ABSTRACT

We employ 76 type Ia supernovae with optical spectrophotometry within 2.5 days of B-band maximum light obtained by the Nearby Supernova Factory to derive the impact of Si and Ca features on supernovae intrinsic luminosity and determine a dust reddening law. We use the equivalent width of Si II λ 4131 in place of light curve stretch to account for first-order intrinsic luminosity variability. The resultant empirical spectral reddening law exhibits strong features associated with Ca II and Si II λ 6355. After applying a correction based on the Ca II H&K equivalent width we find a reddening law consistent with a Cardelli extinction law. Using the same input data, we compare this result to synthetic rest-frame UBVRI-like photometry in order to mimic literature observations. After corrections for signatures correlated with Si II λ 4131 and Ca II H&K equivalent widths, and introducing an empirical correlation between colors, we determine the dust component in each band. We find a value of the total-to-selective extinction ratio, $R_V = 2.8 \pm 0.3$. This agrees with the Milky Way value, in contrast to the low R_V values found in most previous analyses. This result suggests that the long-standing controversy in interpreting SN Ia colors and their compatibility with a classical extinction law, critical to their use as cosmological probes, can be explained by the treatment of the dispersion in colors, and by the variability of features apparent in SN Ia spectra.

Key words. stars: supernovae: general - ISM: extinction - cosmology: observations

1. Introduction

Type Ia supernovae (SNe Ia) luminosity distances are measured via the standardization of their light curves using brightnesswidth (stretch, x_1 , Δm_{15}) and color corrections (Phillips 1993; Tripp 1998; Guy et al. 2007; Jha et al. 2007). While the determination of the intrinsic dispersion related to light curve shape is subject to small differences between fitters, the manner in which color is linked to dust is still controversial, as it may be affected by additional yet unidentified intrinsic dispersion. Whereas earlier work used the total-to-selective extinction ratio of the Milky Way, R_V =3.1, direct estimates from supernovae (SNe) Hubble diagram fits lead to lower values, from R_V =1.7 to R_V =2.5 (Hicken et al. 2009; Tripp 1998; Wang et al. 2009). While the derivation of this value is subject to assumptions about the natural color dispersion of SNe (Freedman et al. 2009; Guy et al. 2010), the reason for a difference between SNe data and the Milky Way average result had remained unknown.

Equivalent widths are good spectral indicators for addressing this issue as they probe the intrinsic variability of SNe Ia and by construction they have little dependence on extinction due to their narrow wavelength baseline. Arsenijevic et al. (2008) showed a strong correlation between the equivalent width of the Si II λ 4131 feature and the SALT2 x_1 width parameter (Guy et al. 2007), and Bronder et al. (2008) showed its correlation with M_B . Walker et al. (2010) used it to standardize the Hubble diagram, but were hindered from drawing firm conclusions by the quality of the low redshift data.

In this work, we take advantage of the Nearby Supernova Factory (SNfactory) spectrophotometric sample to revisit these conclusions, using both spectral data and derived UBVRI-like synthetic photometry. We present in Section 2 the SNe Ia sample and the definition of the Si II λ 4131 and Ca II H&K equivalent widths, which will be used in Section 3.1 to correct the Hubble residuals. These corrected magnitudes are used to derive the relative absorption in each wavelength band, δA_{λ} . The correlations between the δA_{λ} from SN to SN across different bands provide the reddening law, as described in Section 3.2, as well as the dispersion matrix between bands. In Section 4 it is shown that the resulting reddening law agrees with a Cardelli extinction law (CCM, Cardelli et al. 1989; O'Donnell 1994). Our reddening law has a value of R_V that agrees with the Milky-Way value of 3.1, when the proper dispersion matrix is used. We then discuss these results in Section 5 and conclude in Section 6.

2. Data-set and derived quantities

This analysis uses flux calibrated spectra of 76 SNe Ia obtained by the SNfactory collaboration with its SNIFS instrument (Aldering et al. 2002) on the University of Hawaii 2.2-meter telescope on Mauna Kea. This subset is selected in the same way as in Bailey et al. (2009), using only SNe having a measured spectrum within 2.5 days of B-band maximum, but with an enlarged data-set with a redshift range of 0.007 < z < 0.09. The SALT2 x_1 and c parameters (Fig.1), as well as the spectra phases with respect to the B-band maximum light, are derived using fits of the full light curves in three observer frame top hat bandpasses corresponding approximately to BVR.

