ABSTRACT

Although propane gas (C_3H_8) was first detected in the stratosphere of Titan by the 14 Voyager IRIS infrared spectrometer in 1980, obtaining an accurate measurement of its 15 abundance has proved difficult. All existing measurements have been made by modeling 16 the ν_{26} band at 748 cm⁻¹: however different analyzes over time have yielded quite different 17 results, and it also suffers from confusion with the strong nearby ν_5 band of acetylene. 18 In this paper we select large spectral averages of data from the Cassini Composite In-19 frared Spectrometer (CIRS) obtained in limb-viewing mode at low latitudes $(30^{\circ}\text{S}-30^{\circ}\text{N})$, 20 greatly increasing the path length and hence signal-to-noise ratio for optically thin trace 21 species such as propane. By modeling and subtracting the emissions of other gas species, 22 we demonstrate that at least six infrared bands of propane are detected by CIRS, in-23 cluding two not previously identified in Titan spectra. Using a new line list for the range 24 $1300-1400 \text{ cm}^{-1}$, along with an existing GEISA list, we retrieve propane abundances from 25 two bands at 748 and 1376 cm⁻¹. At 748 cm⁻¹ we retrieve $4.2 \pm 0.5 \times 10^{-7}$ (1- σ error) at 2 26 mbar, in good agreement with previous studies, although lack of hotbands in the present 27 spectral atlas remains a problem. We also determine $5.7 \pm 0.8 \times 10^{-7}$ at 2 mbar from the 28 1376 cm^{-1} band - a value that is probably affected by systematic errors including contin-29 uum gradients due to haze and also an imperfect model of the ν_6 band of ethane. This 30 study clearly shows for the first time the ubiquity of propane's emission bands across the 31 thermal infrared spectrum of Titan, and points to an urgent need for further laboratory 32 spectroscopy work, both to provide the line positions and intensities needed to model 33 these bands, and also to further characterize haze spectral opacity. The present lack of 34 accurate modeling capability for propane is an impediment not only for the measurement 35 of propane itself, but also for the search for the emissions of new molecules in many spec-36 tral regions. 37

39 1 Introduction

Propane (C_3H_8) was first detected in the atmosphere of Titan by the Voyager 1 IRIS 40 spectrometer during the 1980 encounter (Maguire et al., 1981), when excess emission at 41 748, 922, 1053 and 1158 $\rm cm^{-1}$ was used to make the identification. Propane is an end-42 product of Titan's active photochemistry. This process begins when methane is dissociated 43 in the upper atmosphere by UV photons and energetic particles to form hydrocarbon 44 radicals and ions, which undergo a complex chain of reactions to form larger molecules 45 and haze particles. The main pathway leading to C_3H_8 is the three-body association: CH_3 46 + $\rm C_2H_5$ + M \rightarrow $\rm C_3H_8$ + M (Yung et al., 1984; Wilson and Atreya, 2004), and most is 47 ultimately removed by condensation in the lower stratosphere. Spectrally, propane is a 48 very important molecule, as it has 27 predicted infrared vibrational modes of which at 49 least 23 are active (see $\S4.1$). 50

Early attempts to measure the abundance of propane from the Voyager dataset suffered 51 from a lack of reliable laboratory spectroscopic data, resulting in initial over-estimates 52 followed by a downward trend of revised abundances until the mid-1990s. Maguire et al. 53 (1981) used laboratory spectra to compute the band intensity of the 748 $\rm cm^{-1}$ band, 54 thereby inferring a uniformly-mixed abundance for Titan's stratosphere of 2×10^{-5} , with 55 an uncertainty factor of three. The value was halved the next year by Kim and Caldwell 56 (1982), who modeled the same band to obtain a propane abundance of 1.2×10^{-5} . 57 Coustenis et al. (1989a) also used a band-model approach, based on newly measured ab-58 sorptions from Giver et al. (1984), and a full radiative transfer treatment to greatly revise 59 the estimate for uniformly-mixed stratospheric propane downwards to $(7 \pm 4) \times 10^{-7}$ at 60 the equator. 61

In 1991 \sim 9000 lines representing the 748 cm⁻¹ band were added to the GEISA atlas (Husson et al., 1992), with the data taken from unpublished measurements at NASA

GSFC by G. Bjoraker circa 1986. These allowed Coustenis and Bézard (1995) to make a 64 full line-by-line model of the blended C_2H_2 and C_3H_8 emissions. For the first time, the 65 latitude variation of propane was reported: a modest increase from $5.0 \pm 1.7 \times 10^{-7}$ at 66 the equator to $1.2 \pm 0.5 \times 10^{-6}$ at 70°N (assuming uniform stratospheric abundances). 67 Simultaneously, enhancements in many other minor gases were detected in the northern 68 (winter) polar stratosphere: especially in the heavier, acetylene-derived gases (C_4H_2 , C_3H_4 , 69 HC_3N , C_2N_2), but also HCN and C_2H_4 . These enhancements have been modeled and 70 explained dynamically, as due to downward advection of short-lived species at the pole(s) 71 in a global circulation cell(s), as these molecules tend to have higher abundances at higher 72 altitudes in the absence of dynamics (Teanby et al., 2009; Lebonnois et al., 2009, and 73 references therein). 74

The launch of the Infrared Space Observatory (ISO) in 1995 provided a new tool 75 for studying planetary atmospheres. In 1997, the Short Wavelength Spectrometer (SWS) 76 was used to acquire spectra of Titan with a mean resolution of 0.4 cm^{-1} - an order of 77 magnitude improvement over the 4.3 cm^{-1} of Voyager IRIS, although spatially unresolved. 78 Low-latitude gaseous abundances were reported by Coustenis et al. (2003), and included 79 a measurement of $q_{C3H8} = 2 \pm 1 \times 10^{-7}$ via the same (748 cm⁻¹) band as Voyager IRIS. 80 The reason for this slightly lower value is unclear, although real seasonal change might 81 be a factor, as well as the higher spectral resolution. 82

