\rm coag}(t_{k-1}, t_k)\right)}_{\Delta n^{\rm aging}(t_{k-1}, t_k)}$

$$n_{a}(t_{k}) - n_{a}(t_{k-1}) = \Delta n_{a}^{\text{emit}}(t_{k-1}, t_{k}) - \Delta n_{a}^{\text{dilution}}(t_{k-1}, t_{k})$$
(16)
+ $\Delta n_{f \rightarrow a}^{\text{coad}}(t_{k-1}, t_{k}) + \Delta n_{a}^{\text{coag}}(t_{k-1}, t_{k}) - \Delta n_{a \rightarrow a}^{\text{coag}}(t_{k-1}, t_{k})$
- $(\Delta n_{a \rightarrow f}^{\text{cond}}(t_{k-1}, t_{k}) + \Delta n_{a \rightarrow f}^{\text{coag}}(t_{k-1}, t_{k})))$
 $M_{f}(t_{k}) - m_{f}(t_{k-1}) = \Delta m_{f}^{\text{emit}}(t_{k-1}, t_{k}) - \Delta m_{f}^{\text{dilution}}(t_{k-1}, t_{k})$ (17)
+ $(\Delta m_{a \rightarrow f}^{\text{coad}}(t_{k-1}, t_{k}) + \Delta m_{a \rightarrow f}^{\text{coag}}(t_{k-1}, t_{k})))$
 $\Delta m^{\text{de-aging}(t_{k-1}, t_{k})}$
- $(\Delta m_{f \rightarrow a}^{\text{coad}}(t_{k-1}, t_{k}) + \Delta m_{f \rightarrow a}^{\text{coag}}(t_{k-1}, t_{k})))$
 $M_{a}(t_{k}) - m_{a}(t_{k-1}) = \Delta m_{a}^{\text{emit}}(t_{k-1}, t_{k}) - \Delta m_{a}^{\text{dilution}}(t_{k-1}, t_{k})$ (18)
+ $(\Delta m_{f \rightarrow a}^{\text{coad}}(t_{k-1}, t_{k}) + \Delta m_{f \rightarrow a}^{\text{coag}}(t_{k-1}, t_{k})))$
 $\Delta m^{\text{aging}(t_{k-1}, t_{k})}$
- $(\Delta m_{f \rightarrow a}^{\text{coad}}(t_{k-1}, t_{k}) + \Delta m_{f \rightarrow a}^{\text{coag}}(t_{k-1}, t_{k})))$
 $\Delta m^{\text{aging}(t_{k-1}, t_{k})}$

Here equation (8) for the discrete conservation of mass during coagulation was used to simplify the mass equations, as in the continuous case.

By comparing the continuous equations (9)-(12) to the discrete equations (15)-(18) using the relationships (4) we see that the continuous aging terms can be approximated by:

$$\dot{N}^{\text{aging}}(t_k) \approx \frac{\Delta n^{\text{aging}}(t_{k-1}, t_k)}{(t_k - t_{k-1})V(t_k)} \tag{19}$$

$$\dot{M}^{\text{aging}}(t_k) \approx \frac{\Delta m^{\text{aging}}(t_{k-1}, t_k)}{(t_k - t_{k-1})V(t_k)},$$
(20)

where the use of V at time t_k is because the computational volume V is updated first within each timestep in the PartMC algorithm (Riemer et al., 2009, Figure 1).

From equations (13) and (14) and the relationships (4), the aging time-scales $\tau_{\rm N}$ and $\tau_{\rm M}$ are then approximated by:

$$\tau_{\rm N}(t_k) \approx \frac{(t_k - t_{k-1})n_{\rm f}(t_k)}{\Delta n^{\rm aging}(t_{k-1}, t_k)} \tag{21}$$

$$\tau_{\rm M}(t_k) \approx \frac{(t_k - t_{k-1})m_{\rm f}(t_k)}{\Delta m^{\rm aging}(t_{k-1}, t_k)}.$$
(22)

