ABSTRACT

Cold gas streaming along the dark-matter filaments of the cosmic web is predicted to be the major provider of resources for disc buildup, violent disk instability and star formation in massive galaxies in the early universe. We study to what extent these cold streams are traceable in the extended circum-galactic environment of galaxies via $Ly\alpha$ absorption and selected low ionisation metal absorption lines. We model the expected absorption signatures using high resolution zoom-in AMR cosmological simulations. In the postprocessing, we distinguish between self-shielded gas and unshielded gas. In the self-shielded gas, which is optically thick to Lyman continuum radiation, we assume pure collisional ionisation for species with an ionisation potential greater than 13.6 eV. In the optically thin, unshielded gas these species are also photoionised by the metagalactic radiation. In addition to absorption of radiation from background quasars, we compute the absorption line profiles of radiation emitted by the galaxy at the centre of the same halo. We predict the strength of the absorption signal for individual galaxies without stacking. We find that the Ly α absorption profiles produced by the streams are consistent with observations of absorption and emission $Ly\alpha$ profiles in high redshift galaxies. Due to the low metallicities in the streams, and their low covering factors, the metal absorption features are weak and difficult to detect.

Key words: cosmology: theory — galaxies: evolution — galaxies: formation — galaxies: high redshift — intergalactic medium — galaxies: ISM

1 INTRODUCTION

Cold gas is thought to flow into massive haloes $\sim 10^{12} M_{\odot}$ at z = 2 - 3 along filaments with velocities of $\gtrsim 200 \,\mathrm{km \, s^{-1}}$ This phenomenon is predicted by simulations and theoretical analysis, where high-z massive galaxies are continuously fed by narrow, cold, intense, partly clumpy, gaseous streams that penetrate through the shockheated halo gas into the inner galaxy (Birnboim & Dekel 2003;Keres et al. 2005;Dekel & Birnboim 2006;Ocvirk, Pichon & Teyssier 2008;Keres et al. 2009: Dekel et al. 2009;Johansson, Naab & Ostriker form 2009). They dense, unstable, turbulent а

§ orlig@phys.huji.ac.il

disc with a bulge and trigger rapid star formation (Dekel, Sari & Ceverino 2009; Agertz, Teyssier & Moore Ceverino, Dekel & Bournaud 2009;2010;Krumholz & Burkert 2010;Agertz, Teyssier & Moore 2011; Ceverino et al. 2012; Cacciato, Dekel & Genel 2012; Genel, Dekel & Cacciato 2012; Genzel et al. 2011). Nbody simulations suggest that about half the mass in dark-matter halos is built-up smoothly, suggesting that the baryons are also accreted semi-continuously as the galaxies grow (Genel et al. 2010). Indeed, hydrodynamical cosmological simulations reveal that the rather smooth gas components, including mini-minor mergers with mass ratio smaller than 1:10, brings in about two thirds of the mass (Dekel et al. 2009). The massive, clumpy and star-forming discs observed at $z \sim 2$ (Genzel et al. 2008; Genel et al. 2008; Förster Schreiber et al. 2009, 2011) may have been formed primarily via the smooth and steady accretion provided by the cold streams, with a smaller contribution

by major merger events (Agertz, Teyssier & Moore 2011; Ceverino, Dekel & Bournaud 2010).

Pettini et al. (2002);Adelberger et al. (2003): Shapley et al. (2003) explored the kinematics of the intergalactic medium in the early universe in great dept using high-resolution spectroscopy. Steidel et al. (1996) proposed that the predicted inflowing gas could show up as redshifted metal absorption lines in the spectra of Lymanbreak galaxies (LBGs). However, it seems that only a small fraction of the LBGs exhibit redshifted absorption features, which was interpreted as an indication for the absence of cold streams in haloes with $4 \times 10^{11} < M_{\rm v} < 10^{12} M_{\odot}$ (Steidel et al. 2010, hereafter S10). This has to be reconciled with the robust theoretical prediction that the predicted filaments are ubiquitous in haloes in the early universe. The goal of our paper is to predict the absorption-line signatures of the cold flows, for a detailed comparison with observations like S10.

Goerdt et al. (2010) used cosmological hydrodynamical AMR simulations to predict the characteristics of $Ly\alpha$ emission from the cold gas streams. The $Ly\alpha$ luminosity in their simulations is powered by the release of gravitational energy as the gas is flowing with a rather constant velocity down the potential gradient toward the halo centre. The simulated $Ly\alpha$ -blobs (LABs) are similar in many ways to the observed LABs. Some of the observed LABs may thus be regarded as direct detections of the cold streams that drove galaxy evolution at high z. Observations seem to support this picture (Rauch et al. 2011; Erb, Bogosavljević & Steidel 2011). On the other hand, Faucher-Giguere et al. (2010), using SPH simulations, predict lower $Ly\alpha$ luminosities than Goerdt et al. (2010), and find it difficult to explain the observed LAB luminosities with inflow-driven cooling radiation alone. This is partly because Faucher-Giguere et al. (2010) exclude emission from very dense gas, and partly because the SPH simulations underestimate the energy dissipation of the inflowing gas as it interacts with itself and with the hot medium. They make the point that the gas temperature should also be taken into account when distinguishing between the optically thin and thick regimes. New AMR simulations incorporating radiative transfer seem to confirm the Goerdt et al. (2010) model (Rosdahl & Blaizot 2012; Kasen et al. in preparation). In particular, Kasen et al. (in preparation) analysing highresolution cosmological AMR-hydro simulations with full radiative transport for the ionising radiation from background and from stars and for the $Ly\alpha$ scattering find that about half the spatially extended $Ly\alpha$ luminosity originates from fluorescence due to ionising radiation from new stars, and the other half from cooling emission due to the gravitational energy gain, yielding a total luminosity that is comparable to the findings of Goerdt et al. (2010) based on crude approximations for the radiative transport and without the fluorescence. In a pioneering observation, Cantalupo, Lilly & Haehnelt (2012) detected extended Ly α emission from circum-galactic filaments of cold gas that seem to largely arise from fluorescence excited by the UV radiation from an AGN. They detected dark galaxies and circum-galactic filaments that are fluorescently illuminated by a quasar. The properties of these $Ly\alpha$ sources all indicate that the sample is consistent with having much of the $Ly\alpha$

Figure 1. Gas density in a simulated galaxy (resolution 70 pc) at z = 2.3 with $M_{\rm v} = 3.5 \times 10^{11} M_{\odot}$. The colour refers to the maximum density along the line of sight. The contours mark n = 0.1, 0.01 and $0.001 \,{\rm cm}^{-3}$, respectively. The circle shows the virial radius which is 74 kpc. The inflow is dominated by three cold narrow streams that are partly clumpy. The density in the streams is $n = 0.003 - 0.1 \,{\rm cm}^{-3}$, with the clump cores reaching $n \sim 1 \,{\rm cm}^{-3}$. The white open boxes tag main features such as streams. The same type of points is used to identify these features in figure 3.

emission originating in fluorescent reprocessing of quasar radiation.

Bertone & Schaye (2012) investigated the nature and detectability of redshifted rest-frame UV line emission from the IGM at 2 < z < 5. They used simulations to create maps of a set of strong rest-frame UV emission lines. They conclude that several species (e.g., C III, C IV, Si III, Si IV, and O VI) of those from the high-redshift IGM will become detectable in the near future. They also claim that lower ionisation lines provide us with tools to image cold accretion flows as well as cold outflowing clouds.

Van de Voort et al. (2012), using SPH simulations, find that nearly all of the H I absorption arises in gas that has remained fairly cold, at least while it was extragalactic. In addition, the majority of the H I is rapidly falling towards a nearby galaxy, with non-negligible contributions from outflowing and static gas. They identify carefully the environment of the H I absorbers and conclude with this information that cold accretion flows are critical for the success of simulations in reproducing the observed rate of incidence of damped Ly α and particularly that of Lyman limit systems. They propose that cold accretion flows exist and have already been detected in the form of high column density H I absorbers.

Figure 2. Distribution by volume of the neutral hydrogen fractions $x_{\rm HI}$ and total hydrogen gas densities $n_{\rm H}$ in the circumgalactic environment of our simulated galaxy (see text). The left panel shows the distributions for the full radiative transfer calculation including the metagalactic UVX field plus internal sources presented by F11. The middle panel is for the radiative transfer calculation, but with UVX only. The right panel are results employing a pure density criterion of $n_{\rm H,shield} = 0.01 \,\mathrm{cm}^{-3}$ for the boundary between self-shielded and optically thin cells. The units of the colour-bar axis are unity per unit area in the $(\log_{10} X_{\rm HI}, \log_{10} n_{\rm H})$ plane. Contour lines are at 0.0001, 0.001 and 0.01 respectively. Our simplified ionisation model provides a useful crude approximation for the UVX radiative transfer results (see text).