Even this improved spectral resolution was insufficient to actually separate the emission lines of propane at 748 cm⁻¹ from those of the R-branch lines of the 729 cm⁻¹ (ν_5) band of C₂H₂, and weaker contributions from HCN and C₂H₆. The first study to resolve the C₃H₈ emission features from the other gases was made by Roe et al. (2003), who used the R $\simeq 10^5$ TEXES Echelle Spectrograph attached to the NASA Infrared Telescope Facility (IRTF) to make high spectral resolution, disk averaged observations of Titan, resulting in a stratospheric abundance estimate of $(6.2\pm1.2)\times10^{-7}$ at 90–250 km (13.0–0.24 mbar),

in agreement with the low-latitude IRIS values. It is important to note that these authors 90 compared four line lists for the 748 $\rm cm^{-1}$ propane band then available, noting significant 91 discrepancies between all the lists and actual propane spectral data. Only the absorption 92 coefficients that they derived empirically from laboratory data provided a good fit to the 93 planetary data. In addition, this was the first study of Titan's propane to use the ν_{26} 94 designation for this band, rather than the ν_{21} designation that was commonly used by 95 earlier authors. We discuss the dichotomy of propane band designations further in section 96 4.1. 97

In 2004 the Cassini/Huygens spacecraft entered orbit around Saturn, opening a new 98 era in Titan research. The Composite Infrared Spectrometer (CIRS) instrument onboard 99 Cassini is a successor to the Voyager IRIS, although with many improvements including 100 to spectral range and resolution, and spatial resolution (see Section 2.1). Furthermore, 101 the great variety of Titan flyby encounter ranges and relative orbital inclinations, com-102 bined with the much greater available observing time versus the Voyager encounters, 103 permits Cassini CIRS to make a very diverse range of scientific investigations. These in-104 clude low-spectral resolution North–South surface temperature mapping (Jennings et al., 105 2009) and limb temperature mapping (Achterberg et al., 2008), through to high spectral 106 resolution composition measurements on both the disk and the limb (Coustenis et al., 107 2007; Vinatier et al., 2007a; Teanby et al., 2008b, and references therein), with vertical 108 resolution of better than one scale height (40–50 km). 109

¹¹⁰ So far, two analyses of CIRS Titan spectra have considered propane. Coustenis et al. ¹¹¹ (2007) modeled zonally-averaged sets of mid-infrared spectra (600–1400 cm⁻¹) from 70°S– ¹¹² 70°N to measure the latitude variations in hydrocarbons, nitriles and CO₂, including the ¹¹³ 748 cm⁻¹ band of propane for which spectral line data is available in GEISA. C₃H₈ was ¹¹⁴ found to exhibit a very slight increase from the south to the north, from ~ 5 × 10⁻⁷ ¹¹⁵ to ~ 8 × 10⁻⁷. Vinatier et al. (2007a) modeled two high spectral resolution (0.5 cm⁻¹) observation sets of Titan's limb, from the Tb and T3 flybys and directed at 15°S and 80°N respectively. C_3H_8 was found to display an increasing abundance with altitude in the range ~150–350 km (~ 2.0–0.01 mbar) at both latitudes, in accordance with the conventional understanding of photochemical formation in the upper atmosphere and downward advection to the lower stratosphere where removal through condensation occurs (89% according to Wilson and Atreya, 2004).

In this paper we have two objectives. First, we show clearly the very prolific extent 122 of the multiple propane bands that can be detected by CIRS across the mid-infrared. 123 At least six bands are visible in limb spectra after the modeling and removal of other 124 stronger gas emissions. Second, we use a new laboratory line list for propane in the 125 range 1300–1400 cm⁻¹ (Flaud et al., 2001), along with the GEISA list for the 748 cm⁻¹ 126 band to make independent measurements of the propane abundance, and show that the 127 results are probably compatible when systematic errors are accounted for. Finally, we 128 draw conclusions about the current status of propane retrievals in the thermal infrared. 129

130 2 Data Acquisition

In this paper we make use of two spectral datasets. The first is a set of Titan limb spectral data, acquired by Cassini CIRS between 2004 and 2008. The second is a set of laboratory absorption spectra of room temperature propane gas acquired at Pacific Northwest National Laboratory in 2002. Both datasets are now described.

135 2.1 Cassini CIRS Limb Observations

The Composite Infrared Spectrometer (CIRS) carried on-board Cassini is a dual Fourier Transform interferometer design (Kunde et al., 1996; Flasar et al., 2004). A shared

telescope and foreoptics feed incoming radiation simultaneously into two interferometers: 138 a Martin-Puplett (polarizing) type optimized for far-infrared rays (10-600 $\rm cm^{-1}$), and 139 a conventional Michelson design for the mid-infrared ($600-1400 \text{ cm}^{-1}$). The recombined 140 beam of the far-infrared interferometer is focused onto a single circular bolometer detec-141 tor, known as focal plane 1 (FP1), while mid-infrared detection capability is provided by 142 two 1×10 HgCdTe arrays: focal plane 3 (FP3, 600–1100 cm⁻¹) and focal plane 4 (FP4, 143 nominal range $1100-1400 \text{ cm}^{-1}$, see also Appendix A). Both interferometers also share a 144 common scan mirror mechanism and reference laser. The spectral resolution is determined 145 by the commanded scan time, and is variable from 15.5 to 0.5 cm⁻¹. 146

At 5–9 hours from closest approach to Titan $(1.0-1.8 \times 10^5 \text{ km range})$, the CIRS instrument makes observations of the atmospheric limb, placing the mid-infrared arrays perpendicular to the disk edge, and obtaining spectral samples at ~30–50 km resolution, equivalent to approximately one atmospheric scale height. These observations come in two types: (i) temperature maps (shorter dwell, 15.5 cm⁻¹ spectral resolution, repositioning at multiple latitudes) and (ii) composition integrations (longer dwell, 0.5 cm⁻¹ resolution, single latitude).

For the purpose of identifying the weak emission bands, we have created large averages of low-latitude spectra for FP3 and FP4 from the high spectral resolution limb integrations (type (ii) above). Note that we do not attempt to explore the vertical and latitudinal variation of the propane abundance from the CIRS dataset, which has been documented elsewhere (Coustenis et al., 2007; Vinatier et al., 2007a, 2009), but rather to maximise signal-to-noise to emphasize and detect very weak emission features while still maintaining reasonable homogeneity of the dataset.

Therefore we chose to average across all flybys from the prime mission (June 2004 to June 2008) and latitudes in the range 30°S–30°N, in the knowledge that Titan's strato¹⁶³ sphere is slowly varying in this temporal and spatial interval (Coustenis et al., 2007; ¹⁶⁴ Achterberg et al., 2008; Teanby et al., 2008a). However, Titan's atmosphere varies much ¹⁶⁵ more rapidly in the vertical direction, and therefore we restricted our averages to 100– ¹⁶⁶ 150 km (pixel centers) where the signal-to-noise ratio was found to be the most favorable. ¹⁶⁷ The spacecraft distance range was also constrained to be less than 2×10^5 km. See Table ¹⁶⁸ I for additional details.

