Under certain circumstances, three or more interacting particles may form bound states. While the general few-body problem is not analytically solvable, the so-called Efimov trimers appear for a system of three particles with resonant two-body interactions. The binding energies of these trimers are predicted to be universally connected to each other, independent of the microscopic details of the interaction. By exploiting a Feshbach resonance to widely tune the interactions between trapped ultracold lithium atoms, we find evidence for two universally connected Efimov trimers and their associated four-body bound states. A total of eleven precisely determined three- and four-body features are found in the inelastic loss spectrum. Their relative locations on either side of the resonance agree well with universal theory, while a systematic deviation from universality is found when comparing features across the resonance.

One of the most remarkable few-body phenomena is the universally-connected series of three-body bounds states first predicted by Efimov (I). Efimov showed that three particles can bind in the presence of resonant two-body interactions, even in circumstances where any two of the particles are unable to bind. When the two-body scattering length a is much larger than the range of the interaction potential r_0 , the three-body physics becomes independent of the details of the short-range interaction. Surprisingly, if one three-body bound state exists, then another can be found by increasing a by a universal scaling factor, and so on, resulting in an infinite number of trimer states (2). Universality is expected to persist with the addition of a fourth particle (3–7), with two four-body states associated with each trimer (5, 7); intimately tied to the three-body state, these tetramers do not require any additional parameters to describe their properties.

Ultracold atoms are ideal systems for exploring these weakly bound few-body states because of their inherent sensitivity to low-energy phenomena, as well as the ability afforded by Feshbach resonances to continuously tune the interatomic interactions. Pioneering experiments with trapped, ultracold atoms have obtained signatures of individual Efimov states (8–12), as well as two successive Efimov states (13, 14), via their effect on inelastic collisions that lead to trap loss. Evidence of tetramer states associated with the trimers has also been found (13, 15). Although the locations of successive features are consistent with the predicted universal scaling, systematic deviations as large as 60% were observed, and attributed to non-universal short-range physics (13). In the work presented here, we use a Feshbach resonance in 7 Li for which a/r_0 can be tuned over a range spanning 3 decades (16). This enables the observation of multiple features which are compared to universal theory.

We confine ${}^7\mathrm{Li}$ in the $|F=1,m_F=1\rangle$ hyperfine state in an elongated, cylindrically symmetric, hybrid magnetic plus optical dipole trap, as described previously (16). A set of Helmholtz coils provides an axially oriented magnetic bias field used to tune the two-body scattering length a via a Feshbach resonance located near 737 G (17). For a>0, efficient evaporative cooling is achieved by setting the bias field to 717 G, where $a\sim200\,a_0$ (with a_0 the Bohr radius), and reducing the optical trap intensity. Depending on the final trap depth, we create either an ultracold thermal gas just above the condensation temperature T_C , or a Bose-Einstein condensate (BEC) with >90% condensate fraction. For investigations with a<0, we first set the field to 762 G where $a\sim-200\,a_0$ and proceed with optical trap evaporation, which is stopped at a temperature T slightly above T_C . In both cases the field is then adiabatically ramped to a final value of a and held for a variable hold time. The fraction of atoms remaining at each time is measured via a in situ polarization phase contrast imaging (18) for clouds where the density is high, or absorption imaging in the case of lower densities.

Analyzing the time evolution of the number of atoms in the trap determines the three-body loss coefficient L_3 (8, 13, 19) as well as the four-body loss coefficient L_4 (15). Recombination into a dimer is a three-body process since a third atom is needed to conserve both momentum and energy. For a > 0, the dimer can be weakly-bound with binding energy $\epsilon = \hbar^2/(ma^2)$, where m is the atomic mass, while for a < 0 there are only deeply-bound molecular dimers.

The recombination energy released in the collision is sufficient to eject all three atoms from the trap for a < 0, and for a > 0 when $\epsilon \ge U$, where U is the trap depth. In the case of the BEC data, this latter condition holds for $a \le 5000 \, a_0$. Nonetheless, we assume that all three atoms are lost for any recombination event, because even for a larger than $5000 \, a_0$ we observe rapid three-body loss. We ascribe this observation to a high probability for dimers to undergo vibrational relaxation collisions which result in kinetic energies much greater than U. Four-body processes proceed in a similar fashion (6, 15).