Kacprzak et al. (2010) analysed synthetic Mg II absorption spectra from simulated galaxies at z = 1 and they tentatively concluded that most of the Mg II absorption arises in filaments and tidal streams of the galactic halo. This material is infalling with velocities around 200 km s⁻¹. They claim that large equivalent-width (EW) Mg II are associated with outflows.

Faucher-Giguere & Keres (2011), Kimm et al. (2011), Stewart et al. (2011) and Fumagalli et al. (2011, hereafter F11) estimated from simulations the covering factor of the cold streams at z = 2 - 4 for absorption from a background source. They found that it is small and decreasing with time. Stewart et al. (2011) and F11 argue that as a galaxy switches from cold- to hot-mode accretion with decreasing redshift the reduced cold gas accretion naturally results in a suppression of cool circumgalactic gas. This transition occurs when the halo is massive enough to support a stable shock near the virial radius (Birnboim & Dekel 2003; Keres et al. 2005; Dekel & Birnboim 2006). F11 discover that within ~ 500 Myr of reaching this threshold mass, the covering fraction drops. Because the cold-stream covering factor is small compared to the order unity covering fraction expected for galactic winds, the cold streams are generally overwhelmed by outflows in absorption spectra. However, F11 show that there is enough cross section in the cold flows that could make them detectable in $Ly\alpha$ absorption in surveys of background sources. Note the differences with the observations of galaxies at zero impact parameter, i.e. observations in the transverse direction, using e.g. quasars. Van de Voort et al. (2012) and F11 show that in fact there is a significant contribution to the population of absorption line systems that comes from the streams. That is, outflows are prominent, but inflows should be visible as well.

Kimm et al. (2011) and F11 investigated whether the cold gas streams are expected to be detectable in low-ionisation metal absorption lines, such as C11 (1334 Å) or

Si II (1260 Å). They find that the metal absorption signal by the interstellar medium of the central galaxy itself is so deep and so broad in velocity space that it swamps the metal signal from the filamentary gas, which is rather metal poor. A cold filament might be detectable in metal lines if it lies precisely along the line-of-sight, but this would be rare.

Shen et al. (2012) used SPH simulations adopting a blastwave scheme for supernova feedback which, in combination with a high gas density threshold for star formation, has been shown to generate large-scale galactic outflows. Their strong outflows avoid the incoming dense narrow streams, and find their way out in a wide solid angle through the dilute medium between the streams. Showing that the cold inflows are not affected by the outflows. They generate synthetic spectra by drawing sightlines through the simulated CGM at different galactocentric impact parameters, and compared the theoretical interstellar absorption line strengths with the observations. They find that they are in broad agreement with those observed at high-redshift by S10.

As in the observations of S10, we consider separately absorption features of radiation emitted from background sources and from central sources, namely along lines of sight with finite and with vanishing impact parameter with respect to the galaxy at the centre of the halo that hosts the absorbing gas. A theoretical study of absorption in the central-source geometry has not been attempted so far. The same is true for a statistical study of absorption signal in individual galaxies without stacking. We focus on predicting absorption line profiles that correspond to the measurements of S10. We refer to the same ten different lines and mimic their observational procedure by averaging data for several simulated galaxies and many lines of sight. As in F11, we employ high-resolution AMR simulations that are described in Ceverino, Dekel & Bournaud (2010). The spatial resolution in these simulations is 20 times better than in the Horizon MareNostrum simulation (Ocvirk, Pichon & Teyssier 2008)

Figure 3. Hammer equal area projections of HI column densities in our fiducial simulated galaxy (resolution 70 pc, z = 2.3, $M_v = 3.5 \times 10^{11} M_{\odot}$). The upper panel is integrated from 0.3 to 1.0 R_v , the lower panel from 0.1 to 0.3 R_v . The contour lines indicate 10^{20} and 10^{18} cm^{-1} . The narrow major streams with column densities up to $\sim 10^{22} \text{ cm}^{-2}$ can be seen, as well as the vast majority of the stream-free sky (as seen from the central galaxy) having only column densities of $< 10^{15} \text{ cm}^{-2}$. The white open boxes in the upper panel identify the main features such as the streams. The same type of points is used to identify these features in figure 1. The reader should be aware of the fact that these plots are theoretical and not observed in nature since one always looks down to the very centre at r = 0.

used by Kimm et al. (2011, they also used higher resolution simulations for verification purposes). Unlike in F11, we do not employ a full radiative transport analysis, and instead account for self-shielding by a simple density criterion that approximates the radiative-transport results. The computations include explicitly highly ionised species (e.g. C IV) created in the warm highly ionised intergalactic medium (as opposed to C II and others that are created in the cold lowionised neutral medium).

Our paper is organised as follows. In section 2 we introduce the simulations used for this analysis. In section 3 we explain the computation of the absorption features. In section 4 we show the results for the central geometry. In section 5 we show the results for the background geometry. Finally, in section 6 we draw our conclusions.

2 THE SIMULATIONS

We use three simulated galaxies from a suite of simulations, employing Eulerian adaptive mesh refinement (AMR) hydrodynamics in a cosmological setting. These are zoom-in simulations in dark-matter haloes with masses $\sim 5 \times 10^{11} M_{\odot}$ at z = 2.3, with a maximum resolution of $35-70 \,\mathrm{pc}$ in physical coordinates (Ceverino, Dekel & Bournaud 2010, hereafter CDB). Figure 1 shows a density map of one of the three galaxies from the simulation, which serves as our fidu-

cial galaxy. It demonstrates the dominance of typically three co-planar narrow cold streams (see Danovich et al. 2012), originating outside the virial radius along the dark-matter filaments of the cosmic web, penetrating into the discs at the halo centres. The streams consist of a smooth component and clumps with a spectrum of sizes. The typical densities in the streams are in the range $n = 0.003 - 0.1 \,\mathrm{cm}^{-3}$, and they reach $n = 1 \,\mathrm{cm}^{-3}$ near the central disk and at the clump centres. Some of those clumps are satellites with dark matter haloes.

The CDB simulations were run with the ART (adaptive refinement tree; Kravtsov, Klypin & Khokhlov 1997; Kravtsov 2003) code. It incorporates relevant physical processes for galaxy formation, including gas cooling, photo-ionisation, heating, star formation, metal Straichenents and stellar feedback (Ceverino & Klypin 2009). Cooling rates were computed for the given gas density, temperature, metallicity and UV background (based on CLOUDY, Ferland et al. 1998). Cooling is assumed at the centre of a cloud of uniform density with thickness 1 kpc (Ceverino-Rodriguez 2008; Robertson & Kravtsov 2008). Metallicity dependent, metal-line cooling is included, assuming a relative abundance of elements equal to the solar composition. The code implements a "constant" feedback model, in which the combined energy from stellar winds and supernova explosions is released as a constant heating rate over 40 Myr. This is the typical age of the lightest star that explodes as a type-II supernova. Photo-heating is also taken into account self-consistently with radiative cooling. A uniform UV background based on the Haardt & Madau (1996) model is assumed. Local sources are ignored.

This code has a unique feature for the purpose of simulating the detailed structure of the streams and the gravitational instability in the disk. It allows gas cooling to well below 10^4 K. This enables high densities in pressure equilibrium with the hotter and more dilute medium. A non-thermal pressure floor has been implemented to ensure that the Jeans length is resolved by at least seven resolution elements preventing artificial fragmentation on the smallest grid scale (Truelove et al. 1997; Robertson & Kravtsov 2008; Ceverino, Dekel & Bournaud 2010). The pressure floor is effective in the dense $(n > 10 \text{ cm}^{-3})$ and cold $(T < 10^4 K)$ regions inside galactic disks. Most of the absorbing gas in question, which is far outside the disk, is not affected by this pressure floor.

The equation of state remains unchanged at all densities. Stars form in cells where the gas temperature is below 10^4 K and its density is above the threshold $n = 1 \text{ cm}^{-3}$ according to a stochastic model that is roughly consistent with the Kennicutt (1998) law. The ISM is enriched by metals from supernovae type II and type Ia. Metals are released from each stellar particle by SNII at a constant rate for 40 Myr since its birth. A Miller & Scalo (1979) IMF is assumed. This procedure matches the results of Woosley & Weaver (1995). The metal ejection by SNIa assumes an exponentially declining SNIa rate from a maximum at 1 Gyr. The code treats the advection of metals self-consistently and it distinguishes between SNII and SNIa ejecta (Ceverino-Rodriguez 2008).