169 [TABLE I]

170 2.2 PNNL Laboratory Spectroscopy

For comparison with the CIRS spectra, Dr Steven Sharpe at Pacific Northwest National Laboratories (PNNL), has shared with us room temperature (296 K) absorption spectra of propane gas, taken as part of a large-scale survey of molecular infrared spectra. These consist of 6 individual co-added spectra of 98% pure propane gas measured with a Bruker-66V FTIR at 0.112 cm⁻¹ unapodized resolution, covering the FP3 and FP4 part of the CIRS spectral range (600–1400 cm⁻¹). Full experimental details have been published in the literature (Sharpe et al., 2004).

We have convolved the PNNL spectra with a Hamming kernel $h(\Delta \tilde{\nu})$ (instrumental line shape) of FWHM 0.48 cm⁻¹ for approximate comparison with the CIRS spectra, which originate at much lower temperatures (~ 160 K) in Titan's stratosphere:

$$h(\Delta \tilde{\nu}) = \frac{a \left(1.08 - 0.64 a^2 \left[\Delta \tilde{\nu}\right]^2\right) \operatorname{sinc}\left(2\pi a \Delta \tilde{\nu}\right)}{1 - 4a^2 \left[\Delta \tilde{\nu}\right]^2} \tag{1}$$

where h is the weighting factor at each position $\Delta \tilde{\nu} = (\tilde{\nu} - \tilde{\nu}_0)$ relative to a given wavenumber $\tilde{\nu}_0$ in the original spectrum, and a is an effective path difference: $a = 1.815/(2 \times 0.48) = 1.89$ cm that compensates the Nyquist path difference at the desired resolution $(1/(2 \times 0.48) \text{ cm})$ for the FWHM of the Hamming function in Nyquist units (1.815). Note that h is normalized so that: $\int h(\Delta \tilde{\nu}) d(\Delta \tilde{\nu}) = 1.0$ over the desired interval: we used ± 10 samples relative to each wavenumber (21-pt kernel).

188 **3 Data Analysis**

189 3.1 Model Atmosphere

Our model atmosphere consists of 100 layers equally spaced in $\log(p)$ from the sur-190 face (1.45 bar) to 700 km (4 \times 10⁻⁸ bar.) The initial temperature-pressure profile is a 191 smoothed version of the Huygens HASI results (Fulchignoni et al., 2005) (covering from 192 the surface to 7×10^{-12} bar at 10°S, 168°E) with heights calculated from hydrostatic 193 equilibrium. All gases known to be relevant for the 700–1400 $\rm cm^{-1}$ range of Titan's in-194 frared spectrum are included, namely: N₂, CH₄, H₂, HCN, C₂H₂, C₂H₆, C₂H₄ and C₃H₈. 195 In addition, the isotopologues ¹³C¹²CH₂, ¹³CH₄, CH₃D and ¹³CH₃D are included as sepa-196 rate species. The initial abundances and isotopic ratios mostly follow the Huygens GCMS 197 results (Niemann et al., 2005) and previous measurements by CIRS pertaining to low lat-198 itudes (Coustenis et al., 2007). In particular, H_2 and C_2H_4 are uniformly mixed, while 199 CH_4 follows the GCMS profile, N_2 is defined as $q_{N2} = 1.0 - q_{CH4}$, and the other gas 200 primary isotopologues, with the exception of C_2H_2 , have constant abundances in the 201 middle atmosphere, and follow condensation profiles towards the tropopause. The C_2H_2 202 VMR, which is known to have a gradient at low-latitudes, follows the 10°S profile of 203 Vinatier et al. (2007a). Finally, the minor isotopologue species have initial profiles scaled 204 from the primary isotopologue by molecular isotopic ratios previously determined by CIRS 205 (Bézard et al., 2007; Nixon et al., 2008a). Fig. 1 shows the initial gas profiles. 206

Fig. 1. Appears Here.

Finally, our model atmosphere also includes a single aerosol component with constant mass mixing ratio of particles above the tropopause (45 km) as described in Nixon (1998).

209 3.2 Forward Spectral Model

The forward model (NEMESIS, Irwin et al., 2008) computes the emerging radiation 210 field for Titan limb rays using the correlated-k approximation (Lacis and Oinas, 1991) for 211 rapid calculation of atmospheric opacity. The three types of opacity included are: gas vi-212 brational bands, collision-induced absorption (CIA) of N₂, CH₄ and H₂, and aerosol/haze 213 opacity. The k-coefficients for gaseous bands and CIA opacities are computed and pretab-214 ulated over the full range of pressures and temperatures required for the Titan model 215 atmosphere, as well as the CIRS full spectral range, to enable rapid calculations. The 216 spectral opacities are pre-convolved with a Hamming apodization function of FWHM 217 0.48 cm^{-1} , and 50 g-ordinates are used to approximate the k-distributions in each spec-218 tral bin. 219

Spectral line data are taken from the HITRAN 2004 (for CH₄ ν_4 1304 cm⁻¹, HCN ν_2 220 712 cm^{-1} and $C_2H_4 \nu_7 949 \text{ cm}^{-1}$; Rothman et al., 2005) and GEISA 2003 (for $C_2H_2 \nu_5 729$ 221 cm^{-1} , $C_3H_8 \nu_{26}$ band; Jacquinet-Husson et al., 2005) atlases. We also used supplemental 222 sources of line data for the $C_2H_6 \nu_9$ band (822 cm⁻¹ Vander Auwera et al., 2007), for 223 $^{13}\mathrm{CH_3D}$ (ν_6 1156 $\mathrm{cm^{-1}}$ Bézard et al., 2007) and for the 1300–1400 $\mathrm{cm^{-1}}$ bands of $\mathrm{C_3H_8}$ 224 (mostly due to the ν_{18} 1376 cm⁻¹ and the ν_{19} 1338 cm⁻¹ Flaud et al., 2001) that post-225 date the most recently available GEISA and HITRAN atlases. We made additional scaling 226 corrections to the line strengths for the ν_{26} band of C_3H_8 , and also to the line width and 227 temperature dependence parameters for both the GEISA and the Flaud et al. (2001) line 228 lists, justified in detail in Appendix B. 229

Additionally, for the ν_6 (1378 cm⁻¹) and ν_8 (1468 cm⁻¹) bands of C₂H₆, which are not

included in any current line atlases, we used a 'pseudo-linelist' made publicly available by the Jet Propulsion Laboratory (http:// mark4sun.jpl.nasa.gov/pseudo.html). This list is an approximation which seeks to model the overall absorption of these bands by using a uniform distribution of 'pseudo' lines of varying strengths, without actual knowledge of the real line positions or intensities.