The equation describing the dynamics of three- and four-body loss is

$$\frac{1}{N}\frac{dN}{dt} = -\frac{g^{(3)}}{3!}L_3\langle n^2 \rangle - \frac{g^{(4)}}{4!}L_4\langle n^3 \rangle,\tag{1}$$

where the brackets denote averages over the density distribution (17). For a thermal gas the spatial correlation coefficients $g^{(3)}$ and $g^{(4)}$ are respectively 3! and 4!, while for a BEC we set both to 1 (20, 21). We have verified that heating from recombination is small for our short observation times and therefore omit this effect in our analysis (15, 19). By fitting the time evolution of the number of atoms to the solution of Eq. 1 we extract L_3 and L_4 as a function of a. Figure S1 shows the loss of atoms as a function of time in regimes where either L_3 or L_4 dominates (17). Four-body loss is readily distinguished from three-body loss by the shape of the loss curve.

Figure 1 shows the extracted values of L_3 across the Feshbach resonance, exhibiting the expected a^4 scaling (22, 23), but with several dips and peaks punctuating this trend. Two prominent peaks dominate the landscape for a < 0, which are labeled a_1^- and a_2^- in Fig. 1A. We attribute these peaks to the crossings of the energies of the first two trimer states with the free atom threshold, thus providing additional pathways into deeply-bound molecular states (23). For a > 0, the dominant features are dips, indicated in Fig. 1A as a_1^+ and a_2^+ , corresponding to recombination minima. These minima are associated with the merging of the same two trimer states into the atom-dimer continuum, and have been attributed to destructive interference between two different decay pathways into weakly-bound dimers (22, 23). We fit the data to $L_3(a) = 3C(a)\hbar a^4/m$, where C(a) is a logarithmically periodic function characterizing effects from the Efimov states (17). The analytic expression for C(a) contains the location of one universal trimer resonance $a^- < 0$ or recombination minimum $a^+ > 0$, and an inelasticity parameter η related to the lifetime of the Efimov state (2). The observed features are fit individually to extract these parameters (Table 1). The universal theory describing Efimov physics (2) predicts a logarithmic spacing in the two-body scattering length between trimer states of $e^{\pi/s_0} \approx 22.7$, where $s_0 = 1.00624$ is a universal parameter (1). Table 2 shows that the ratios a_2^+/a_1^+ and $a_2^-/a_1^$ agree well with the universal theory.

A local maximum in L_3 , indicated as a_2^* and shown in detail in Fig. 1B, can be discerned between the two recombination minima a_1^+ and a_2^+ . We associate this feature with an atom-dimer resonance, given its location with respect to the nearby minima. A simple model (13) has been proposed to explain the enhanced losses present at the atom-dimer resonance. This

model describes an avalanche process whereby a single dimer travelling through a collisionally thick gas shares its kinetic energy with multiple atoms, thereby increasing from 3 the effective number of atoms lost for each dimer formed (24).

For a < 0, L_3 achieves its maximum value of $\sim 10^{-19}$ cm⁶/s at a_2^- . This value is reasonably consistent with the expected unitarity limit (19, 25). At even larger values of |a|, L_3 saturates to a value below the unitarity limit, a behavior previously seen in experiment (8) and in numerical calculations (25, 26).

The four-body loss coefficient L_4 for a < 0 was also extracted from the data, and the results are presented in Fig. 2. Three resonant peaks in L_4 are observed, which we associate with the crossings of tetramer states with the free atom continuum (3-7, 13, 15, 27). Two universal tetramers are predicted to accompany each Efimov trimer (5, 7). The solid line in Fig. 2 is calculated using only the observed three-body locations and widths in addition to an overall scaling, without any other free parameters (17). The agreement between this curve and the data lead us to assign the peaks to the second tetramer of the first Efimov trimer $a_{1,2}^T$ and both tetramers of the second Efimov trimer $a_{2,1}^T$ and $a_{2,2}^T$ (15). While we do not have the resolution to detect an enhancement in L_4 at the expected location of the first tetramer $a_{1,1}^T$, an enhancement of L_3 is observed at the expected location (Fig. 1A) which we tentatively identify with $a_{1,1}^T$ (7, 13). The existence of two tetramer states tied to a single trimer state has also been verified in $a_{1,1}^{T}$ (15) and $a_{1,1}^{T}$ $a_{1,1}^{T}$