The dark matter particle mass is $5.5 \times 10^5 M_{\odot}$. The minimum star particle mass is $10^4 M_{\odot}$. The initial conditions for the CDB simulations were created using a low-resolution

Figure 4. Cumulative Ly α sky covering fractions f_c higher than column density $N_{\rm HI}$. It is integrated from 0.3 to 1.0 $R_{\rm v}$ for all gas inflowing and outflowing. For the blue dashed line we use our three simulated galaxies (resolution 70 pc) at z = 2.3 with $M_{\rm v} = 3.5 \times 10^{11} M_{\odot}$ and $R_{\rm v} = 74$ kpc, for the red solid line we use two simulated galaxies at z = 1.38 with $M_{\rm v} = 1.38 \times 10^{12} M_{\odot}$ and $R_{\rm v} = 150$ kpc. The observational visibility limit at 10^{13} cm⁻² is indicated by the vertical line. We see very low (< 0.3) covering fraction over almost the whole range of column densities and a a sharp jump of the covering fraction at the visibility limit. The higher redshift galaxy has a considerably higher covering fraction over the whole range of column densities.

cosmological N-body simulation in a co-moving box of side 29 Mpc. Its cosmological parameters were motivated by WMAP5 (Komatsu et al. 2009). The values are: $\Omega_{\rm m} = 0.27$, $\Omega_{\Lambda} = 0.73$, $\Omega_{\rm b} = 0.045$, h = 0.7 and $\sigma_8 = 0.82$. At z = 1, three haloes of $M_{\rm v} \simeq 10^{12} M_{\odot}$ each have been selected, avoiding haloes that were subject to a major merger at that time. The three halo masses at z = 2.3 are $3.5, 4, 6 \times 10^{11} M_{\odot}$, their virial radii are around 74 kpc and they end up as $(3 - 4) \times 10^{12} M_{\odot}$ haloes today. Around each halo, a concentric sphere of radius twice the virial radius was selected for resimulation with high resolution. Gas was added to the box following the dark matter distribution with a fraction $f_{\rm b} = 0.15$. The whole box was then re-simulated, with refined resolution only in the selected volume about the respective galaxy.

3 COMPUTING THE IONISATION STATES

A reliable estimate of the ionisation state of the gas is essential for any study of absorption line systems. Ideally, the determination of the ionisation states of the gas should be coupled to the hydrodynamic calculations, but due to the numerical complexity of the problem this type of calculation remains computationally expensive for high resolution simulations especially at lower redshifts. In order to compute them via post-processing we take the densities, tem-

Figure 5. Same cumulative sky covering fractions as in figure 4 this time for metal lines. In the right panel we use our three simulated galaxies (resolution 70 pc, z = 2.3, $M_v = 3.5 \times 10^{11} M_{\odot}$ and $R_v = 74$ kpc), in the left panel we use two simulated galaxies at z = 1.38 with $M_v = 1.38 \times 10^{12} M_{\odot}$ and $R_v = 150$ kpc. The observational visibility limit at 10^{13} cm⁻² is indicated by the vertical line. Together with figure 4 this plot shows that a full sky map of column densities exhibits a few very high peaks corresponding to the streams extending only over a fairly tiny solid angle and a majority of very low column density solid angle corresponding to the space without streams. This effect is stronger for the low redshift panels.

peratures and metallicities from the simulation. We assume a primordial helium mass fraction Y = 0.24, corresponding to a helium particle abundance of 1/12 relative to hydrogen. For the heavy elements we assume the Asplund et al. (2009) solar photosphere pattern.

We determine whether a given simulation cell is "selfshielded", i.e. optically thick to Lyman continuum radiation, via a simple density criterion. Cells with total hydrogen exceeding $n_{\text{shield}} \equiv 0.01 \text{ cm}^{-3}$ are assumed to be self-shielded. For lower densities the cells are assumed to be optically thin. We find that setting $n_{\text{shield}} = 0.01 \text{ cm}^{-3}$ gives the best agreement with a radiative transfer calculation as we demonstrate in figure 2 (see discussion below). For a further discussion of the density criterion, see the discussion by Cox (2005) or the appendix A2 of F11. We calculate the atomic and ionic fractions x_{Ai} using CLOUDY (Ferland et al. 1998), where x_{Ai} is defined as the fractions of element A in ionisation state i. The specific species we are interested in are HI, OI, CII, CIV, SIII and SIIV. These are the most important ions that are visible and detected in optical spectra at z = 2 - 3 and discussed in great detail by S10. We also consider Mg II and FeII since they are assumed to be very suitable for future observational programmes. Table 1 lists the wavelengths and oscillator strengths of the various absorption lines we consider.

In our CLOUDY computations we distinguish between self-shielded and optically thin cells as follows. For optically thin cells, we assume that the gas is exposed to the full Haardt & Madau (1996) UV to X-ray (UVX) metagalac-

ion	λ_0 [Å]	f_{λ}	$\gamma_{\lambda} \ [s^{-1}]$
$Ly\alpha$	1215.6701	0.4164	6.265×10^8
C II	1334.5323	0.1278	2.870×10^8
Si II	1260.4221	1.115	2.533×10^{9}
Οı	1302.1685	0.04887	5.750×10^8
Si II	1526.7066	0.1155	1.960×10^{9}
Si II	1304.3702	0.09345	1.720×10^9
CIV	1548.195	0.1908	2.654×10^8
Si IV	1393.755	0.514	8.825×10^8
CIV	1550.770	0.09522	2.641×10^8
Si IV	1402.770	0.2553	$8.656 imes 10^8$
Mg II	2796.352	0.6123	2.612×10^8
FeII	2382.765	0.3006	3.100×10^8

Table 1. Basic parameters of the various absorption lines, we quote wavelength λ_0 , oscillator strength f_{λ} and the damping width γ_{λ} which is the sum over the spontaneous emission coefficients. Data is taken from Morton (1991), except for the f_{λ} -values for the three Si II lines, which are from Dufton et al. (1983).

tic background field at the appropriate redshift. We do not include any radiation from "local sources". The ionisation state is then controlled by the combined effects of electronimpact collisional ionisation and photoionisation for the full spectral range of the background field. For shielded cells, we truncate the radiation field and include only photons with energies below the Lyman limit. Hydrogen and other species with ionisation potentials (IP) greater than 13.6 eV are then

Figure 6. Example $Ly\alpha$ absorption line profiles seen from a single direction in the central source geometry integrated from 0.3 to 1.0 R_v . Positive velocities are inflowing into the galaxy and negative velocities are out of the galaxy. The letters correspond to the indicated position of the Hammer projection from the upper left panel of figure 8. Values for neutral hydrogen column density and EW are quoted in each panel. Uppermost panel: various modes of inflowing streams, intermediate upper panel: different examples of outflowing material, intermediate lower panel: low absorption profiles and lowermost panel: extraordinary cases which are all showing clear signatures of inflows. Some of the lines are saturated like A, C, K and L whereas others are not.

Figure 7. Same figure as figure 6, panel D (the panel with the deepest signal) this time for selected metal lines providing also the deepest signal, namely: C II (1334 Å), Si II (1260 Å), Mg II (2796 Å) and Fe II (2383 Å). Panel D is fully saturated in Ly α but still shows peak absorption line depths of 0.2 and EW of ~ 0.1 Å for these metal lines. The C II panel of this plot disagrees with the results of Kimm et al. (2011, their figure 2, lower panel) due to different line computing algorithms.

produced by collisional ionisation only¹. For the shielded cells we neglect photoionisation by penetrating X-rays. So for pure collisional ionisation in shielded cells the hydrogen becomes ionised for $T \gtrsim 2 \times 10^4$ K (Gnat & Sternberg 2007). However, "low-ions" with IPs below 13.6 eV continue to be produced by photoionisation as well. Thus, for a given cell, the ionisation state is determined by its total hydrogen density $n_{\rm H}$ and temperature T, and the adopted radiation field, which is either the "full" or "truncated" Haardt & Madau (1996) field, depending on whether the cell is characterised as shielded or not.