To fit the continuum we used two further sources of opacity; (i) collision-induced opacity of six molecular pairs of H₂, N₂ and CH₄ (see detailed references in Teanby et al., 2006), and (ii) a simple haze with a constant (scaleable) number of particles per gram of atmosphere above the tropopause. The haze had either (A) a uniform grey spectral absorption, or (B) a spectral absorption cross-section derived by applying Mie theory to 0.2 μ m radius spheres (no scattering), using the real and imaginary refractive index data for laboratory haze analogue (tholin) as measured by Khare et al. (1984).

Previously, most models of CIRS Titan mid-infrared limb spectra (Teanby et al., 2007; 243 Vinatier et al., 2007a,b; Nixon et al., 2008b; Jennings et al., 2008; Coustenis et al., 2008) 244 have used the approximation of a single limb ray originating from the center of the detec-245 tor fields of view (FOVs) projected onto the limb: the 'infinitesimal' FOV approximation. 246 However, Teanby and Irwin (2007) have investigated the spatial smoothing effect of the 247 small but finite mid-IR detector FOVs when applied to Titan limb sounding. They con-248 clude that approximating a limb view using an infinitesimal ray introduces non-negligible 249 errors when the highest spectral resolution of CIRS (0.5 cm^{-1}) is used and many spectra 250 are co-added to lower the NESR. 251

More recently Nixon et al. (2009) have analyzed laboratory and in-flight field-of-view response measurements of CIRS, and computed real 1-D spatial response functions for all 20 mid-infrared detectors. Using these functions, they investigated systematic errors introduced by either the infinitesimal ray approximation or the finite (or 'boxcar') approximation for Titan limb viewing, relative to using the real detector spatial responses.
Their conclusion was that, for limb averages of as few as 20 spectra, the errors due to
both approximations became significant compared to the noise level.

Therefore, in this work we have included the actual 1-D spatial responses for each detector as follows. For the n^{th} individual spectrum, recorded by detector m, let a_n be the tangent altitude (in km) at the FOV center projected onto Titan's limb and d_n be the spacecraft-tangent point distance in km. Then the n^{th} spatial weighting function quantized onto a vertical grid z_i of 1-km altitude increments is then (c.f. Eq. 10 of Nixon et al., 2009):

$$w_n(z_i) = \frac{\overline{R}_m((z_i - a_n)/d_n)}{\sum_i \overline{R}_m((z_i - a_n)/d_n)}$$
(2)

264

Where \overline{R}_m is the 1-D (Y-averaged) response function of detector m expressed in angular units (tabulated in Table 4 of Nixon et al., 2009). For the average of all N spectra then the spatial weighting function is:

268
$$W(z_i) = \frac{1}{N} \sum_{n=1}^{N} w_n(z_i)$$
(3)

269 .

This 'effective' spatial weighting function is used to compute a mean model spectrum, by weighting synthetic spectra calculated for limb rays at each altitude:

$$\bar{I}(\tilde{\nu}) = \sum_{z=z_{\min}}^{z=z_{\max}} W(z_i) I(z_i, \tilde{\nu})$$
(4)

where z_{\min} and z_{\max} are the lowest and highest altitudes where $W(z_i) \neq 0$, and $\tilde{\nu}$ is wavenumber.

In practice, the 1 km resolution calculation grid is both unnecessarily fine to achieve

sufficient modelling accuracy, and also prohibitively slow, as it necessitates the calculation 276 of ~ 50 individual limb rays to produce a single spectrum at each modelling iteration. We 277 performed trial retrievals at various grid spacings, finding that 5 km grid point spacing 278 is sufficient for > 99% accuracy on both FP3 and FP4 (at which level the accuracy 279 becomes dominated by other effects, such as knowledge of limb pointing), and we therefore 280 interpolated the function $W(z_i)$ at 5 km increments relative to the mean limb tangent 281 altitude of the average spectrum, cutting off at a minimum weighting of 0.001. 5 km 282 resolution is approximately 10% of the scale height in Titan's lower stratosphere. 283

The resampled $W(z_i)$ functions in 5 km steps for the FP3 and FP4 spectral averages analyzed herein are shown in Fig. 2.

Fig. 2. Appears Here.

286 3.3 Retrieval Algorithm

The retrieval algorithm is a mathematical formalism used to find the 'optimal estimate' 287 set of model parameters, by iteration (Rodgers, 2000). At each step of the retrieval, the 288 forward model is used to calculate a synthetic spectrum, as described above, which is 289 then compared to the data spectrum. A cost function is calculated which is similar to 290 a χ^2 test of the difference between the data and model spectrum, with an additional 291 term to provide smoothing of the solution, also known as the a priori constraint. Model 292 parameters are then adjusted along the downhill gradients that tend to decrease the cost 293 function, so that divergence between the model and data will be reduced on the next step. 294 When a preset convergence limit is reached - i.e. when the percentage change in the cost 295 function falls below a threshold value, the retrieval ceases. This algorithm is identical to 296 that used in Nixon et al. (2008a) - see also Irwin et al. (2008) for further details. 297

298 4 Results

Fig. 3. Appears Here.

In this study we first used the 1225–1325 cm⁻¹ spectral region of the ν_4 methane band 299 to retrieve atmospheric temperatures, holding the methane abundance constant. Fig. 3 300 shows the result. Note that the retrieved temperatures in the main information region 301 of the lower stratosphere are significantly colder than the HASI profile, by as much as 302 10 K - much greater than expected due to latitude variation alone (HASI = 10° S; CIRS 303 $= 2^{\circ}$ N). This discrepancy has been noted and remarked on in several previous studies of 304 CIRS data (see §2 of Flasar and Achterberg, 2009, and references therein), and can be 305 seen to be part of a larger difference where the HASI stratopause is considerably lower 306 (by ~ 60 km) than that determined by fitting CIRS data. The spectroscopic parameters 307 for the methane ν_4 band are well-studied, and the CIRS data cannot be reconciled with 308 the HASI temperature profile, so a solution to this problem has not yet been reached. 309

The error on the temperature profile includes both spectral noise and also the 5% uncertainty on the Huygens GCMS methane abundance quoted by Niemann et al. (2005). See Nixon et al. (2008a) for description of the error propagation. Fig. 4 shows the vertical error variation.

Fig. 4. Appears Here.