Two additional peaks in L_3 are observed on the a>0 side of the resonance (Figs. 1C and 1D). Features at these relative positions have not been previously observed or predicted, although they occur very close to where the two tetramer states associated with the second trimer are expected to merge with the dimer-dimer continuum (28). We have no explanation of how a dimer-dimer resonance would affect the inelastic loss rate, as we expect the dimer fraction to be small and consequently, the probability of dimer-dimer collisions to be negligible. One possibility is that they arise because of an interference effect, similar to that occurring in the three-body process at a_1^+ and a_2^+ . Presently, we tentatively associate these features with dimer-dimer resonances located at $a_{2,1}^*$ and $a_{2,2}^*$.

In Table 2 we present the relative spacings of observed loss features along with those predicted by the universal theory. Universal scaling is expected when $|a| \gg r_0$, where r_0 is the van der Waals radius (33 a_0 for Li) (29). Another requirement for universality is that $|a| \gg |R_e|$, where R_e is the effective range (14). Figure S4 shows that R_e is relatively small over the relevant field range, and is $\sim -10 a_0$ on resonance (17). For comparison, in the $|1,0\rangle$ state of 7 Li, $R_e \sim -30 a_0$ at the resonance near 894 G (14). Both conditions for universality are well-satisfied for the second Efimov state, but the requirement that $|a| \gg r_0$ is only marginally satisfied for the first. Nonetheless, we find good agreement with the universal scaling relations between features on each side of the Feshbach resonance separately.

The relationships of features across a Feshbach resonance are also thought to be universally connected (2, 26). However, when we compare features across the Feshbach resonance, we find a systematic discrepancy with theory of a factor of 2 (Table 2). This discrepancy can be

expressed as a difference in the three-body short-range phase between the two sides of the Feshbach resonance $\Delta\Phi = s_0 \ln(|a^-|/a^+)$ (22, 26). The locations of the features reported here result in phase differences of 0.92(10)(0) and 0.86(4)(17) (the uncertainties are defined in Table 1) for the first and second trimer, respectively, whereas the universal prediction is 1.61(3) (2). One of the effects of finite temperature is to both broaden the trimer resonances and to push them towards smaller |a| (8, 25, 26). This would decrease the values of $\Delta\Phi$ since we extract L_3 from a thermal cloud at a^- and a much colder BEC at a^+ . Measurements of 39 K also show a discrepancy with theory across the resonance, but with $\Delta\Phi=1.91(7)$ (13). On the other hand, measurements of the first trimer resonance and second trimer recombination minimum in the $|1,0\rangle$ state of 7 Li result in $\Delta\Phi=1.7(2)$ in good agreement with universal theory, assuming the universal scaling of 22.7 between trimer states (14). These variations in $\Delta\Phi$ may indicate the need for additional physics to be included in the universal model (26, 30).

References: * (2); † (7); ‡ (28).