To verify our procedure for distinguishing between shielded and optically thin cells, we compare our results for the hydrogen ionisation states with the more detailed radiative transfer computations presented by F11. In figure 2 we plot the distributions by volume of the neutral hydrogen fractions $x_{\rm HI}$ and total hydrogen gas densities $n_{\rm H}$ in the simulation cells, for three different computations of the ionisation structure, all for the same simulated galaxy. The left-hand panel shows the neutral fraction versus density distributions for the detailed radiative transfer computation of F11. This includes the combined effects of the external UVX and internal sources of photoionising radiation. The middle panel shows the F11 results for UVX only. Cells with densities higher than 0.1 cm^{-3} , which usually are close to the disc or the satellites, are not included in figure 2. The righthand panel shows our results for $x_{\rm HI}$ versus $n_{\rm H}$ using our simple criterion of assuming the cells are fully shielded for $n_{\rm H} > n_{\rm H,shield} = 0.01 \ {\rm cm}^{-3}$. Again, in the post-processing we assume that the hydrogen is collisionally ionised in the shielded cells, and collisionally plus photoionised in the optically thin cells. It is apparent that this simplified model provides a useful crude approximation for the results of the UVX radiative transfer (middle panel). The only significant disparity occurs near the transition density of 0.01 cm^{-3} and neutral fraction of $x_{\rm HI} \approx 0.1$, where the ionisation states appear to be sensitive to the details of the radiative transfer computations. At the end of section 5 we will compare our "final product" (figures 24 and 25) to similar results already published in the literature computed with full radiative transfer including ionising radiation from local sources (figure 13 of F11). The differences are small, justifying our simplifying model.

4 CENTRAL SOURCE

In this section we consider the $Ly\alpha$ and metal line absorption that occurs as UV light emitted by the central galaxy is absorbed by gas in the circum-galactic environment. As defined by S10, the circumgalactic medium is situated in the spherical zone from just outside the galactic disk to around the virial radius $R_{\rm v}$. Observations of absorption against the central galaxy itself have the advantage of being able to discriminate between inflows and outflows because the absorptions may be assumed to occur in foreground material only. Radiation emitted or scattered from behind the galaxy is blocked by the galaxy itself. However, such absorptions do not provide spatial information about the distance from the galaxy centre as they are all by definition at an impact parameter b = 0 from the galaxy centre. S10 employed this technique of observing absorptions against the central galaxy by stacking a sample of 89 galaxies with $z = 2.3 \pm 0.3$ using both rest-frame far-UV and $H\alpha$ spectra, to investigate the kinematics of the gas flows in the circumgalactic regions. Here we predict the spectral line profiles and equivalent widths (=EW) produced in absorption against the central galaxy, for a direct comparison to the S10 observations (as presented in their section 4).

The absorption-line profiles depend on the column densities along the line-of-sight. We compute the column densities along radial rays from an innermost radius r_i (usually around the galactic disk) to the virial radius R_v . The column $N_{\rm Ai}(\phi, \theta)$ of element A in ionisation state *i*, at angular position (ϕ, θ) is calculated by

$$N_{\rm Ai}(\phi,\theta) = \int_{r_{\rm i}}^{R_{\rm v}} x_{\rm Ai}(\vec{r}) \ n_{\rm A}(\vec{r}) \ dr, \tag{1}$$

where $n_A(\vec{r})$ is the total gas density of element A at position $\vec{r} = (\phi, \theta, r)$ and x_{Ai} is the ionisation fraction. In figure 3 we show two Hammer equal area projections (Snyder 1993) of

 $^{^1}$ The reader should note that all our species listed in Table 1 have IPs greater than 13.6 eV.

Figure 8. Hammer equal area projections of EW (left panels) and of EW-weighted velocity (right panels) in our fiducial galaxy. The upper four panels show $Ly\alpha$ whereas the lowermost panels show CII. In the uppermost as well as in the lowermost panels the data were computed between 0.3 and 1.0 R_v , whereas in the middle panel the data were computed between 0.1 and 0.3 R_v . Positive velocities are inflowing into the galaxy (shown in red) and negative velocities are out of the galaxy (shown in blue). The contour lines indicate EWs of 1.0, 0.1, 0.01, 0.001 and 0.0001 Å or velocities of +200, 0 and -200 km s⁻¹, respectively. In the upper left panel the positions of the example line profiles from figure 6 are indicated by the circles having letters attached. Comparing right and left panels gives a comprehensive picture of inflows and outflows. The velocity pattern of $Ly\alpha$ and CII is the same even if their EWs are very different. In the panels spanning the outer radius range the narrow major streams are clearly seen as well as the vast majority of the "stream-free" sky (as seen from the central galaxy). In the middle panel representing a narrow radius range very close to the central galaxy this bi-modality is not as obvious as in the other two cases. The radial velocities show different behaviour in the two different radius regimes, the $Ly\alpha$ and CII panels of the same radius regime on the other hand are very similar.

H I column densities for our fiducial galaxy (z = 2.3, $M_v = 3.5 \times 10^{11} M_{\odot}$, $R_v = 74 \,\mathrm{kpc}$). In the upper panel the column densities are integrated from 0.3 to 1.0 R_v whereas in the lower panel they are integrated from 0.1 to 0.3 R_v . Excluding the very inner sphere is somewhat artificial since in practise absorption will occur from close to the very centre at r = 0. However, these plots are useful in giving an impression of the distribution of column densities along different sight-lines. In the upper panel the main stream features are identified and tagged to the same features shown in figure 1 by white open symbols. The same symbols types in figures 1 and 3 indicate

identical features in the galaxy but for different geometries. In figure 3 the narrow major streams with column densities up to $\sim 10^{22}~{\rm cm}^{-2}$ can be seen, as well as the vast majority of the "stream-free" sky (as seen from the central galaxy) having only column densities of $< 10^{15}~{\rm cm}^{-2}$.

To quantify the column density distribution, we compute the cumulative fraction f_c of the sky (as viewed from the central galaxy) that is covered with column densities greater than $N_{\rm Ai}$. The covering fractions for hydrogen and the various metal ions are plotted in figures 4 and 5. These plots include inflowing and outflowing gas. The data in the

10 Tobias Goerdt et al.

blue dashed line of figure 4 as well as in the right panel of figure 5 is averaged over our three simulated galaxies at z = 2.3with $M_{\rm v} = 3.5 \times 10^{11} M_{\odot}$. For better comparability with future observations we also use a second set of data consisting of two galaxies at z = 1.38 with $M_{\rm v} = 1.4 \times 10^{12} M_{\odot}$ (red, solid line). The plot shows that the whole sky, as seen from the central galaxy, has a minimum $N_{\rm HI}$ of 10^{12} cm⁻² and above this value $f_{\rm c}$ decreases strongly from 1.0 to 0.3 at 10^{14} $\rm cm^{-2}$. The H_I covering fraction then decreases more slowly down to ~ 1% at 10^{21} cm⁻². The f_c for the metals are of course much lower. The highest metal columns are usually around 10^{15} cm⁻² and at 10^9 cm⁻² the covering fractions vary between 0.10 (Fe II) and 0.75 (C IV). This verifies our initial qualitative impression that a full sky map of column densities exhibits a few very high peaks corresponding to the streams extending only over a fairly tiny solidPafigle applacements majority of very low column density solid angle corresponding to the space without streams. This effect is even more impressive for the low redshift panels. Also there is a decrease of the covering fraction with decreasing redshift.

Given the computed column densities we can construct simulated absorption line profiles. We start with a single line of sight (i.e. a single pixel in figure 3). Along a given sight-line the gas has a varying density, temperature and radial velocity as function of radial position r from the central galaxy. The convolutions of the different densities and radial velocities in the gas along the line of sight are the main ingredients to compute an absorption line profile. This is done as follows: the radial velocity offset Δw relative to central source at rest of all the gas is measured. We assume Voigt profiles with a thermal Doppler broadening parameter

$$b = \sqrt{\frac{2\,k\,T}{m_{\rm A}}},\tag{2}$$

where k is the Boltzmann constant, T is the temperature of the gas and m_A is the mass of the element A. So for angular position (ϕ, θ) we can compute the optical depth $\tau_{\nu}(\phi, \theta, \Delta w)$ at the velocity offset Δw as (cf. equation 10.24 of Böhm-Vitense 1990)

$$\tau_{\nu}(\phi, \theta, \Delta w) = \frac{\sqrt{\pi} e^2 f_{\lambda} \lambda_0}{m_{\rm e} c} \int_{r_{\rm i}}^{R_{\rm v}} \frac{n_{\rm A}(\vec{r}) x_{\rm Ai}(\vec{r})}{b(\vec{r})} \times H\left[\frac{\gamma_{\lambda} \lambda_0}{4 \pi b(\vec{r})}, \frac{\Delta w - v(\vec{r})}{b(\vec{r})}\right] dr, \qquad (3)$$

where e is the electron charge, $m_{\rm e}$ is the electron mass, c is the speed of light, λ_0 is the transition wavelength, $n_{\rm A}(\vec{r})$ is the gas density of element A at position $\vec{r} = (\phi, \theta, r)$, x_{Ai} is the ionisation fraction of element A in state i, v is the velocity of the gas, f_{λ} is the oscillator strength of the absorption line and γ_{λ} is the sum over the spontaneous emission coefficients or the damping width. We took these f_{λ} and γ_{λ} values from Morton (1991). The Voigt profile is

$$H(a,u) = \frac{a}{\pi} \int_{-\infty}^{\infty} \frac{\exp(-y^2)}{(u-y)^2 + a^2} \, dy,$$
(4)

where a is the ratio of the damping width to the Doppler width and u is the offset from line centre in units of Doppler widths. Knowing $\tau_{\nu}(\Delta w)$ it is now possible to compute an absorption line profile $I(\Delta w)$ for a given direction which is simply the function