The temperature profile was then fixed, and we carried out numerous separate retrievals on specific spectral regions suspected to harbor propane emission bands. In these retrievals, the grey 'aerosol' opacity was scaled to obtain a fit to the continuum level, and simultaneously relevant minor gas VMR profiles for each spectral region were adjusted to fit the emission bands.

Two separate models were calculated for each spectral region: (i) a best fit spectrum without propane, to reveal the propane signature in the residual, and (ii) for spectral regions where C_3H_8 line data were available, we fitted a model for all gases including propane, to obtain a C_3H_8 abundance, allowing the values from multiple C_3H_8 bands to be intercompared. The results are now discussed in detail.

324 4.1 Propane Band Detections

Figs. 5 and 6 show the results of modeling various CIRS spectral regions that were candidates for propane emissions. In each figure, the left hand column shows the data spectrum and model (grey haze used), while the right hand column shows the residual after subtraction of model from data, along with the corresponding portion of the PNNL laboratory absorption spectrum. The laboratory spectrum has been convolved with a 0.48 cm⁻¹ Hamming kernel for direct comparison to CIRS data, and arbitrary scaling is used.

Fig. 5. Appears Here.

Fig. 6. Appears Here.

Four strong bands are clearly detected on FP3 and four on FP4, as indicated on the figures, along with the locations of several weaker undetected bands. Note that the band at 1053 cm^{-1} is detected on both FP3 and FP4 where the spectral ranges overlap. The band assignments for all vibrational modes of C₃H₈ are listed in Table II. At this juncture, we are obliged to discuss a confusion regarding propane band numbering in the pre-existing literature.

337 [TABLE II]

Historically, there has been some inconsistency over the actual band designations for propane's infrared spectrum. This appears to be traceable to two original studies - a 1965 paper by Gayles and King, hereafter GK65, and a 1972 paper by Shimanouchi, hereafter S72 - that introduced differing numbering schemes (see Table II). The GK65 scheme was

apparently followed by Maguire et al. (1981), Giver et al. (1984) and all subsequent anal-342 yses of the IRIS dataset, and thence propagated into the Cassini CIRS community. The 343 S72 scheme however was adopted by Flaud et al. (2001), Roe et al. (2003) and also by the 344 U.S. National Institute of Standards and Technology (NIST), and appears preferable now 345 both because of that official endorsement, and also because all 27 predicted vibrational 346 modes are accounted for. Therefore, we use the S72/NIST numbering scheme in this work. 347 Table II lists both sets of band designations as an aid to translating band numbers from 348 earlier works (especially Voyager papers). 349

Under the NIST numbering scheme, we clearly detect the ν_{26} (748 cm⁻¹), ν_{21} (922 350 cm^{-1}) and ν_{20} (1053 cm^{-1}) bands on FP3, which all have strong central Q-branch peaks. 351 All three of these bands were claimed to be detected by Voyager (Maguire et al., 1981). 352 Note that the shape of the ν_{21} band appears somewhat different at room temperature 353 (PNNL spectrum) compared to the colder Titan spectrum, due to the presence of hot 354 bands on the short-wavelength side of the fundamental in the lab spectrum. The ν_8 band 355 on the other hand lacks a Q-branch, and the detection is uncertain at this time, although 356 we do appear to see a minimum in the right location near the band center at 869 $\rm cm^{-1}$. 357 Note that the residual of the ethane fitting appears surprisingly large, given that we are 358 using very recently updated line parameters for the ν_9 band (Vander Auwera et al., 2007). 359 This appears to be caused by trying to minimize the overall χ^2 fit, in the presence of the 360 non-flat continuum. 361

We must be careful here to emphasize possible aerosol effects: a non-grey aerosol could easily account for some or all of the gradient in the residual. So long as we cannot positively distinguish between the two opacity sources, the propane ν_8 detection should be regarded as still somewhat tentative. A clear way to make progress would be to derive spectroscopic parameters for the band from lab data and include it in the gas model: any remaining residual gradient would then likely be due to aerosol alone. On FP4, the strongest propane feature inside the clean spectral range (1100–1400 cm⁻¹) is the Q-branch of ν_{18} at 1376 cm⁻¹. The ν_7 band (1158 cm⁻¹) is similar in shape to the ν_8 of FP3, and is also evident here after the modeling/removal of CH₃D and ¹³CH₃D emissions. In previous works, this band has sometimes been modeled with a band opacity model to improve the D/H determination (e.g. Coustenis et al., 1989b). Other weaker Qbranch peaks of ν_{25} (1192 cm⁻¹) and ν_{19} (1338 cm⁻¹) fall inside the FP4 nominal range, but are at the noise level.

Proceeding with caution outside the nominal range (see Appendix A), we see a clear 375 signal of the Q-branch of ν_{20} (1053 cm⁻¹), with improved signal-to-noise (S/N) over 376 the FP3 detection. (We can discount aliasing here, as there is no noticeable emission at 377 the aliased frequency of 987 $\rm cm^{-1}$.) In the short-wavelength non-clean band, we also 378 apparently detect the Q-branch peak of ν_{24} (1472 cm⁻¹), although it is apparent here that 379 significant residual remains after modeling which is not attributable to propane. There 380 may be several factors at work here to undermine our model: (i) the ethane pseudo-linelist 381 is likely to be imperfect; (ii) the ethane ν_8 (1468 cm⁻¹) and ν_{11} (1469 cm⁻¹) bands remain 382 strong out to ~ 1600 cm⁻¹, and therefore will contribute significantly through aliasing 383 ('folding' around 1529 cm^{-1}); (iii) the continuum may have haze opacity that is difficult 384 to assess in the presence of the other uncertainties. 385

386 4.2 Propane Gas Abundance

³⁸⁷ Having demonstrated the detection of multiple propane bands by CIRS, we wished ³⁸⁸ to model those for which line data is available. As stated earlier, only the ν_{26} band at ³⁸⁹ 748 cm⁻¹ has been previously analyzed to obtain abundances of C₃H₈ on Titan, due to ³⁹⁰ its unique availability in an existing atlas (GEISA). However, due to more recent work ³⁹¹ by Flaud et al. (2001), line parameters for propane bands in range 1300-1500 cm⁻¹ were available to us, allowing the new possibility of retrieving propane abundances from these bands also. After some experimentation, we concluded that accurate modeling of the ν_{24} band at 1472 cm⁻¹ was not possible, due to the uncertainties in ethane and haze opacity, combined with the complexitity of folding the (unknown) aliased spectrum above 1529 cm⁻¹. However, fitting the ν_{18} at 1376 cm⁻¹ proved to be a more tractable problem.