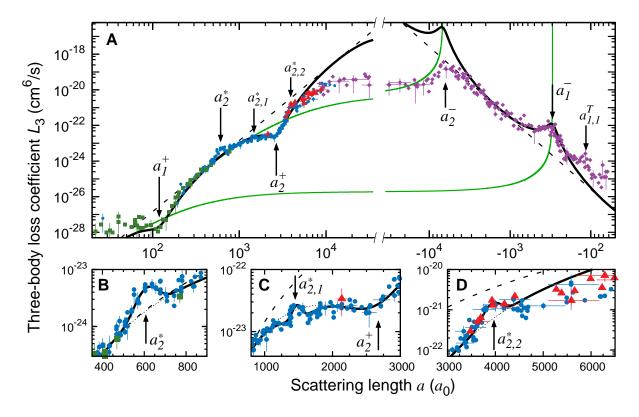

Fig. 1. (A) L_3 as a function of a. Data shown with (\blacklozenge) correspond to a thermal gas with $N \sim 10^6$, $T \sim 1-3\,\mu\mathrm{K}$ (31), and $U \sim 6\,\mu\mathrm{K}$ and were taken with radial and axial trapping frequencies $\omega_r = (2\pi)\,820\,\mathrm{Hz}$ and $\omega_z = (2\pi)\,7.3\,\mathrm{Hz}$, respectively. The remaining data correspond to a BEC with $N \sim 4 \times 10^5$, $T < 0.5\,T_C$, $U \sim 0.5\,\mu\mathrm{K}$, and $\omega_r = (2\pi)\,236\,\mathrm{Hz}$. We adjust ω_z (17) to enhance or reduce three-body loss, where $\omega_z = (2\pi)\,1.6\,\mathrm{Hz}$ (\spadesuit), $\omega_z = (2\pi)\,4.6\,\mathrm{Hz}$ (\spadesuit), and $\omega_z = (2\pi)\,16\,\mathrm{Hz}$ (\blacksquare). The dashed lines show an a^4 scaling. The solid thick lines are fits to an analytic theory (2, 17). The thin green lines show the square of the energies, in arbitrary units, of the first and second Efimov states as predicted from the universal theory (2) where we have fixed the location of the first Efimov state to overlap with a_1^- , and the atom-dimer continuum is coincident with the dashed line for a > 0. Several representative error bars are shown (17). (B—D) Detail around the loss features associated with the atom-dimer and two possible dimer-dimer resonances. The dotted lines are the fit to Eq. S4, while the solid lines include additional superimposed Gaussian fits to account for the features not described by Eq. S4.

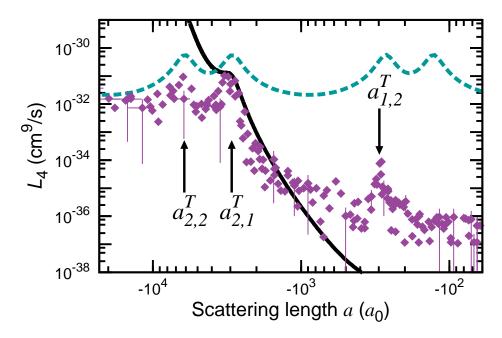

Fig. 2. L_4 extracted from a thermal gas. The solid curve is motivated by theory (17,27), and the dashed curve is the solid curve divided by a^7 (6). The uncertainty in L_4 from the fit is a factor of 2, while the systematic uncertainty is a factor of 3 due to uncertainties in ω_r , ω_z , N and T. For $|a| > 2 \times 10^4 \, a_0$ differentiation between three- and four-body losses becomes unreliable due to the very fast decay rates. Data with $L_4 < 10^{-36} \, \mathrm{cm}^9/\mathrm{s}$ are consistent with no four-body loss.

Universality in Three- and Four-Body Bound States of Ultracold Atoms

S. E. Pollack, D. Dries, R. G. Hulet

Materials and Methods

A set of non-Helmholtz coils are used to add or subtract additional axial confinement in the hybrid magnetic plus optical dipole trap used in the experiment. The radial trapping frequency ω_r is determined from atom loss by parametric excitation, and the axial trapping frequency ω_z is determined from collective dipole oscillations.

Determination of Scattering Length

The *s*-wave scattering length *a* is controlled via a magnetic Feshbach resonance (*S1*). We extract a (for a > 0) as a function of magnetic field *B* from the axial size of a Bose-Einstein condensate (*S2*). The measured functional form of a vs. B is well described by a Feshbach resonance fit $a(B) = a_{BG}[1 + \Delta/(B - B_{\infty})]$, where the values $a_{BG} = -24.5^{+3.0}_{-0.2} a_0$, $\Delta = 192.3(3)$ G, and $B_{\infty} = 736.8(2)$ G were previously reported (*S2*). The standard deviation of the residuals from the Feshbach resonance fit is 15% for $a < 10^3 a_0$ and 30% for $a > 10^3 a_0$ (Fig. S2).