Figure 9. Cumulative EW sky covering fractions f_c higher than W_0 for a central source integrated from 0.3 to 1.0 R_v for Ly α . Please note the different x-axis scaling with respect to figure 10. In solid red we show the average of our three simulated galaxies (resolution 70 pc, z = 2.3, $M_v = 3.5 \times 10^{11} M_{\odot}$, $R_v = 74$ kpc). Whereas in dashed blue we show the average of two simulated galaxies at z = 1.38 ($M_v = 1.38 \times 10^{12} M_{\odot}$, $R_v = 150$ kpc). At higher redshift there is a higher covering fraction of high EW visible, implying that there are more pronounced streams present.

$$I(\Delta w) = \exp[-\tau_{\nu}(\Delta w)]. \tag{5}$$

For a fair comparison to the observations done by S10, we mimic a Gaussian point spread function. This will be done from now on up to the end of this section. It is in contrast to figures 3, 4 or 5 where no point spread function was applied. It has a beam-size (= FWHM η of the Gaussian) of 4 kpc. It is done by splitting up a cylinder with a radius of three times the beam-size into as many parallel fibres as the resolution permits, determining the absorption line profile for every individual fibre and then computing a Gaussian weighted average absorption line profile from all fibres. Also from now on up to the end of this section (except for figures 11 and 12) we degrade our velocity space resolution down to 50 km/s, to match the velocity resolution used in the corresponding figures of S10.

A selection of the large variety of different possible absorption line profiles depending on the respective viewing angles are shown in figures 6 (Ly α) and 7 (selected metal lines). One can see various modes of inflowing streams, different examples of outflowing material as well as very shallow absorption line profiles corresponding to a line of sight with very low column density. In Ly α some of the lines are saturated like A, C, K and L, whereas the others are not. Panel D which shows the strongest lines is fully saturated in Ly α but still shows peak absorption line depths of 0.2 and EW of ~ 0.1 Å for selected metal lines. The reader should note that some of the weaker lines (panels G or H for example) might be completely erased by noise and the ISM component at v = 0.

Absorption in cold streams feeding high-z galaxies 11

Figure 10. Same cumulative EW sky covering fractions f_c as in figure 9 this time for the metal lines. Note the different x-axis scaling with respect to figure 9. In the upper panels we show our three simulated galaxies (resolution 70 pc, z = 2.3, $M_v = 3.5 \times 10^{11} M_{\odot}$, $R_v = 74$ kpc). Whereas in the lower panels we use two simulated galaxies at z = 1.38 with $M_v = 1.38 \times 10^{12} M_{\odot}$ and $R_v = 150$ kpc. The C_{IV} and Si_{IV} lines in the middle panels clearly stand out. Those lines can be produced in hot medium whereas all the others can only be produced in cold gas only. So C_{IV} and Si_{IV} reach covering fractions as high as unity. The low ionised metal lines (left and right panel) have higher peak values of EW by up to one order of magnitude.

The leftmost panel of figure 7 is comparable to the lower panel of figure 3 in Kimm et al. (2011). They get for CII a maximum line depth (MLD) of ~ 0.9 with a FWHM η of 650 km s⁻¹. The differences stem from the fact that they used a lower resolution simulation, the Horizon MareNostrum simulation (Ocvirk, Pichon & Teyssier 2008). Further on they used higher mass haloes ($M_v > 10^{12} M_{\odot}$) and a very different prescription for the Gaussian velocity distribution. They obtain their dispersion from the neighbouring 26 cells instead of the algorithm from equations (2) to (4). Some statistical properties of the ensemble of all possible example line profiles will be shown later.

Each of these absorption line profiles has a certain total absorption which can be expressed as a single number, the "rest equivalent width" (EW). This is usually given in wavelength units and it is defined as:

$$W_0 = \frac{\lambda_0}{c} \int_{-\infty}^{\infty} \left\{ 1 - \exp[-\tau_\nu(w)] \right\} \, dw$$

$$= \frac{\lambda_0}{c} \int_{-\infty}^{\infty} [1 - I(w)] \, dw. \tag{6}$$

An EW can now be calculated for every angular position on the sky. With these numbers we can plot a whole full sky map of EW. This is done in the left panels of figure 8. There we show the resulting Hammer projections of EW for our fiducial galaxy. The upper two panels show $Ly\alpha$ whereas the lowermost panel shows CII. In the uppermost and lowermost panels the EWs were computed for the gas in the radius range between 0.3 and 1.0 $R_{\rm v}$, whereas in the middle panels the EWs were determined for gas in a somewhat narrower and innermore radius range between 0.1 and 0.3 $R_{\rm v}$. In the upper left panel the positions of the example line profiles from figure 6 are indicated by the circles with the letters attached to them. In the panels spanning the outer radius range one can again clearly see the narrow major streams having EWs of > 1Å (Ly α) or > 0.01Å (CII). One can also see the vast majority of the "stream-free" sky (as seen from the central galaxy) with EWs of ~ 0.01 Å

Figure 11. Fraction $h_{\rm elp}$ of all possible example line profiles in the central geometry whose EW is higher than W_0 and whose line centre is at a velocity offset indicating an inflow at least as fast as Δw . Here for the Ly α line. The example line profiles are integrated from $1.0 R_{\rm v}$ down to $0.3 R_{\rm v}$. Positive velocities are inflowing into the galaxy and negative velocities are out of the galaxy. Contour lines are at 0.1, 0.01, 0.001 and 0.0001 respectively. Note the different y-axis scalings with respect to figure 12. This figure shows that the probability of detecting an inflow which is flowing in with at least $150 \,\rm km \, s^{-1}$ with a signal of at least $3.9 \,\rm \AA$ in a single observation of a single galaxy without averaging is $\sim 4 \,\%$.

(Ly α) or < 10⁻⁵ Å (CII). In the middle panel representing a narrow radius range very close to the central galaxy $(0.3R_{\rm v} > r > 0.1R_{\rm v})$ this bi-modality is by far not as obvious as in the other two cases. This is due to the fact that at this distance from the galaxy centre the inflowing streams slowly dissipate into a region with more complex gas motions ("messy region"). Since the EWs are significantly lower for the CII line and even lower for the other lines, as we will see later, we do not show Hammer projections of EW of other metal lines than CII. We do show Hammer projections of EW-weighted velocity in the right panels of this figure. Positive velocities are inflowing into the galaxy (shown in red) and negative velocities are out of the galaxy (shown in blue). The contour lines indicate velocities of +200, 0 and -200 km s^{-1} . Regions with very high velocity outflows have a low EW, while velocities close to systemic velocity are at very high EW. This agrees very well with the high EW seen by S10 at $v_{\rm r} = 0 \,{\rm km \, s^{-1}}$. The velocity pattern of Ly α and C II is the same even if their EWs are so different. Comparing the upper two panels one can see that the distribution of velocities in the two different radius regimes varies. The term "outflow" can be misleading here. In our simulations some of the material that is receding from the centre of the galaxy is not necessarily diffuse gas driven by some kind of feedback processes. It could also be a clump or satellite galaxy which is merging with the central galaxy. It just had its first flyby with the central object and is therefore now "outflowing".

To present the statistics from these maps we determine the sky covering fractions. In figures 9 and 10 we show the fraction $f_{\rm c}$ of the sky as seen from the central galaxy that is

covered with absorption line profiles which have EW higher than W_0 . Here we integrate in the central source geometry from 0.3 to 1.0 $R_{\rm v}$. In figure 9 this is done for Ly α whereas in figure 10 this is done for the metal lines (note the different x-axis scaling in both figures). We use our three simulated galaxies (resolution 70 pc) at z = 2.3 with $M_{\rm v} = 3.5 \times 10^{11} M_{\odot}$ and $R_{\rm v} = 74 \, \rm kpc$. These are shown in solid red in figure 9 and on the upper panels of figure 10. Again for better comparability with future observations we also use a second set of data consisting of two galaxies at z = 1.38 with $M_{\rm v} = 1.4 \times 10^{12} M_{\odot}$ and $R_{\rm v} = 150$ kpc. These are shown in dashed blue in figure 9 and on the upper panels of figure 10. We concentrate on the lines studied in great detail in S10 which are: Ly α (1216 Å), C11 (1334 Å), O1 (1302 Å), Si II (1260 Å, 1304 Å and 1526 Å), C IV (1548 Å and 1550 Å) as well as Si IV (1393 Å and 1402 Å). In addition to these ten lines observed by S10 we also use here seven new ones: Mg II (2803 Å and 2796 Å) and Fe II (2600 Å, 2383 Å, 2344 Å, 2587 Å and 2374 Å). These lines have not been observed in this geometry or redshift range yet, but may be very suitable for future observational programmes at $z \sim 1$. For Ly α one can see that at higher redshift there is a higher covering fraction of large EW, implying that the streams are much more pronounced. The CIV and SiIV lines in the middle panels of figure 10 clearly stand out since they reach covering fractions as high as unity but for low column densities only. This is because these lines can be produced in the hot and diffuse medium whereas all the others can only be produced in cold gas only. Another interesting feature for the metal lines is that low ionised metal lines have higher peak values of EW by up to one order of magnitude, but low overall covering fraction. This is because low-ionised ions are more abundant in high-density, cold regions with low covering fraction, like streams.