We used two spectral windows for the abundance measurements: 740–760 cm⁻¹ (ν_{26}) and 1370–1390 cm⁻¹ (ν_{18}), choosing relatively narrow spectral regions to avoid the effects of, respectively, the very strong acetylene band at 729 cm⁻¹ and large instrumental noise spike at 768 cm⁻¹ (FP3), and a non-flat continuum that showed apparent broad haze features at the scale of ~20 cm⁻¹ (FP4). Haze spectral features are the intended subject of a future study, and are not pursued further herein.

We then added propane gas back into the model atmosphere and separately retrieved 403 its best-fit abundance for each window using the previously determined temperature pro-404 file. Our objective was not to determine the absolute abundance of propane at a single 405 altitude to high accuracy, where we could have fitted all regions simultaneously, but rather 406 to compare the relative results for FP3 and FP4. Early retrieval attempts using these win-407 dows alerted us to a problem with the GEISA line strengths for the ν_{26} band, which is 408 decribed in detail in Appendix B. This problem was remedied by rescaling the spectral 409 lines prior to the final retrievals. 410

Fig. 7. Appears Here.

The final results of the fitting are shown in Fig. 7. The red line shows the residual for a forward-model calculation using the retrieved abundances of all gases except propane, which is removed to show its contribution. The other lines show the residual after fitting with all gases including propane and either grey haze (blue line) or tholin haze (green line). The fits with the two haze models are indistinguishable over the narrow 20 cm⁻¹ 416 window.

417 [TABLE III]

The individual abundances determined from each model fit are given in Table III, along with errors. Included in the error calculation (added in quadrature) are (i) the 1- σ random noise on the spectrum; (ii) propagated temperature retrieval error from two sources, (a) the spectral noise from the temperature retrieval, and (b) the 5% uncertainty in the methane abundance quoted by Niemann et al. (2005), combined as described in § 3.5 of Nixon et al. (2008a); (iii) the uncertainty in the line intensities of propane in the spectral line lists, estimated at ~10%.

The results show that the ν_{18} yields systematically higher values than the ν_{26} , compatible at the 2- σ error level but not at 1- σ . We suggest that two remaining systematic effects are the sources of the difference: (i) any residual structure in the continuum at a scale of less than 20 cm⁻¹ for either spectral region that is not included in our slowlyvarying haze models, and (ii) any imperfections in the pseudo-linelist for the the ethane ν_6 band at 1378 cm⁻¹. An actual linelist for the ν_6 and ν_8 bands would be very valuable in eliminating this source of error.

We also note that the ν_{26} result is in very good agreement with the CIRS limb mea-432 surement of Vinatier et al. (2007a) for 15°S, 3 mbar: $\sim 4 \pm 1.5 \times 10^{-7}$, also derived from 433 the ν_{26} band using a different (line-by-line) model and retrieval algorithm. Note that while 434 Vinatier et al. (2007a) did not scale the GEISA line intensities by the 0.42 factor used 435 by us, they partly compensated for the known problem with the ν_{26} band intensity by 436 omitting the vibrational part of the partition function when calculating the line strength. 437 This would tend to underestimate the line strengths, providing a similar correction factor 438 to ours, and the agreement between the results is not anomalous. 439

440 5 Summary and Conclusions

We have modeled a low-latitude limb spectral average of Titan, removing all gas emis-441 sions except propane. By examining the residual, we demonstrate that CIRS has detected 442 at least six separate bands of C_3H_8 , including the well-known 748 cm⁻¹ band (ν_{26}). We 443 also show clearly the structure of the ν_7 band at 1158 cm⁻¹ that underlies the ν_6 band 444 of CH₃D; the ν_{21} and ν_{20} bands at 922 and 1053 that were weakly detected by IRIS; 445 and at least two others in the range 1300–1500 cm⁻¹ (ν_{18} and ν_{24}) that are evident after 446 the removal of methane emission. Detection of the weak ν_8 centered on 869 cm⁻¹ that 447 underlies the wing of the $C_2H_6 \nu_9$ band is uncertain. 448

We have modeled the ν_{26} band using GEISA line data, and also the ν_{18} band using 449 spectral line data from the work of Flaud et al. (2001). None of these determinations are 450 problem-free: the ν_{26} band lacks spectroscopic data for the hot band lines at 749.5 cm⁻¹, 451 whereas the ν_{18} band suffers from a lack of accurate continuum shape, and possible in-452 accuracies due to the use of the JPL pseudo-linelist for the ν_6 band of C_2H_6 , for which 453 no formal lists are available. Despite these uncertainties, the values agree at a $2-\sigma$ er-454 ror level. We suspect that systematic uncertainties (haze, ethane line list) are still of 455 greater concern for FP4 than FP3, and therefore we recommend that the lower value 456 $(4.2 \pm 0.5) \times 10^{-7}$, which agrees with previous analysis, is considered valid at the 2 mbar 457 level for low latitudes probed by these retrievals. 458

Further work is required to accurately characterize the broad spectral features of Titan's mid-infrared continuum, as has been performed for the far-infrared (de Kok et al., 2007). Additional laboratory spectroscopy of alkanes is also required to support modeling of planetary spectra. It is vital that high-quality laboratory line lists are prepared for all bands of propane in the range 700–1300 cm⁻¹, and also the ν_6 and ν_8 bands of ethane. The present lack of accurate spectral information is a serious obstacle, not only to accurate measurement the abundance of propane on Titan and the giant planets, and deriving underlying haze opacities, but also because our inability to model and remove propane's prolific signature in many infrared spectral regions is a major hindrance to the search for the signatures of new stratospheric trace species.

469 Acknowledgements

The acquisition of CIRS data is the result of the collective efforts of a large number 470 of people, including the following who worked on various aspect of CIRS science plan-471 ning, instrument commanding, uplink, calibration and databasing: S.B. Calcutt, R.C. 472 Carlson, M.H. Elliott, E. Guandique, M. Kaelberer, E. Lellouch, A. Mamoutkine, P.J. 473 Schinder, M.E. Segura, J.S. Tingley, and also many engineers and science planners at the 474 Jet Propulsion Laboratory. We are indebted to J. Vander Auwera, for supplying us with 475 the recent ethane ν_9 line data base in advance of its inclusion in the next GEISA release, 476 and Steven Sharpe and colleagues at Pacific Northwest National Laboratory (PNNL) for 477 the laboratory propane absorption spectra. We thank Geoff Toon and Armin Kleinboehl 478 of JPL for the use of their C_2H_6 pseudo-linelist, which was generated using unpublished 479 laboratory spectra recorded with Fourier transform spectrometers at the PNNL and the 480 Kitt Peak National Observatory. We also thank W. Blass, G.L. Bjoraker, S. Daunt and 481 T. Fouchet for e-mail exchanges regarding the GEISA propane data, and J.C. Brasunas 482 for helpful discussions regarding aliasing and numerical filtering in the instrument. The 483 US-based co-authors acknowledge the support of the NASA Cassini Project during the 484 period in which this work was completed. 485

⁴⁸⁶ A Spectral range of CIRS FP4

The subject of the useable spectral range of CIRS FP4 is of considerable interest in this paper, due to the existence of many propane bands at the extremes of FP4 sensitivity. Further details of the CIRS spectral bandpass are available in an internal CIRS team report Brasunas (2004).