To repeatably achieve very large values of a it is necessary to have both high field stability and accurate knowledge of the location of B_{∞} . We determine the shot-to-shot stability and calibration of the magnetic field from radio frequency spectroscopy on the $|1,1\rangle \rightarrow |2,2\rangle$ transition. We have improved the control of the current in the coils that provide the magnetic bias field in our experiment such that a Lorentzian characterizing the shot-to-shot field stability has a full width at half maximum of 115 kHz, corresponding to 42 mG at a bias field of 717 G (Fig. S3C). With this improved field stability we have increased the precision in the determination of the resonance location to $B_{\infty} = 736.97(7)$ G. The uncertainty in B_{∞} is dominated by systematic uncertainty in the extracted values of a from the measured axial sizes (S2). The fractional uncertainty in the determination of a is given by $\delta a/a = \delta B/(B - B_{\infty}) \approx 1.5 \times 10^{-5} a/a_0$, where δB is dominated by the uncertainty in B_{∞} .

Since we have only measured a for a > 0, we have no direct knowledge of a < 0. However, a coupled-channels calculation (S3) agrees with the Feshbach resonance fit to within 10% over the range of $10 < a/a_0 < 4 \times 10^4$ (Fig. S3) which gives us confidence that the Feshbach resonance fit is equally reliable on the a < 0 side of the resonance.

Determination of the Loss Coefficients

Extraction of L_3 and L_4 from the measured atom number loss curves N(t) requires the evaluation of the spatially-averaged moments of the density distribution $\langle n^2 \rangle$ and $\langle n^3 \rangle$. By comparing the measured distributions with a Thomas-Fermi inverted parabola in the case of a pure Bose-Einstein condensate, we find to a good approximation that the distributions remain in thermal equilibrium throughout the decay process. For a condensate, the axial Thomas-Fermi radius is $R = (15\hbar^2\omega_r^2Na/m^2\omega_z^4)^{1/5}$, the peak density is $n_0 = (15N\omega_r^2)/(8\pi R^3\omega_z^2)$, and $\langle n^2 \rangle = \gamma^{2/5}N^{4/5}$, where $\gamma = (25\,m^6\omega_r^4\omega_z^2)/(6272\,\sqrt{42}\,\pi^5\hbar^6a^3)$. The observed decay fits well to a purely three-body loss process for a condensate, so we neglect L_4 in this case. Since we are not explicitly fitting for L_4 , four-body effects if present may lead to an increase in the extracted loss rate L_3 (S4). The decay is then described by

$$\frac{1}{N}\frac{dN}{dt} = -\frac{g^{(3)}}{3!}L_3\gamma^{2/5}N^{4/5},\tag{S2}$$

which has the solution

$$N(t) = \frac{N_0}{\left(1 + \frac{4}{5} \frac{g^{(3)} L_3}{3!} \gamma^{2/5} N_0^{4/5} t\right)^{5/4}}.$$
 (S3)

A thermal gas is well described by a cylindrically-symmetric Gaussian where $\langle n^2 \rangle = n_p^2 / \sqrt{27}$, $\langle n^3 \rangle = n_p^3 / 8$, and the peak density is $n_p = N(\omega_z/\omega_r)[m\omega_r^2/2\pi k_BT]^{3/2}$. Heating due to recombination is expected to become important when $\epsilon \lesssim U(S5)$. However, there is no appreciable change observed in the Gaussian width during the decay even though the loss mechanism preferentially targets atoms at higher densities. This may be due to a lack of rethermalization during the decay (S6). We find that both L_3 and L_4 contribute to the loss for the thermal gas. Since we have not found a closed-form solution to Eq. 1, we instead use the following implicit solution to extract L_3 and L_4 :

$$t = \frac{3\sqrt{3}}{2n_p^2 L_3} \left[\left(\frac{N_0}{N} \right)^2 - 1 \right] + \frac{27L_4}{8n_p L_3^2} \left(1 - \frac{N_0}{N} \right) - \frac{81\sqrt{3}L_4^2}{64L_3^3} \log \left[\left(\frac{N}{N_0} \right) \frac{8\sqrt{3}L_3 + 9L_4n_p}{8\sqrt{3}L_3 + 9L_4n_p(N_0/N)} \right],$$
 (S4)

where we have assumed $g^{(3)} = 3!$ and $g^{(4)} = 4!$ for a non-condensed gas.