After flux calibration, host galaxy subtraction and correction for Milky Way extinction, the 76 spectra are transformed into rest frame. For the spectral analysis, they are rebinned with a resolution of 1500 km s⁻¹. In addition, synthetic magnitudes are derived from the spectra after photon integration in a set of five UBVRI-like top-hat bandpasses with a constant resolution over the whole spectral range (3276 – 8635 Å, see Fig.3 and caption). The uncorrected Hubble residuals $\delta M(\lambda) = M(\lambda) - \langle M(\lambda) \rangle$ are independently computed for each band of mean wavelength λ , relative to a flat Λ CDM universe with $\Omega_{\rm M}$ = 0.28 and H_0 = $70 \text{ km s}^{-1} \text{ Mpc}^{-1}$. For the spectral analysis, the Hubble residuals are corrected for phase dependence using linear interpolation. For broad bands, we instead interpolate the magnitudes to the date of B maximum using the light curve shape of each SN Ia as defined by the SALT2 x_1 parameter, but with each band's peak magnitude fitted separately. The data are presented in the online Table 1. Error on Hubble residuals include statistical, calibration (~ 2% for peak luminosity) and redshift uncertainties. They are correlated between bands with a correlation coefficient varying from 0.64 to 0.98.

The equivalent widths Ew^{Si} and Ew^{Ca} corresponding to the Si II λ 4131 and the Ca II H&K features are computed in the same way as in Bronder et al. (2008, eq 1). The errors are derived using a Monte Carlo procedure taking into account photon noise and the impact of the method used to select the feature boundaries. Ew^{Si} and Ew^{Ca} are insensitive to extinction by dust, changing by less than 1% when adding an artificial reddening with a CCM law with $R_V = 3.1$ and E(B - V) = 0.5.

3. Method

3.1. Intrinsic corrections and absorption measurements

The Hubble residuals exhibit a dependency on observables such as Ew^{Si} and Ew^{Ca} which are uncorrelated with dust extinction. As shown in Fig. 1 as an example, the δM_B dependence on Ew^{Si} exhibits a linear behaviour, with an asymmetrical magnitude dispersion attributed to extinction and remaining intrinsic

Fig. 1. Correlations of Ew^{Si} , SALT2 x_1 (*top left*) and *c* (*top right*) parameters and measured peak absolute magnitude up to a constant term, δM_B (*bottom*). The *open circles* in the bottom panel are the data points excluded from the fit, which is displayed as a *solid line*. s_B^{Si} is equivalent for the B band to the red curve shown in Fig. 3a.

variability. Similar dependence with equivalent widths is found for other bands. We may thus model the Hubble residuals for a given SN, *i*, as a sum of intrinsic and dust components, making various assumptions about the number of spectral energy distribution (SED) correction vectors, s_{λ} , from none (Eq.1a) to two (Eq.1c):

$$\delta A^0_{\lambda,i} \tag{1a}$$

$$\delta M_{\lambda,i} = \begin{cases} \operatorname{Ew}_{i}^{\operatorname{Si}} s_{\lambda}^{\operatorname{Si}} + \delta A_{\lambda,i}^{\operatorname{Si}} \end{cases}$$
(1b)

$$\left(EW_i^{Si} s_{\lambda}^{Si} + EW_i^{Ca} s_{\lambda}^{Ca} + \delta A_{\lambda,i}^{Si+Ca} \right)$$
(1c)

After finding s_{λ}^{Si} and the $\delta A_{\lambda,i}^{Si}$ by a least squares minimization over all SNe from Eq. 1b, with an asymmetrical 2σ clipping, s_{λ}^{Si} is kept constant and s_{λ}^{Ca} and the $\delta A_{\lambda,i}^{Si+Ca}$ are then computed in the same manner. An example of the fit using Ew^{Si} for the B band is given is Fig. 1 (*solid line*), s_{B}^{Si} being the correction applied to find the δA_{Bi}^{Si} .