⁴⁹¹ The nominal spectral range is $1100-1400 \text{ cm}^{-1}$, which significantly underestimates

the original bandpass: from 1020–1529 cm⁻¹, based on initial Nyquist sampling of the interferogram signal in the instrument. Frequencies from outside this range are aliased into the range, according to the formula:

495
$$\tilde{\nu}_{\text{nominal}} + \tilde{\nu}_{\text{aliased}} = 2 \times \tilde{\nu}_{\text{bandpass}}$$
 (A.1)

A second-stage numerical filter is then applied that tapers the response towards the ends of the range, and leads to a definition of the 'clean' bandpass where the strength of the aliased signal has a relative response strength of less than 1%:

499
$$\tilde{\nu}_{\text{clean}} = (2 \times \tilde{\nu}_{\text{bandpass}}) - \tilde{\nu}_{1\text{pc}}$$
 (A.2)

where $\tilde{\nu}_{1pc}$ is defined as the (aliased) frequency where the response of the numerical filter $R = F_{FP4}(\tilde{\nu})$ has dropped to 1% of the peak response: $\tilde{\nu}_{1pc} = F_{FP4}^{-1}(R_{peak} \times 0.01)$. By this definition, the clean bandpass of FP4 is 1131–1433 cm⁻¹, close to the canonical wavenumber range (1100–1400 cm⁻¹).

⁵⁰⁴ Between the Nyquist and 'clean' bandpass limits at the low wavenumber side (1020– ⁵⁰⁵ 1131 cm⁻¹), the aliased signal comes from the region 889–1020 cm⁻¹, where there is little ⁵⁰⁶ emission except from the relatively weak lines of C_2H_4 . In addition, roll-off of detector re-⁵⁰⁷ sponse at long wavelengths means that the 'clean' bandpass is somewhat underestimated. ⁵⁰⁸ These effects mean that the range 1020–1131 cm⁻¹ is very useful, especially as the aliased ⁵⁰⁹ spectral range 889–1020 cm⁻¹ is known from the FP3 spectrum and its importance can ⁵¹⁰ therefore be directly assessed.

The non-clean range from 1433–1529 is more problematic, because the detector reponse remains strong, and more critically because we have no knowledge of the signal in the aliasing range above 1529 cm⁻¹, except from predictations of emission bands of known gases (e.g. the weak ν_2 band of methane at 1534 cm⁻¹). Therefore, interpretation of this ⁵¹⁵ spectral range must proceed with caution.

516 B Modifications to propane spectral line lists

In this work we used propane line data from two sources: (i) the GEISA atlas, for the ν_{26} 517 band at 748 cm^{-1} , and (ii) recent measurements by Flaud et al. (2001) for the bands in the 518 range 1300–1500 cm⁻¹. During preliminary intercomparisons of the propane abundance 519 derived from the two spectral regions, we found large differences in the retrieved values 520 amounting to a factor ~ 2 (FP4 higher than FP3). We investigated possible causes of 521 this discrepancy, and discovered that the propane line strengths that are in the GEISA 522 2003 atlas are incorrectly scaled: this problem is expected to be fixed in the forthcoming 523 GEISA 2009 release, that should be available at the time of publication of this article. 524 We also suggest modifications to the Lorentzian Half-Width at Half Maximum (HWHM) 525 and temperature exponent of the spectral lines. A detailed discussion follows. 526

527 B.1 Radiative Transfer Treatment of Spectral Lines

For atmospheric radiative transfer applications we wish to compute the spectral dependence of the absorption co-efficient k_{ν} for each molecular energy transition (i.e. spectral line). Absorption due to all individual lines in a given spectral region is then included in the overall opacity calculation, along with other sources (particles, collision-induced opacity). Following Goody and Yung (1989), the spectral absorption due to an individual line is:

534
$$k_{\nu} = Sf(\nu - \nu_0)$$
 (B.1)

where ν is frequency, ν_0 is the unperturbed frequency, f is a normalized function describing the line shape, and S is the line strength defined as:

$$S = \int k_{\nu} d\nu \tag{B.2}$$

The lineshape function may be given by the classical Doppler (thermal) or Lorentzian (pressure/collision) profiles, or more generally a convolution of both, known as the Voigt profile:

$$f(\nu - \nu_0) = \int_{-\infty}^{+\infty} \frac{(\alpha_L/\pi)}{\left[\left\{(\nu - \nu_0) - (u\nu_0/c)\right\}^2 + \alpha_L^2\right]} \left(\frac{m}{2\pi kT}\right)^{\frac{1}{2}} \exp\left(\frac{-mu^2}{2kT}\right) du$$
(B.3)

In the above formula k, h and c are the usual constants of Boltzmann, Planck and speed of light; m is the molecular mass, T is temperature and α_L is the Lorentzian HWHM.

Therefore, in order to compute k_{ν} we must know the following: m and T, which are specified by the atmospheric problem; and α_L and S, which are parameters obtained from experimental measurement and tabulated in a database. Both of these parameters have a temperature dependence, and in addition α_L is a function of pressure also. First, the dependence of α_L on atmospheric conditions is specified by:

$$\alpha_L(P,T) = \alpha_{L,0} \frac{P}{P_0} \left[\frac{T_0}{T}\right]^n \tag{B.4}$$

where $(\alpha_{L,0}, P_0, T_0)$ is a laboratory (usually) room temperature measurement, and n is a free scaling parameter known as the Temperature Dependence of Width (TDW). Second, the line strength as a function of temperature is given by (e.g. Lacis and Oinas, 1991, p9033):

554
$$S = S_0 \frac{V_0 R_0}{V R} \exp\left\{\frac{hc}{k} E'' \left[\frac{1}{T_0} - \frac{1}{T}\right]\right\}$$
(B.5)

where E'' is the energy of the lower state of the transition, and R and V are the rotational and vibrational *partition functions* (sums over microphysical state probabilities). The rotational partition function is $R(T) = T^x$ where x = 1 for linear molecules and x = 3/2for non-linear molecules, such as propane. The vibrational partition function is usually approximated by a quantum harmonic oscillator so that:

560
$$V(T) = \prod_{j} \left(1 - \exp(-h\nu_j/kT)\right)^{-g_j}$$
(B.6)

where ν_j is the frequency of the j^{th} vibrational mode, for each of the 27 mode frequencies given in Table II, and g_j is the degeneracy of each mode, equal to 1 for this gas.

