November 11, 2018

Our aim in this proposal is by using the Faraday's law of induction as a simple lecture demonstration to measure the Earth's magnetic field ( $\vec{B}$ ). This will also enable the students to learn about how electric power is generated from the rotational motion. Obviously the idea is not original, yet it may be attractive in the sense that no sophisticated devices are used. All equipment that we need are available in an elementary physics laboratory which are displayed in Fig. 1. The square, wooden coil and handmade belt system to rotate the coil may require some craftsmanship, which once made, can be used for years. First of all by using a compass we orient the table parallel to the direction of the Earth's horizontal component of  $\vec{B}$  field. This is necessary to maximize the Earth's field which can suppress the noise effects as much as possible. It is preferable to minimize also any environmental effects by conducting the experiment away from power lines, if possible of course.

The induced  $emf$  according to the law of induction is given by[1, 2]

$$\varepsilon = -N \frac{d\phi}{dt} \quad (1)$$

where  $N$  = number of turns in the coil and  $\phi$  is the magnetic flux which is changing in time due to rotation.

## Apparatus and Experiment

1) A square shaped wooden block of area  $0.25m^2$  to serve as coil having  $N = 100$  turns of copper wire (with  $1.1mm$  in diameter).

2) A hand-driven mechanical system connected through a belt to the wooden coil. The handle is mounted on an empty wooden box fixed appropriately on the table. (Remark: A car's wiper motor also can serve even better, to rotate the coil. Since we conducted the experiment in both ways we reached the conclusion that a wiper motor gives more efficient results).

3) A  $200mV$  voltmeter (or digital avometer) and a rheostat with their cables.

4) A compass to align the experiment table parallel to the Earth's horizontal component of  $\vec{B}$  field. As the coil rotates in this particular case its axis remains perpendicular to  $\vec{B}$ .

The experiment table is shown in Fig 1. This shows also the the brush system which collects the generated alternating current (voltage) from the rotating coil. As remarked before, we set the coil in rotation, either manual or by getting power from a wiper motor. For each 10 rotations we read the *emf* from the voltmeter and prepare the Tab. 1. Then, the amplitude of *emf* versus the inverse of the period  $T$  of rotation of the coil is given by

$$\varepsilon = \varepsilon_o + 2\pi NAB \frac{1}{T}. \quad (2)$$

Here  $\varepsilon_o$  is due to the background effect while  $A$  stands for the area of the coil. We plot  $\varepsilon$  versus  $\frac{1}{T}$ , which is a straight line with intercept  $\varepsilon_o$ , shown in Fig. 3. The total magnetic field  $B$  of the Earth is obtained as  $B = 0.41$  Gauss within the error limits.

We proceed next to determine the dip angle for the Earth's magnetic field. For this purpose we mount our system such that it is rotated by  $90^\circ$  to make the axis of rotation vertical (Fig. 2). We record the data for the horizontal component  $B_h$  and tabulate it in Tab. 2. We plot the induced emf corresponding to  $B_h$  in Fig. 4. This determines  $B_h$  as  $B_h = 0.21$  gauss. The dip angle  $\theta$  follows from

$$\cos \theta = \frac{B_h}{B} \quad (3)$$

which turns out to be  $\theta \cong 59^\circ$  for Cyprus. The reason that we obtained more than expected ( $\approx 50^\circ$  for the Mediterranean region) is due to the power lines in the surrounding.

**Acknowledgement 1** *We wish to thank the anonymous reviewer whose suggestions helped us to improve the experiment.*