3.2. The empirical reddening law

As we expect the relation between the δA_{λ} to be linear for dust extinction, as shown in Fig. 2 for the U and V bands, we model the empirical reddening law as:

$$\delta A_{\lambda,i} = \gamma_{\lambda} \, \delta A^*_{V,i} + \eta_{\lambda} \tag{2}$$

where $\delta A_{\lambda,i}$ are the measured values, the slopes $\gamma_{\lambda} (= \partial A_{\lambda}/\partial A_{V}^{*})$ the reddening law coefficients, $\delta A_{V,i}^{*}$ the fitted relative extinction for the SN *i*, and η_{λ} a free zero point. $\delta A_{V,i}^{*}$, γ_{λ} and η_{λ} are obtained by a χ^{2} fit using the full wavelength covariance matrix C_{i} of the $\delta A_{\lambda,i}$ measurements. However, the data are more dispersed than their measurement error (Fig. 2), and another source of dispersion must be introduced. We adopt an iterative approach by using the fit residuals, $r_{\lambda,i} = \delta A_{\lambda,i} - (\gamma_{\lambda} \, \delta A_{V,i}^{*} + \eta_{\lambda})$, to determine the covariance remaining after accounting for the measurement error covariance, $C_{\lambda_{1}\lambda_{2},i}$. This empirical covariance matrix, D, is given by:

$$D_{\lambda_1 \lambda_2} = \frac{1}{N} \sum_{i=1}^{N} (r_{\lambda_1, i} r_{\lambda_2, i} - C_{\lambda_1 \lambda_2, i})$$
(3)

Fig. 2. Relation between δA_U and δA_V after Ew^{Si} correction (*triangles up*) and after Ew^{Si} and Ew^{Ca} corrections (*triangles down*). The δA_U are displayed with an added arbitrary constant. The ellipses represent the full measured covariance matrix between the two bands. They are enlarged by the additional subtraction error after Ew^{Ca} correction. The result of the fits are also displayed. The γ_U^{Si} and $\gamma_U^{\text{Si+Ca}}$ respectively correspond to the ones in Fig. 3b and Fig. 3c for the U band.

Fig. 3. *Black:* Reddening law presented as $\gamma_{\lambda} \equiv \partial A_{\lambda}/\partial A_{V}^{*}$ as a function of wavelength. Filled circles correspond to the results obtained using the UBVRI-like bands, curves are for the spectral analysis. *Red:* Linear slope s_{λ} (mag/Å) of equivalent widths versus δM_{λ} . *Dotted lines:* CCM law fit corresponding to the broad bands analysis. *Panel a:* δM_{λ} corrected only for the phase dependence (eq. 1a). *Panel b:* δM_{λ} corrected for phase and Ew^{Si} (eq. 1b). *Panel c:* δM_{λ} corrected for phase, Ew^{Si} and Ew^{Ca} (eq. 1c). The vertical dotted lines represent the UBVRI-like bands boundaries. The shaded vertical bands represent the Si and Ca domain. The shaded band around the curves are the statistical errors.

where N is the number of SNe. In the next iteration, the total covariance matrix is given by $C_i + D$. We have checked that the converged matrix does not depend on initial conditions.

4. Results

4.1. Ew^{Si} and Ew^{Ca} impacts on the derived extinction law

Results for the SED correction vector, s_{λ} , and the reddening law, γ_{λ} , are presented in Fig. 3 for different assumptions about the number of intrinsic components. If SNe were perfect standard candles affected only by dust as assumed by Eq. 1a and Fig. 3a, the empirical reddening law γ_{λ}^{0} would be a CCM-like law with an average R_{V} for our galaxy sample. However, γ_{λ}^{0} clearly exhibits small-scale SN-like features. These features correlate strongly with some of the features in the Ew^{Si} correction spectrum, s_{λ}^{Si} , derived via Eq. 1b and illustrated in red in Fig. 3a.