563 B.2 GEISA Line Strengths for ν_{26}

The spectroscopic line list provided in the current GEISA 2003 edition is unchanged since first added in 1991, and consists of \sim 9000 lines assigned by S. Daunt (unpublished) from room temperature spectra. S. Daunt (private communication) has told us that the integrated band intensity:

$$S = \int_{i} S_{i} d\nu \tag{B.7}$$

for ~ 3500 lines for the fundamental mode only (excluding hotbands - transitions from 569 non-ground state energy levels) was scaled to match the band sum for the entire region 570 as reported by Giver et al. (1984), which included hot bands. The value of S reported by 571 Giver et al. (1984) is 4.33×10^{-19} cm molecule⁻¹, and we have separately estimated from 572 the PNNL propane spectra a value of 4.27×10^{-19} cm molecule⁻¹, in good agreement. 573 However, the integrated band intensity of the GEISA lines is slightly lower (3.76×10^{-19}) 574 cm molecule⁻¹). We have calculated V(296K) = 2.71, which is approximately the ratio 575 of S for all transitions to ground state transitions only, and therefore, we estimate that 576

the S for the ν_{26} fundamental mode should be $(1/2.71) \times 4.27 \times 10^{-19} = 1.58 \times 10^{-19}$ cm molecule⁻¹. The strengths of individual lines in the atlas should therefore by scaled by the ratio of the current GEISA S to the predicted: i.e. by 1.58/3.76 = 0.420. We have hence rescaled the GEISA lines for the ν_{26} band by this factor prior to computation of the k-tables, which were used in our retrievals.

582 B.3 Lorentz Broadening Parameters

In the current GEISA 2003 edition, the Lorentz HWHM α_L is given as 0.08 cm⁻¹ 583 for the ν_{26} band. However, the FWHM for the pressure broadening of C_3H_8 by N_2 has 584 been separately reported as 0.119 cm^{-1} by Nadler and Jennings (1989) (at 296 K) and 585 $0.146~{\rm cm^{-1}}$ by Hillman et al. (1992) (at 175 K). The latter authors also used these two 586 measurements at different temperatures to infer a value for the n exponent in Eq. B.4 of 587 0.50, which is lower than the 0.75 in GEISA at present. We have therefore adopted values 588 of $\alpha_{L,0} = 0.12 \text{ cm}^{-1}$ and n = 0.50 for all the bands of propane available to us, including 589 the FP4 bands. 590

Figure Captions

Fig. 1 Initial gas profiles for Titan spectral model. Upper plot: major isotopic species.
Lower plot: minor isotopic species.

Fig. 2 Plots of $W(z_i)$ spatial weighting function for limb spectral averages, resampled onto a 10 km grid relative to the mean tangent altitude, and normalized such that $\Sigma_i W(z_i) = 1.0$. Dashed line: FP3. Solid line: FP4. The effective weighting function of the final mean FP3 and FP4 spectra is different, due to two effects: (i) the different real detector spatial responses, and (ii) the slightly different distributions of center altitudes of the spectral sets comprising each average.

Fig. 3 A priori (dashed line) and retrieved temperature profile (solid line, with 1σ error 787 bars) from Titan low-latitude (30°S–30°N) spectral average from limb data (100–150 km 788 tangent altitude). The grey shaded box shows the approximate region of real temperature 789 information in the retrieval, as bounded by the min and max values of FWHM pressure 790 levels of all temperature contribution functions assessed across the entire wavenumber 791 range. At higher and lower levels the temperature profiles is smoothly joined to the a 792 priori. A second weaker information region also exists above ~ 500 km due to methane 793 hotband emissions. 794

Fig. 4 Comparison of various contributions to the error on retrieved temperatures from fitting the methane ν_4 band. Dotted line: initial *a priori* error estimate. Dashed line: retrieval error due to spectral noise. Dot-dashed line: error due to methane abundance profile uncertainty. The combination of these two (spectral and methane profile errors) lead to the final vertical temperature error: solid line.

Fig. 5 Identification of propane spectral bands from CIRS Focal Plane 3 (600–1100 cm⁻¹). Left column: CIRS averaged limb spectra (9°N, 130 km), four selected data ranges (black line) and synthetic spectral fit (red) with all gases except C_3H_8 in model. Right column: residual spectrum after model subtraction (red) compared to PNNL laboratory absorption spectra (blue) and 1- σ NESR (grey). Propane bands are identified by text and dashed lines. Note: incomplete removal of C₂H₆ ν_9 band emission is evident in the residual (d)at 840–850 cm⁻¹.

Fig. 6 Identification of propane spectral bands from CIRS Focal Plane 4 (1000– 807 1500 cm⁻¹). Left column: CIRS averaged limb spectra (2°N, 125 km), four selected data 808 ranges (black line) and synthetic spectral fit (red) with all gases exept C_3H_8 in model. 809 Right column: residual spectrum after model subtraction (red) compared to PNNL labo-810 ratory absorption spectra (blue) and 1- σ NESR (grey). Propane bands are identified by 811 text and dashed lines. Note: spectral baseline in the range $1440-1480 \text{ cm}^{-1}$ (panel (h)) 812 is not well modeled by grey haze, leading to over-estimation of the ethane abundance 813 (features marked with '*') as the retrieval attempts to minimize the overall χ^2 of the fit. 814

Fig. 7 Residuals of fitting the two propane spectral regions. Red lines: residual of 815 forward calculation with no propane in model atmosphere, all other gases at previously 816 retrieved values. Blue line: residual after fitting with propane included, and grey haze 817 model. Green line: residual after fitting with propane included, and tholin particle haze 818 model. Grey bands are the 1- σ NESR. (a) ν_{26} band region, fitted by GEISA 2003 propane 819 line data modified as described in Appendix B. Note that the propane spectral data does 820 not include the hot band at 749.5 cm^{-1} , and also the significant difference to the 'baseline' 821 level due to propane. (b) The ν_{18} band fitted with the recent spectral data of Flaud et al. 822 (2001).823