In Fig. 1 the vertical error bars correspond to the range in L_3 for which the χ^2 of the fit to Eq. S3 increases by one, while simultaneously adjusting L_4 and N_0 to minimize χ^2 . Systematic uncertainties in ω_r , ω_z , N, and T, which are not included in these error bars, contribute as much as a factor of 2 in the uncertainty of L_3 . The representative horizontal error bars are due to shot-to-shot variation in the magnetic field and the determination of a from the Feshbach resonance fit. Background loss limits the sensitivity of the measurement to $L_3 > 2(1) \times 10^{-28}$ cm⁶/s. The error bars in Fig. 2 are similarly determined.

Comparing with Theory

The universal theory (S7) describing Efimov physics predicts that the three-body loss rate coefficient is described by $L_3(a) = 3C(a)\hbar a^4/m$ where C(a) is a logarithmically periodic modulation. The following expression describes this modulation:

$$C(a) = \begin{cases} \frac{4590 \sinh(2\eta^{-})}{\sin^{2}(s_{0}\ln(a/a^{-})) + \sinh^{2}\eta^{-}} & (a < 0), \\ 67.12e^{-2\eta^{+}} \left[\sin^{2}(s_{0}\ln(a/a^{+})) + \sinh^{2}\eta^{+}\right] + 16.84(1 - e^{-4\eta^{+}}) & (a > 0), \end{cases}$$
(S5)

where the first and second terms for a > 0 account for coupling to weakly- and deeply-bound dimer states, respectively (*S7*, *S8*). The value a^- denotes the resonance location when the energy of the Efimov trimer is degenerate with the free atom continuum, and the value a^+ is the location of a recombination minimum (*S9*). This expression is log-periodic with $C(e^{\pi/s_0}a) = C(a)$, where the universal parameter $s_0 = 1.00624$ is known from theory (*S7*, *S10*).

The four-body loss coefficient L_4 is predicted to have a similar form to that of L_3 :

$$L_4(a, a^T) = 4 C_4 \frac{\hbar |a|^7}{m} \frac{\sinh(2\eta^-)}{\sin^2(s_0 \ln(a/a^T)) + \sinh^2 \eta^-}$$
 (a < 0), (S6)

where C_4 is a theoretically undetermined universal constant (S11). Eq. S5 is phenomenologically derived from the theory of Ref. S11 (S12). We find that $C_4 = 16(8) \times 10^4$ in the region $1000 < -a/a_0 < 2500$, assuming that $\eta^- = 0.13$, as for the three-body resonance. In Fig. 2 we plot $\frac{1}{2}\{L_4(a, 0.90 \, a_1^-) + L_4(a, 0.43 \, a_1^-)\}$ where we have replaced a^T with the predicted locations of the two tetramer states linked to the first trimer state (S4, S11).

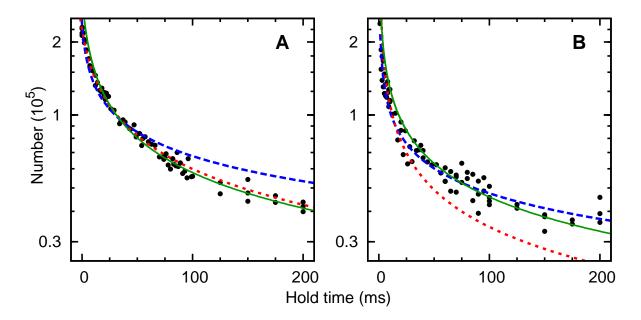

Fig. S1. Loss dynamics at two values of a < 0 for a thermal gas. The dots are data. The dotted red line is a fit of the data to the solution of Eq. 1 with only three-body loss accounted for, the dashed blue line is the fit when only four-body loss is included, and the solid green line is a fit accounting for both effects (Eq. S3). (A) $a = -1800 a_0$, where three-body losses dominate; (B) $a = -3300 a_0$, near $a_{2,1}^T$ where four-body losses dominate.