The reddening law obtained after Ew^{Si} correction (Fig. 3b) is closer to a CCM law, except in the Ca II H&K and IR triplet, and the Si II $\lambda 6355$ region. This indicates the presence of a second source of intrinsic variability. We select Ew^{Ca} to trace a second spectral correction vector, s_{λ}^{Ca} (Eq. 1c), since Ca is clearly a major contributor to the observed variability and Ew^{Ca} and Ew^{Si} also happen to be uncorrelated ($\rho = 0.06 \pm 0.12$). As shown in Fig. 3b, s_{λ}^{Ca} does a good job of reproducing the shape of the deviation of $\gamma_{\lambda}^{S_{i}}$ relative to the CCM law.

The mean reddening law, γ_{λ}^{Si+Ca} , obtained after the additional correction by Ew^{Ca} (Fig. 3c) is a much smoother curve with small residual features, and agrees well with a CCM extinction law. Thus it appears that these two components can account for SN Ia spectral variations at optical wavelengths. Any intrinsic component that might remain would have to be largely uncorrelated with SN spectral features fixed in wavelength, as well as being coincidentally compatible with a CCM law.

4.2. R_V determination

We apply the same treatment as above to our UBVRI-like synthetic photometric bands, and find agreement with the spectral analysis, as shown by the black points in the three panels in Fig. 3. After the EwSi correction (Eq. 1b, Fig.3b), the U and I band values deviate significantly from a CCM law, which is recovered after the full EW^{Si} and EW^{Ca} correction (Eq. 1c, Fig.3c). The empirical fit presented in subsection 3.2 can be forced to follow a CCM extinction law by substituting $\delta A_{\lambda,i} = (a_{\lambda} + b_{\lambda}/R_V) \, \delta A_{V,i}^* + \eta_{\lambda}$, where a_{λ} and b_{λ} are the wavelength dependent parameters given in Cardelli et al. (1989) and O'Donnell (1994), and a single R_V is fit over all bands. This fit applied to $\delta A_{\lambda}^{Si+Ca}$ leads to an average $R_V = 2.78 \pm 0.34$ for the SN host galaxies in our sample. This value is compatible with the Milky Way average of $R_V = 3.1$ The quoted uncertainty is statistical and derived with a jackknife procedure, removing one supernova at a time.

We tested the robustness of our R_V determination in several ways. Since the s_λ are measured in sequence, each one using the corrected magnitudes from the previous step, we swap the order in which the correction is applied, and find $R_V = 2.70$. Using the whole sample to compute the s_λ instead of applying a 2σ clipping cut leads to $R_V = 2.79$, showing the small influence of clipping at this stage. Host galaxy subtraction is performed using the full spatio-spectral information from the host obtained after the SN Ia has faded, and we do not see evidence for residual host galaxy features in our spectra. The measurement covariance matrix C_i is dependent on the assumed calibration accuracy: for the present result, this is estimated from repeated measurements of standard stars. Another estimate can be obtained from the residuals to a SALT2 light-curve fit. Using this in C_i values leads to $R_V = 2.76$. The stability of the result with respect to our choice of bandpasses is checked by removing one band at a time, and we obtain a RMS of ±0.23 around the mean result. Finally, a Monte Carlo simulation was performed using the converged γ_{λ} , $\delta A_{V_i}^*$, η_{λ} and dispersion matrix *D* as an input, and setting $R_V = 2.78$. The $\delta A_{\lambda,i}$ are then randomly generated adding Gaussian noise with covariance $C_i + D$. Over 100 generations, the D matrix is recovered with a maximal bias of 5% on the diagonal elements and the mean fitted value is $R_V = 2.68 \pm 0.03$, indicating that, if anything, our method slightly underestimates R_V .