As already mentioned earlier we want to show statistics of how many absorption lines show signatures of inflow versus how many absorption lines show signatures of outflow and how strong are those. This is done in figures 11 and 12. These figures are intended to give the likelihood of a detection of a cold stream while looking at a single galaxy from a single direction without averaging. They show the fraction $h_{\rm elp}$ of all possible example line profiles in the central geometry whose EW is higher than W_0 and whose line centre is at a velocity offset indicating an inflow at least as fast as Δw . The example line profiles are integrated from $1.0 R_{\rm v}$ down to $0.3 R_{\rm v}$. Positive velocities are inflowing into the galaxy and negative velocities are out of the galaxy. In these two figures no velocity degrading is used. The $Ly\alpha$ panel shows that the probability of detecting an inflow which is flowing in with at least $150\,{\rm km\,s^{-1}}$ with a signal of at least $3.9\,{\rm \AA}$ in a single observation of a single galaxy without averaging is ~ 4%. In CII one sees an inflow > $150 \,\mathrm{km \, s^{-1}}$ with an EW > 0.17 Å in 0.4 % of all observations. For Mg II one sees an inflow > $150 \,\mathrm{km \, s^{-1}}$ with an EW > $0.2 \,\mathrm{\AA}$ in $1.3 \,\%$ of all observations. These values should be achievable by future observations. Since it is the likely scenario that the inflowing streams and the wide-angle outflowing gas avoid each other to a great extent the streams as measured in our simulations where the outflows are a factor of 2-3 weaker than in the extreme observed cases can be regarded as a sensible approximation.

As a last application for this geometry we mimic the

Figure 12. Same cumulative fraction h_{elp} as in figure 11. Here for the metal lines. Positive velocities are inflowing into the galaxy and negative velocities are out of the galaxy. Contour lines are at 0.1, 0.01, 0.001 and 0.0001 respectively. Note the different y-axis scalings with respect to figure 11 as well as from row to row. In CII one sees an inflow > 150 km s⁻¹ with an EW > 0.17 Å in 0.4% of all observations. For MgII one sees an inflow > 150 km s⁻¹ with an EW > 0.2 Å in 1.3% of all observations. The line which has by far the strongest signal is the MgII line followed by the FeII line. These values should be achievable by future observations.

S10 stacking procedure (see their figures 6 and 10) they used to increase the signal to noise ratio. They stacked 89 galaxies with $z = 2.3 \pm 0.3$ to investigate the kinematics of the galaxy-scale outflows. We produce stacked spectra using our simulations by summing up the line profiles of several thousand different directions for each of the three galaxies and stack them together. We determine the absorption line profile for a spherical shell between an outer radius and an inner radius r_i . The outer radius is always kept constant at 1.0 $R_{\rm v}$ which corresponds roughly to 74 kpc. The inner radius $r_{\rm i}$ however is varied between 0.3 $R_{\rm v}$ and 0.02 $R_{\rm v}$. This is done for the following reason: As one can see from figure 1, there are very clean, unperturbed streams into the galaxy down to as far as $\sim 0.25 R_{\rm v}$. In the immediate vicinity of the galaxy there is the "messy region" without well defined streams and with no well defined gas disk either. The galactic disk itself has no sharp edge and therefore its extent is not determined easily either. In order to account for these uncertainties we show several different absorption line profiles for different inner radii for every wavelength in question. All are averaged in the aforementioned way. In figures 13 and 14 the resulting profiles are shown for all the lines. These figures can be directly compared to figures 6 or 10 in S10. The plots reveal that we have for $Ly\alpha$ a FWHM η of up to \sim 1900 km $\rm s^{-1}$ with a line depth of up to 0.90 for an inner radius r_i going as deep as 0.02 R_v (1.5 kpc). The Ly α lines for high r_i having a shallow total MLD show very extended wings at the edges of the line profile whereas lines for small r_i having a deep total MLD the edges of the $r_{i} = 0.02 R_{v}.$ This confirms our initial guess that metal lines material is mainly unprocessed primordial gas with very low metallicity. The predicted metal line absorption profiles ar pear tiny compared to the corresponding line. figures 6 or 10 of S10 having a ¹¹ m s⁻¹ in metala T and the observed values by S10 are given in Table 2.

It is hard to compare our $Ly\alpha$ absorption line profiles to the observations of S10 as they actually show emission line profiles. One could still draw interesting conclusions by comparing the underlying optical depths τ of the S10 observations with our simulations. However, the $Lv\alpha$ emission is not only an indicator of cold streams. Probably the most suitable lines for the purpose of detecting cold streams in absorption are CII and MgII since they have the strongest signal. Out of those MgII is closer to being observed with the needed sensitivity and resolution (cf. for example Matejek & Simcoe 2012). As S10 point out, the easiest way for a $Ly\alpha$ photon to reach the observer is to acquire the velocity of the outflowing material on the far side of the galaxy, and to be emitted in the observer's direction. In this case the photon is redshifted by several hundred km s^{-1} relative to the bulk of the material through which it must pass to reach us. This picture would explain qualitatively why the dominant component of $Ly\alpha$ emission always appears redshifted relative to the galaxy systemic velocity (see e.g, Pettini et al. 2002; Adelberger et al. 2003), implying that their results for $Ly\alpha$ have to be interpreted with caution. Our results for $Ly\alpha$

Table 2. Comparison of maximum line depths (MLD), FWHM η and EW W_0 in the central geometry between S10's observations (their figure 10) and our predictions from the simulations (the " $r_i = 0.02 R_v$ " line in our figures 13 and 14).

Figure 13. Ly α absorption line profile for a central source geometry averaged over different viewing angles and all three galaxies. We integrated from 1.0 R_v down to different inner radii r_i . Positive velocities are inflowing into the galaxy and negative velocities are out of the galaxy. Note the different scaling of both axes in comparison to figure 14. The profiles always peak in the positive, indicating inflow. Lines for high r_i having a shallow total MLD show very extended wings at the edges of the distribution whereas lines for small r_i having a deep total MLD the edges of the profiles are much sharper since the centre of the line is much deeper.

absorption in the simulations are not subject to this complication, therefore one should be cautious when comparing our Ly α results to the S10 data. Metal lines are less problematic.

There are two main conclusions from our analysis of the central-source geometry, which are discouraging concerning

Figure 14. Same absorption line profiles for a central source as in figure 13, this time for the metal lines. Positive velocities are inflowing into the galaxy and negative velocities are out of the galaxy. Note the different y-axis scaling from row to row and the different overall axes scaling with respect to figure 13. The metal lines are much weaker than the $Ly\alpha$ line, since the inflowing material is mainly unprocessed primordial gas with very low metallicity. These metal lines also appear tiny compared to the corresponding lines presented by S10. The profiles always peak in the positive, indicating inflow. The lines with the strongest signals are Si II and Mg II. A more detailed quantitative comparison to the observations is presented in table 2.

Figure 15. Map of the projected neutral hydrogen column densities $(N_{\rm HI})$ for the background geometry of our fiducial galaxy at z = 2.3. The box side is 138 kpc (physical). The outer circle marks the virial radius and the inner circle is at $1/3 R_{\rm v}$. Contours are shown for 10^{17} , 10^{19} and $10^{21} \,{\rm cm}^{-2}$. One can see the three major streams outside $1/3 R_{\rm v}$ as well as clumps which are actually satellites with dark matter haloes. Both of them have $N_{\rm HI} > 10^{17} \,{\rm cm}^{-2}$. The background has $N_{\rm HI} < 10^{15} \,{\rm cm}^{-2}$. Inside $1/3 R_{\rm v}$ there is the messy region. It has column densities with values between those of the stream and the background.

the potential for detecting cold streams. First stacking of absorption line profiles does not strengthen but weakens the signature of cold streams this might be counter intuitive, but compare figure 6 with figures 13 and 14). See figures 11 and 12 for the predicted strengths of a cold stream absorption signal when observing without stacking. Second, the Ly α signal detected by observations is naturally dominated by outflows which are expected to have much higher covering factor and metallicity (Faucher-Giguere & Keres 2011).