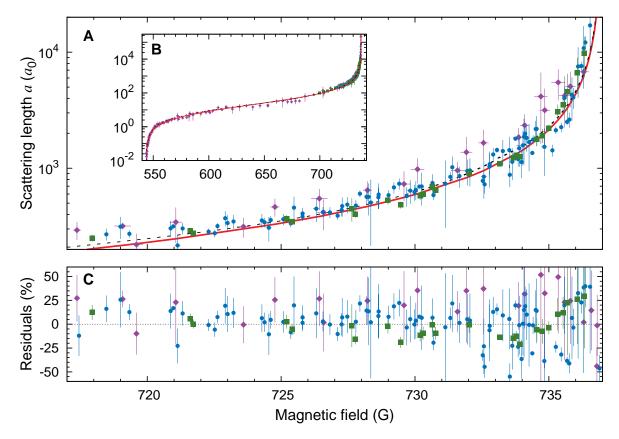

Fig. S2. (**A**) a extracted from the axial size of Bose-Einstein condensates as a function of magnetic field. Results of a coupled-channels calculation are shown by the solid red line. The dashed black line is the Feshbach resonance fit. (•) Data previously reported with trapping frequencies $\omega_r = (2\pi) \, 193 \, \text{Hz}$ and $\omega_z = (2\pi) \, 3 \, \text{Hz}$ (S2). Data with $\omega_r = (2\pi) \, 236 \, \text{Hz}$ and $\omega_z = (2\pi) \, 4.6 \, \text{Hz}$ (•) or $\omega_z = (2\pi) \, 16 \, \text{Hz}$ (•). Beyond mean field effects become important when $n_0 a^3 \gtrsim 0.1 \, (S13)$. We apply a mean field correction for data with $0.1 < n_0 a^3 < 1$, and omit data with $n_0 a^3 > 1$ in the Feshbach resonance fit (S2). (**B**) Full range of data spanning 7 decades in a. (**C**) Fractional residuals of the extracted values of a from the Feshbach resonance fit.

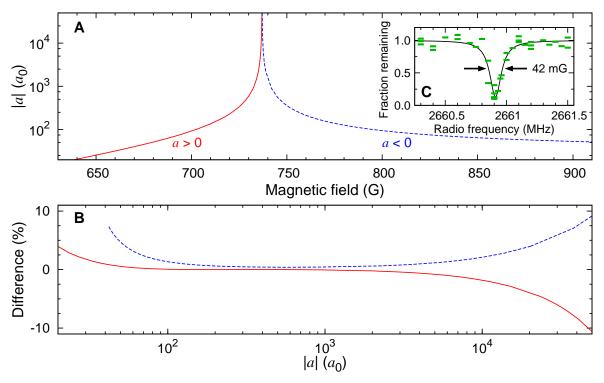

Fig. S3. (**A**) a vs. magnetic field from a coupled-channels calculation. (**B**) Fractional difference between the coupled-channels calculation and the Feshbach resonance fit used to determine a (solid red line a > 0, dashed blue line a < 0). (**C**) Radio frequency spectroscopy signal at 717 G showing a full width at half maximum of 115 kHz.

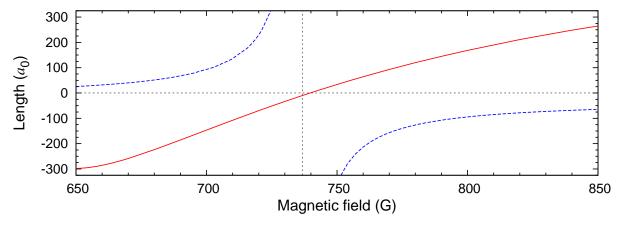

Fig. S4. The effective range R_e (solid red) and scattering length a (dashed blue) vs. magnetic field, extracted from a coupled-channels calculation through a low energy expansion $k \cot \delta = -1/a + R_e k^2/2$, where δ is the scattering phase shift (S1). The dotted vertical line is the location of B_{∞} .