For the analysis in Section 5 we additionally define the aging time-scale $\tau_{\rm N}^{\rm cond}$ ignoring the impact of coagulation, an average time-scale $\tau_{\rm N,day}$ during the day, and an average time-scale $\tau_{\rm N,night}$ during the night, given by:

$$\tau_{\rm N}^{\rm cond}(t_k) \approx \frac{(t_k - t_{k-1})n_{\rm f}(t_k)}{\Delta n_{\rm f \to a}^{\rm cond}(t_{k-1}, t_k)}$$
(23)

$$(\tau_{\rm N,day})^{-1} = \frac{1}{3 \text{ hours}} \int_{12:00 \text{ LST}}^{15:00 \text{ LST}} (\tau_{\rm N}(t))^{-1} dt$$
(24)

$$(\tau_{\rm N,night})^{-1} = \frac{1}{10 \,\rm hours} \int_{18:00 \,\rm LST}^{04:00 \,\rm LST} \left(\tau_{\rm N}(t)\right)^{-1} dt, \tag{25}$$

and similarly for $\tau_{\rm M}^{\rm cond}$, $\tau_{\rm M,day}$, $\tau_{\rm M,night}$, $\tau_{\rm N,day}^{\rm cond}$, and so on.

322 5 Results

In this section we show results for supersaturation thresholds ranging between 323 $S_{\rm c} = 0.1\%$ and $S_{\rm c} = 1.0\%$, as these are typically achieved in updrafts in 324 stratus and cumulus clouds (Warner, 1968). To limit the number of figures we 325 use $S_{\rm c} = 0.6\%$ as a base case. Figure 5 shows the time series for $N_{\rm f}$, $N_{\rm a}$, and 326 $N_{\rm BC} = N_{\rm f} + N_{\rm a}$ for $S_{\rm c} = 0.6\%$. The total number concentration $N_{\rm BC}$ of BC-327 containing particles increased until 18:00 LST due to the emission of particles. 328 After the emissions stopped, $N_{\rm BC}$ decreased as a result of continued dilution 329 and coagulation. The time series for $N_{\rm f}$ and $N_{\rm a}$ show that both increased 330 in the morning hours. A pronounced transfer from fresh to aged occurred 331 after 11:30 LST, the time when nitrate formation started taking place on the 332 dry particles (compare Figure 2). This process efficiently contributed to the 333 conversion of fresh particles to aged particles, which was reflected by a short 334 aging time-scale. 335

The left column of Figure 6 compares the aging time-scales $\tau_{\rm N}$ and $\tau_{\rm N}^{\rm cond}$ computed according to equations (21) and (23) for different supersaturation thresholds. The top, middle and bottom panels shows the results for supersaturation thresholds $S_{\rm c} = 0.1\%$, $S_{\rm c} = 0.6\%$, and $S_{\rm c} = 1\%$, respectively. The grey shading is the raw data, and the black lines are results computed from smoothing the transfer rates with a Hann filter with a window width of 1 hour.

The solid lines represent $\tau_{\rm N}$, including the contributions due to both coagulation and condensation according to equation (21). For $S_{\rm c} = 0.6\%$, $\tau_{\rm N}$ started off in the morning with values of $\tau_{\rm N} \approx 20$ hours. It decreased sharply after 11:00 LST, which is the time when photochemistry was at its peak, and nitrate formation was most pronounced, hence leading to a fast aging process. Between 12:00 LST and 16:00 LST, $\tau_{\rm N}$ was less than 1 hour, and reached values as low as 0.2 hours. After 16:00 LST, as photochemistry slowed down, $\tau_{\rm N}$ increased again, reaching a plateau of $\tau_{\rm N} \approx 10$ hours during the evening and night.

The broken lines represent $\tau_{\rm N}^{\rm cond}$ as defined in equation (23), i.e. the contribution due to coagulation is ignored. There was only a small difference between $\tau_{\rm N}$ and $\tau_{\rm N}^{\rm cond}$ during midday and early afternoon when condensation was operating very effectively. However during morning, afternoon and night, neglecting coagulation lead to larger time-scales (up to one order of magnitude).

A similar pattern was found for $S_{\rm c} = 1\%$, shown in the bottom panel. For 356 $S_{\rm c} = 0.1\%$ we generally obtained larger time-scales. During the morning, $\tau_{\rm N}$ 357 was about 50 hours and decreased to 10 hours in the early afternoon. There 358 was a short period around 16:00 LST when $\tau_{\rm N}$ dropped to 2 hours. Obviously, 359 at $S_{\rm c} = 0.1\%$, even after the growth due to condensation of ammonium nitrate, 360 the particles were still too small to be activated to the same extent as seen 361 for the larger supersaturations. During the following night $\tau_{\rm N}$ was around 10– 362 20 hours. For this low supersaturation the contrast between day and night was 363 not as pronounced as for $S_c = 0.6\%$ or $S_c = 1\%$. 364

Qualitatively, the temporal evolution of $\tau_{\rm M}$ (right column) was similar to the number-based result $\tau_{\rm N}$. However the day/night contrast was more pronounced for the case with $S_{\rm c} = 0.1\%$, and the time-scales based on mass during the day were lower than the ones based on number.