5 BACKGROUND SOURCE

In this section we consider the Ly α and metal line absorption that occurs as UV light emitted by a background galaxy or a quasar is absorbed by gas in the circum-galactic environment of the foreground galaxy under investigation. In this geometry one cannot distinguish between inflowing and outflowing gas. However, the distribution of impact parameters allows us to explore the spatial distribution of the circumgalactic gas surrounding the foreground galaxies. S10 constructed a sample of 512 close angular pairs, (1 - 15''), of galaxies in the redshift range $z \sim 2 - 3$ with a large redshift difference such that one is at the background of the

Figure 16. Area weighted average column density $N_{\rm Ai}$ as a function of impact parameter b for H I and five different metal lines in the background source geometry. The H I column density decreases through the interaction region in the greater disc vicinity, from 10^{22} cm² near the centre of the galaxy to 10^{20} cm² at 0.5 $R_{\rm v}$. It remains roughly constant at 10^{19} cm² in the stream regime out to 1.5 $R_{\rm v}$, and is not much lower out to 2.5 $R_{\rm v}$.

other with no physical association. The pair separations correspond to galactocentric impact parameters in the range 3 - 125 kpc (physical) at z = 2.2, providing a map of cool gas as a function of galactocentric distance for a wellcharacterised population of galaxies. The discussion in this section will lead to a prediction of absorption line profiles that are directly comparable to the ones observed and published in section 6 of S10.

For a first impression of the simulation data in the background-source geometry we show in figure 15 a map of projected neutral hydrogen column density. The box of 140 kpc is centred on our fiducial galaxy of $M_{\rm v} \simeq 4 \times 10^{11} M_{\odot}$ at z = 2.3, which serves as the foreground galaxy. The column density $N_{\rm Ai}(x, y)$ of element A and ionisation state *i* at the position (x, y) itself is now calculated by

$$N_{\rm Ai}(x,y) = \int_{-\rm bs}^{\rm bs} x_{\rm Ai}(\vec{x}) \ n_{\rm A}(\vec{x}) \ dz, \tag{7}$$

where bs indicates the box size of twice the virial radius, $n_A(\vec{x})$ is the total gas density of element A at position $\vec{x} = (x, y, z)$ and x_{Ai} is the ionisation fraction of element A in state *i*. This equation is the analog of equation 1 for the central geometry. The map in figure 15 corresponds to figure 3 in the central geometry. The outer circle marks the virial radius and the inner circle is at 1/3 R_v . Contours are shown for 10^{17} , 10^{19} and 10^{21} cm⁻². One can see the three major streams which are very pronounced outside $1/3 R_v$. They have neutral hydrogen column densities of $N_{\rm HI} > 10^{17}$ cm⁻². The background outside $1/3 R_v$ has neutral hydrogen column densities of $N_{\rm HI} < 10^{15}$ cm⁻². In the messy region inside $1/3 R_v$ one cannot distinguish between streams, galac-

Figure 17. Area covering fraction g_c as a function of impact parameter b and cumulative column density for different ionisation states i of the elements A in the background source geometry. The panels show for every impact parameter bin b the fraction of the area within this impact parameter bin which has a column density of $N_{\rm Ai}$ or above. The contours mark area covering fractions g_c of 1.0, 0.1 and 0.01. The values are averaged over three different galaxies and over three orthogonal directions. We see that H_I shows the highest column densities over the whole radius range. It also reaches a area covering fraction of 1.0 at 10^{13} cm⁻² over the whole radius range. The 0.1 and 0.01 area covering fraction lines a decreasing monotonically with radius for all panels. The metal ionisation states with the highest area covering fractions are C_{II} and C_{IV}. The H_I panel agrees with the results of F11 (their figure 4), Faucher-Giguere & Keres (2011, their Table 1) as well as with the results of Shen et al. (2012) (their figure 10).

tic disk or background. The neutral hydrogen column densities within this region vary between 10^{15} cm⁻² and 10^{17} cm⁻². One should note that this ideal map cannot be directly compared to any observed galaxy, because it requires a background point source along the same line of sight of each pixel in the map.

The impression from figure 15 is that the column density tends to decrease with increasing distance from the galaxy centre. Figure 16 shows the area-weighted average column density, for HI and five different metal lines, as a function of the impact parameter b. The HI column density decreases through the interaction region in the greater disc vicinity, from 10^{22} cm⁻² near the centre of the galaxy to 10^{20} cm⁻² at 0.5 R_v . It remains roughly constant at 10^{19} cm⁻² in the stream regime out to 1.5 R_v , and is not much lower out to 2.5 R_v . The metal ionisation states also decrease inside 0.5 R_v and are roughly constant at values between 10^{14} cm⁻² (O I) and 10^{11} cm⁻² (Si IV) in the outer halo and beyond.

Figure 15 is limited to the angle-averaged column density. Figure 17 presents the distribution of column densities, for the purpose of evaluating the likelihood of an observation through a given line of sight. We plot area covering

Figure 18. Example $Ly\alpha$ absorption line profiles seen from a single direction in the background geometry integrated from 0.3 to 1.0 R_v . For a background source one cannot tell from the redshift or blueshift of the line relative to the central restframe whether it represents inflow or outflow with respect to the galaxy centre. From inspection of the three-dimensional information in the simulations, we know that almost in every case a significant coherent shift of the line is associated with inflow. Values for neutral hydrogen column density and EW are quoted in each panel. Uppermost panel: various modes of bimodal streaming, intermediate upper panel: different examples of strong unidirectional streaming, intermediate lower panel: low absorption profiles and lowermost panel: extraordinary cases. Some of the lines are saturated like B, C, D, E, F, K and L, whereas others are not. The letters correspond to the indicated position of the map from figure 20.

Figure 19. Same figure as figure 18, panel K (the panel with the deepest signal) this time for selected metal lines providing also the deepest signal, namely: C II (1334 Å), Si II (1260 Å), Mg II (2796 Å) and Fe II (2383 Å). Panel K is fully saturated in Ly α but still shows peak absorption line depths of 0.25 and EW of ~ 0.2 Å for these metal lines. The C II panel of this plot shows slight differences with the results of Kimm et al. (2011, their figure 2, lower panel) due to different line computing algorithms.

fractions $g_{\rm c}$ as a function of impact parameter b and cumulative column density $N_{\rm Ai}$. The values are averaged over three different galaxies and three orthogonal projections per galaxy. The panels show for every impact parameter b the fraction of the area within an annulus of radius b and width δb which has a column density of $N_{\rm Ai}$ or above. One can see that there are obviously much higher columns of HI present than of the other metal ionisation state. HI has column densities which are several orders of magnitude higher, depending on the actual radius and the area covering fraction one wants to look at. The columns of the metal ionisation states lie closely to each other and decrease rather smoothly with increasing radius. The $g_c = 0.1$ lines of the two carbon lines are fairly similar, both fall off almost linearly from $\sim 10^{15}$ $\rm cm^{-2}$ at the left edge of the graph to $\sim 10^{10} \rm \ cm^{-2}$ at the right edge of the graph. This is also true for the $g_c = 0.1$ lines of the two silicon lines. They fall off from around $10^{14}\,$ to below 10^8 . The $q_c = 0.01$ line, which lies much higher, on the other hand has more differences between the low-ionised metals (like CII, SiII or FeII) on the higher ionised metals (like C IV or Si IV): In case of the low-ionised metals the line has considerably more features like the extended bumps at impact parameters of 1.0 $R_{\rm v}$ or 2.0 $R_{\rm v}$. The distribution for CII indicates the highest, the one for MgII indicates the lowest overall column densities.