5. Discussion

In this work, we selected EW^{Si} as a first variable for correction as it provides a good proxy for x_1 , and it is a model-independent variable. In our data-set the Pearson correlation coefficient of EW^{Si} with x_1 is -0.83 ± 0.04 (Fig. 1), confirming the result found in Arsenijevic et al. (2008). Computing the Hubble residuals in the B band using (x_1, c) or (EW^{Si}, c) to standardize SNe both lead to a dispersion of residuals of 0.16 mag, also confirming this result. We find that EW^{Si} is uncorrelated with $c (\rho = -0.04 \pm 0.12,$ Fig. 1), as opposed to the recent claim by Nordin et al. (2010). As EW^{Si} and x_1 are highly correlated, it is possible to redo the analysis with x_1 in place of EW^{Si} . The resulting SED correction vector $s_{\lambda}^{x_1}$ is similar to s_{λ}^{Si} , and the conclusions identical, yielding $R_V = 2.69$.

Computing the Hubble residuals with ($\text{Ew}^{\text{Si}}, \text{Ew}^{\text{Ca}}, c$) to standardize supernovae leads to a dispersion of 0.15 mag, which is a small improvement. Indeed, we do observe a correlation of Ew^{Ca} and c, with $\rho = 0.34 \pm 0.10$. This correlation is even increased to $\rho = 0.50$ when c is computed with a U band in addition to BVR in the light-curve fit. This shows that c contains an intrinsic component, and that the SALT2 analysis is already accounting for some of this Ca effect. This is illustrated in Fig. 3b: the SALT2 color model is derived taking into account a variability measured by one intrinsic parameter only, and thus can be compared to $\gamma_{\lambda}^{\text{Si}}$. The observed U band contribution in broad filters explains the UV rise in the empirical color models. The presence of a second intrinsic parameter induces an increased variability in the UV as was already noticed by Ellis et al. (2008), but without a clear attribution to the Ca II H&K line.

Much lower effective R_V values have been found previously: $R_V = 1.1$ in Tripp (1998), $R_V = 2.2$ in Kessler et al. (2009); Guy et al. (2010) and $R_V \approx 1 - 2$ in Folatelli et al. (2010). These values were derived accounting only for one intrinsic parameter beyond color. If we derive an effective value after the sole EwSi correction to mimic these analyses, we obtain $R_V = 3.1$, so the explanation for the difference has little to do with the number of intrinsic parameters entering the correction. This difference is explained by the assumption on the dispersion matrix. Indeed, if we instead use the one of Guy et al. (2010), corresponding to an RMS between 0.09 and 0.11 mag on the diagonal, and all offdiagonal terms with an identical RMS of 0.09 mag, we obtain $R_V = 1.86$. This value is representative of previous analyses, but the matrix used is incompatible with our best fit matrix. D has diagonal values of 0.07, 0.04, 0.05, 0.05 and 0.10 for UBVRI respectively, lower than the values quoted by Guy et al. (2010). However, while adjacent bands are correlated in our matrix, an anti-correlation growing to -1 when the wavelength difference increases is observed for other bands, which implies a large color dispersion. As shown by Freedman et al. (2009) and Kessler et al. (2009), increasing the color dispersion leads to higher R_V value. This long-range anti-correlation implies that uncorrected variability in the SN spectra and/or the reddening law remains.

6. Conclusions

Equivalent widths are essentially independent of host reddening and provide a handle on the intrinsic properties of the SNe Ia. In particular, Ew^{Si} measured at maximum light is confirmed to be as powerful as stretch. After correction for this intrinsic contribution to the magnitude, we have derived a reddening law, and proposed a natural method to assess the dispersion due to additional fluctuations. We found that this empirical reddening law is affected by features linked to the SN physics, and showed that the Ca II H&K line provides a second intrinsic variable uncorrelated with EW^{Si} or x_1 . Correcting Hubble residuals with EW^{Si} and EW^{Ca} leads to a reddening law consistent with a canonical CCM extinction law, while adding a dispersion in colors during the fit leads to a value of R_V close to the Milky Way value of 3.1. Due to the coupling of R_V with the residual dispersion matrix, the derived value of R_V may be affected as the remaining variability becomes better understood and corrected. Our plan to study the same SNe Ia over a range of phases should help address this issue. The evolution of SNe Ia will be one of the main limitations to their use in precision cosmology surveys at high redshift. Our findings show that the accurate measurements of the Ca II H&K line provides an additional tool to improve the separation of dust and intrinsic variability. The presence of remaining scatter offers the possibility of improvements in the future.