Figure 7 shows the individual transfer terms of BC-containing particles for the 369 case $S_{\rm c} = 0.6\%$. The transfer rate $\dot{N}_{\rm a \to f}^{\rm coag}$ due to coagulation from aged to fresh 370 was very small throughout the whole day, remaining below $0.01 \text{ cm}^{-3} \text{ s}^{-1}$. The 371 transfer rate $\dot{N}_{f\to a}^{coag}$ due to coagulation from fresh to aged followed the time 372 series of $N_{\rm f}$. The minimum of $N_{\rm f}$ during the early afternoon was reflected in 373 a minimum of the transfer rate $\dot{N}_{f\to a}^{coag}$. The transfer rate $\dot{N}_{f\to a}^{cond}$ due to conden-374 sation from fresh to aged was large between 11:30 and 15:00 LST, consistent 375 with the decrease of $\tau_{\rm N}$ in Figure 6. Lastly, there was a non-zero transfer $\dot{N}_{\rm a \to f}^{\rm cond}$ 376 from aged to fresh due to condensation, which was larger than $\dot{N}_{f \rightarrow a}^{cond}$ towards 377 the end of the simulation. This was related to a shrinking of the particles due 378 to decreasing relative humidity (compare Figure 1). 379

Figure 8 summarizes the results for the different aging time-scale definitions. We calculated $\tau_{N,day}$ and $\tau_{N,night}$ according to equation (23) for several hundred different supersaturation thresholds between $S_c = 0.1\%$ and $S_c = 1\%$. We also distinguished between the definition of τ including the transfer due to coagulation and condensation (solid lines), and including only the transfer due to condensation, $\tau_{N,day}^{cond}$ and $\tau_{N,night}^{cond}$ (broken lines).

For this particular urban plume scenario the following general features emerge:
during the day, condensation of semi-volatile species, in our case especially ammonium nitrate, was the dominant process for aging. The time-scales based

on number were larger than the time-scales based on mass during the day. 389 by roughly a factor of five. The aging time-scales had a strong dependence 390 on supersaturation threshold. For $S_{\rm c} = 0.1\%$, $\tau_{\rm N,day}$ was 10 hours, whereas for 391 $S_{\rm c} = 1\%$, $\tau_{\rm N,day}$ was only 0.2 hours. During the night condensation was limited, 392 hence coagulation was the dominant aging process. For low supersaturation 393 thresholds, the time-scales based on number were smaller than the time-scales 394 based on mass, but this difference decreased for higher supersaturation thresh-395 olds. 396

397 6 Conclusions

In this paper we presented a method for explicitly calculating aging time-398 scales of black carbon aerosol using particle-resolved model simulations with 399 PartMC-MOSAIC. We developed number-based and mass-based aging time-400 scales using the activation of the particles at a given supersaturation as a cri-401 terion for aging. We applied this method to an urban plume scenario (Riemer 402 et al., 2009) for a range of supersaturation thresholds between 0.1% and 1%403 and considered condensation of secondary substances and coagulation as aging 404 mechanisms. Aging due to heterogeneous processes (chemical aging) were not 405 included. 406

For this particular scenario we found a separation into day and night regimes. 407 During the day the condensation-induced aging dominated, in particular due 408 to the formation of ammonium nitrate. Therefore the condensation-only number-409 based aging time-scale $\tau_{\rm N,day}^{\rm cond}$ was almost the same as the total time-scale $\tau_{\rm N,day}$ 410 and similarly for mass. The daytime aging number-based time-scale $\tau_{N,day}$ was 411 about 10 hours for a supersaturation threshold of $S_{\rm c} = 0.1\%$ and decreased to 412 0.06 hours for a threshold of $S_{\rm c} = 1\%$. The daytime mass-based aging time-413 scale $\tau_{M,day}$ was about a factor of five lower than $\tau_{N,day}$ for all supersaturation 414 thresholds. 415

During the night, the absence of condensable species caused the number-based 416 aging time-scale $\tau_{N,night}$ to be about one order of magnitude larger than during 417 the day. Coagulation became dominant, which was reflected by the fact that 418 the condensation-only time-scale $\tau_{N,night}^{cond}$ was an order of magnitude larger 419 than the total time-scale $\tau_{N,night}$. The nighttime aging time-scales therefore 420 depended on the particle number concentrations. We suspect that chemical 421 aging would have its largest impact during periods when condensation is not 422 dominant, i.e. during the night in our case. 423

424 Compared to the time-scales used in global models, which are typically on the
425 order of 30 hours (Chung and Seinfeld, 2002; Koch, 2001, e.g.), our time-scales
426 were much shorter, in particular during the day. This confirmed findings by

Riemer et al. (2004) who showed with a completely different approach that daytime and nighttime aging regimes exists, and that aging during the day proceeds very rapidly.

However some caveats need to be emphasized: our urban plume scenario represents only one scenario, with very polluted conditions and fairly high number concentrations during the night ($N_{\rm BC} \approx 5000 \text{ cm}^{-3}$). For lower number concentrations, we expect the aging time-scales during the night to increase.

Table 1

Initial and emitted aerosol distribution parameters. The initial aerosol distribution is also used as the background aerosol distribution. The percentages for the composition are by mass. E is the area source strength of particle emissions. Dividing E by the mixing height and multiplying by a normalized composition distribution gives the number distribution emission rate.

Terms	Description
$N_{\rm f}(t),N_{\rm a}(t)$	Number concentration of fresh/aged BC-containing particles.
$\dot{N}_{\mathrm{f}}^{\mathrm{emit}}(t),\dot{N}_{\mathrm{a}}^{\mathrm{emit}}(t)$	Gain rate of number concentration of fresh/aged BC-containing particles due to emission.
$\dot{N}_{\rm f}^{\rm dilution}(t),~\dot{N}_{\rm a}^{\rm dilution}(t)$	Loss rate of number concentration of fresh/aged BC-containing particles due to dilution.
$\dot{N}_{\mathrm{f} \rightarrow \mathrm{a}}^{\mathrm{cond}}(t), \dot{N}_{\mathrm{a} \rightarrow \mathrm{f}}^{\mathrm{cond}}(t)$	Gain rate of number concentration of aged/fresh BC-containing particles due to condensation or evaporation on fresh/aged particles.
$\dot{N}_{\mathrm{f}}^{\mathrm{coag}}(t),\dot{N}_{\mathrm{a}}^{\mathrm{coag}}(t)$	Gain rate of number concentration of fresh/aged BC-containing particles from coagulation events.
$\dot{N}_{\mathrm{f} ightarrow \mathrm{f}}^{\mathrm{coag}}(t), \dot{N}_{\mathrm{f} ightarrow \mathrm{a}}^{\mathrm{coag}}(t)$	Loss rate of number concentration of fresh BC-containing particles to coagulation events resulting in fresh/aged particles.
$\dot{N}_{\mathrm{a} \rightarrow \mathrm{a}}^{\mathrm{coag}}(t), \ \dot{N}_{\mathrm{a} \rightarrow \mathrm{f}}^{\mathrm{coag}}(t)$	Loss rate of number concentration of aged BC-containing particles to coagulation events resulting in aged/fresh particles.
$\dot{N}_{\rm f}^{\rm density}(t),\dot{N}_{\rm a}^{\rm density}(t)$	Gain rate of number concentration of fresh/aged BC-containing particles due to air density changes.
$\dot{N}^{\text{aging}}(t), \dot{N}^{\text{de-aging}}(t)$	Net transfer rate of fresh-to-aged/aged-to-fresh number concentration of BC-containing particles.

Table 2

Description of individual terms in equations (9) and (10). With the exception of $\dot{N}_{\rm f}^{\rm density}(t)$ and $\dot{N}_{\rm a}^{\rm density}(t)$ all of these terms must be non-negative. The same notation is for the terms in equations (11) and (12) for mass concentration, and for the corresponding discrete equations (15)–(18). The discrete terms are expressed as a change in number or mass within a timestep, so that $\Delta n_{\rm f\to a}^{\rm cond}(t_{k-1}, t_k)$ is the number of BC-containing particles in the computational volume that change from fresh to aged due only to condensation during the timestep from time t_{k-1} to t_k , for example. There are no discrete terms for air density changes as they are incorporated by changing the computational volume V.

Particle 1	Particle 2	Resulting particle	Non-zero loss terms	Non-zero gain terms
fresh	fresh	fresh	$\Delta n_{\rm f \rightarrow f}^{\rm coag} = 2$	$\Delta n_{\rm f}^{\rm coag} = 1$
fresh	fresh	aged	$\Delta n_{\rm f \rightarrow a}^{\rm coag} = 2$	$\Delta n_{\rm a}^{\rm coag} = 1$
aged	fresh	fresh	$\Delta n_{\rm a \rightarrow f}^{\rm coag} = 1, \Delta n_{\rm f \rightarrow f}^{\rm coag} = 1$	$\Delta n_{\rm f}^{\rm coag} = 1$
aged	fresh	aged	$\Delta n_{\mathrm{a} \rightarrow \mathrm{a}}^{\mathrm{coag}} = 1, \Delta n_{\mathrm{f} \rightarrow \mathrm{a}}^{\mathrm{coag}} = 1$	$\Delta n_{\rm a}^{\rm coag} = 1$
aged	aged	aged	$\Delta n_{\mathrm{a} \to \mathrm{a}}^{\mathrm{coag}} = 2$	$\Delta n_{\rm a}^{\rm coag} = 1$
fresh	non-BC	fresh	$\Delta n_{\rm f \rightarrow f}^{\rm coag} = 1$	$\Delta n_{\rm f}^{\rm coag} = 1$
fresh	non-BC	aged	$\Delta n_{\rm f \rightarrow a}^{\rm coag} = 1$	$\Delta n_{\rm a}^{\rm coag} = 1$
aged	non-BC	fresh	$\Delta n_{\rm a \rightarrow f}^{\rm coag} = 1$	$\Delta n_{\rm f}^{\rm coag} = 1$
aged	non-BC	aged	$\Delta n_{\rm a \to a}^{\rm coag} = 1$	$\Delta n_{\rm a}^{\rm coag} = 1$

Table 3

The different coagulation events and the resulting expressions for the loss and gain terms of the number of fresh and aged BC-containing particles. Similar expressions exist for mass changes Δm in the particle-resolved model and for the number rates \dot{N} and mass rates \dot{M} in the continuous model.

Fig. 1. Time series of temperature, relative humidity, and mixing height over the course of the 24 hour simulation. The pressure and water mixing ratio were kept constant.

Fig. 2. Time series of mass concentrations of selected aerosol species: nitrate (NO_3) , ammonium (NH_4) , POA, sulfate (SO_4) , BC, and SOA. Particle and gas phase emissions were present from 06:00 to 18:00 LST.

Fig. 3. Normalized two-dimensional number distributions after 1 hour (07:00 LST) and 24 hours (06:00 LST the next day) of simulation. The top panels show the normalized value of the two-dimensional distribution $\partial^2 N_{\rm BC,dry}(D,w)/(\partial \log_{10} D \ \partial w)$ with respect to diameter D and BC dry mass fraction $w_{\rm BC,dry}$, while the bottom panels show the normalized value of the two-dimensional distribution $\partial^2 N_{\rm S}(D, S_{\rm c})/(\partial \log_{10} D \ \partial \log_{10} S_{\rm c})$ with respect to diameter D and critical supersaturation $S_{\rm c}$.

Fig. 4. Cloud condensation nuclei spectra after 1 hour (07:00 LST) and 24 hours (06:00 LST the next day) of simulation based on the simulation results shown in Figure 3.

Fig. 5. Time series of total number concentration $N_{\rm BC}$ of BC-containing particles and number concentrations $N_{\rm f}$ and $N_{\rm a}$ for fresh and aged BC-containing particles, respectively. The critical supersaturation separating fresh and aged particles is set to $S_{\rm c} = 0.6\%$.

Fig. 6. Comparison of aging time-scales based on number (left) and mass (right), showing both the time-scales due to condensation and coagulation ($\tau_{\rm N}$ and $\tau_{\rm M}$) and the time-scales due to condensation alone ($\tau_{\rm N}^{\rm cond}$ and $\tau_{\rm M}^{\rm cond}$). The top panels have the critical supersaturation separating fresh from aged particles set to $S_{\rm c} = 0.1\%$, while the middle panels have $S_{\rm c} = 0.6\%$, and the bottom panels have $S_{\rm c} = 1.0\%$.

Fig. 7. Transfer rates due to condensation (top) and coagulation (bottom). The critical supersaturation separating fresh and aged particles is set to $S_{\rm c} = 0.6\%$. The notation is according to Table 2.

Fig. 8. Day (left) and night (right) averages of the aging time-scale, as defined in equations (23)–(25). As can be see from Figure 6, during the day the condensation-induced aging dominates, so $\tau_{N,day}^{cond}$ is almost indistinguishable from $\tau_{N,day}$, and similarly for mass.