The H_I panel of figure 17 is comparable to figure 4 of F11, who implemented a full radiative transfer calculation. A comparison between the two allows us to evaluate the accuracy of our simplified treatment of self-shielding. For impact parameter other than $b = 2.0 R_{\rm v}$ the latter show in their figure 4 values which are normalised to the value it would have at $b = 2.0 R_{\rm v}$. In the following we will only quote the unnormalised values. In our results the same covering factors correspond to column densities that are usually smaller by a factor of ~ 3 . For example at $b = 2.0 R_v$ F11 have a covering factor of 0.01 at 3×10^{20} cm⁻² and of 0.1 at 10^{17} cm⁻². In our results these covering factors correspond to column densities of 10^{20} cm⁻² and 3×10^{16} cm⁻², respectively. The H_I panel of figure 17 is also roughly comparable to Table 1 of Faucher-Giguere & Keres (2011). In our results we have covering factors which are on average smaller by a factor of 1.5. For example at $b = 0.5 R_{\rm v}$ they have an average cover-

Figure 20. Map of the Ly α absorption line EWs for the background geometry of one of our simulated galaxies. The box side is 276 kpc (physical). The outer circle marks the virial radius and the inner circle is at $1/3 R_v$. The contour lines indicate an EW of 1 and 0.1 Å respectively. The circles with the letters attached to it indicate the position of the example line profiles from figure 18. The three major streams as well as clumps (satellites with dark matter haloes) have $W_0 > 1$ Å. The background has $W_0 < 1$ Å.

ing factor of ~ 0.3 at $10^{17.2} \lesssim N_{\rm HI} \lesssim 2 \times 10^{20}$ and of ~ 0.08 at > 2 × 10^{20} cm⁻². Our corresponding covering factors are 0.2 and 0.1. In their figure 10, Shen et al. (2012) quote a H I covering factor of column densities higher than $10^{17.2}$ cm⁻² for $r < R_{\rm v}$ ($r < 2R_{\rm v}$) of 27% (10%). Our corresponding covering factors are 0.2 and 0.5. We conclude that our results

based on the simplified treatment of self-shielding (section 3) provide a rather good approximation to the results from the full radiative transport analysis.

We next compute example absorption line profiles for a background source, in analogy to the line profiles for a central source, using equations (2) to (5). From now on, we apply a Gaussian point spread function with a beamsize (= FWHM) of 4 kpc, following the algorithm described in section 4. In addition, the velocity resolution is now downgraded to $50 \,\mathrm{km \, s^{-1}}$, to match the velocity resolution used in the corresponding figures of S10. In figure 18 and 19 we show a selection of absorption line profiles, for $Ly\alpha$ and metal lines, respectively, demonstrating a large variety. These figures are the analogs of figures 6 and 7 for a central source. Some line profiles show a single dominant stream, others indicate two streams, some display weak absorption and others show strong absorption. For a background source one cannot tell from the redshift or blueshift of the line relative to the central restframe whether it represents inflow or outflow with respect to the galaxy centre. From inspection of the three-dimensional information in the simulations, we know that almost in every case a significant coherent shift of the line is associated with inflow. In the case of $Ly\alpha$, 7 out of 12 lines in the sample are saturated (B, C, D, E, F, K, L). Panel K, which shows the strongest absorption in $Ly\alpha$, has for selected metal lines a maximum absorption depths of only 0.25 and an equivalent width EW of only ~ 0.2 Å. Some of the weaker $Ly\alpha$ lines (e.g. panels I or even H) might be completely erased by noise and the ISM component at v = 0. The leftmost panel of figure 19 is analogous to the lower panel of figure 3 in Kimm et al. (2011). The latter obtain for CII a maximum line depth of \sim 0.9 with a FWHM η of 650 km s⁻¹. The difference from our result most likely stems from the fact that they used a simulation with a resolution lower by a factor of 20, the Horizon MareNostrum simulation (Ocvirk, Pichon & Teyssier 2008), and addressed haloes more massive by a factor of a few. Furthermore, they used a different prescription for the Gaussian velocity distribution, where they obtained their velocity dispersion from the neighbouring 26 cells instead of the more appropriate algorithm described in equations (2) to (4).

As for the central source, we compute the equivalent widths from the absorption line profiles using equation (6). The EWs for a background source are mapped for our fiducial galaxy in figure 20. The outer circle marks the virial radius and the inner circle is at $1/3 R_v$. This plot is the analog of figure 8 for a central source. The EWs shown in it span two and a half orders of magnitude. The three major streams are fairly prominent, in addition to the central region in the greater vicinity of the disc. Also very prominent are the parts of the IGM which are stream-less.

Figure 20 illustrates the dependence of the EWs on the projected distance from the centre, or impact parameter b. In the galaxy vicinity at the halo centre, b < 10 kpc, say, we see the highest absorption, which gradually declines toward larger radii, as the volume becomes dominated by the dilute medium between the streams. Figure 21 shows the average EW as a function of impact parameter b, averaged over the three simulated galaxies at z = 2.3, where the virial masses are $M_{\rm v} \simeq 4 \times 10^{11} M_{\odot}$. For Ly α , we show for comparison the observational results of S10 (their Table 4), assuming a virial radius of 74 kpc. In our simulation results for all the lines,

the inner galaxy is responsible for a steep peak in EWs in the range $b \leq 0.5R_v$. Outside of this radius the EW is lower and it shows an overall gradually declining with b. A comparison with the observations shown in figure 21 of S10 indicates that the observational EW for the Ly α line lies a factor of two or less below our predicted value at low b, and is consistent with our prediction at larger radii. The simulation results in figure 14 of F11 and in figure 9 of Shen et al. (2012) for Ly α are in excellent agreement with our current results, and so are the F11 predictions for Si II (1260 Å). The observational results of S10 for the EW of the metal lines are two orders of magnitude above our predictions. These are likely to reflect massive, cold, dense and metal-rich outflows that are not reproduced in an appropriate amplitude in our simulations.

The probability to observe a given EW along a given line of sight of impact parameter b is shown in figures 22 and 23. Shown in colour is the area covering fraction $q_{\rm c}$ as a function of impact parameter b and cumulative EW for different absorption lines. The panels show for every impact parameter bin b the fraction of the area within this impact parameter bin which has an EW of the indicated value W_0 or above. The contours mark fractions of 1.0, 0.1, 0.01 and 0.001. The values are averaged over three different galaxies and three orthogonal projections, in both directions each. This figure is the analog of figure 10 for a central source. We see that in Ly α we have EWs > 0.01 Å everywhere. Peak EWs go as high as 10 Å. The 0.1 area covering fraction line is falling monotonically with b, whereas the 0.01 and 0.001 lines show noisy distortions at $b > 1.5 R_{\rm v}$. For the metal lines the peak EWs lie near 0.1 Å and their minimum values are well below 10^{-6} Å. In all cases the EWs are declining mainly monotonic with radius. For $Ly\alpha$ the decline is rather gradual, only by an order of magnitude over the studied radius range. For the metal lines the decline is by more than five orders of magnitude. We see some noisy distortions in the high b, low g_c regime. Over all the strongest lines are CII and MgII.

Finally, we try to produce absorption line profiles that could be compared to those presented in figures 6 and 10 of S10. They stacked spectra of several galaxies in order to increase the signal to noise ratio. Their sample contains 512 close (1''-15'') angular pairs of $z \sim 2-3$ galaxies with redshift differences that indicate no physical association. The sample explores the cool gas as a function of galactocentric impact parameter in the range 3 - 125 kpc (physical) at z = 2.2. In figures 24 and 25 we show the resulting absorption line profiles for $Ly\alpha$ and metal lines in our simulations, stacked over six principal different viewing directions (three orthogonal axis in both directions). We show the line profiles for the same three different impact parameter bins as in S10: 10-41 kpc, 41-82 kpc and 82-125 kpc. (Note the different scales in figures 24, 25 and from row to row within figure 25). The lines for 10 - 41 kpc in those figures correspond to figure 18 in S10, the lines for 41 - 82 kpc correspond to figure 19 in S10, and the lines for 82 - 125 kpc correspond to figure 20 in S10. For Ly α we have a FWHM (= η) of up to $\sim 550 \text{ km s}^{-1}$ and a relative intensity of 40-50% at the line centre of the innermost radius bin. It is not easy to compare our $Ly\alpha$ absorption line profiles to the observations of S10 as they actually show emission line profiles. One could still draw interesting conclusions by comparing the underlying optical depths τ of the S10 observations with our

Figure 21. Average EW W_0 as a function of impact parameter b, averaged over the three simulated galaxies. For Ly α , we show for comparison the observational results of S10 (their Table 4). The inner galaxy is responsible for a steep peak in EWs in the range $b \leq 0.5R_v$. Outside of this radius the EW is lower and it shows an overall gradually declining with b. As expected there is a strong negative correlation between impact parameter b and EW. This behaviour is the same for all ten lines. The Ly α and the Si II (1260 Å) lines agree with the theoretical results of F11 (their figure 14). The Ly α line also agrees with the theoretical results of Shen et al. (2012) (their figure 9). The observational results of S10 for Ly α (their Table 4 and their figure 21) are also in fairly good agreement.

 2 the

Horizon

Figure 22. Area covering fraction g_c as a function of impact parameter b and cumulative EW W_0 for the Ly α absorption line in the background source geometry. Shown is for every impact parameter bin b the fraction of the area within this impact parameter bin which has a EW of W_0 or above. The contours mark fractions of 1.0, 0.1, 0.01 and 0.001. The values are averaged over three different galaxies and the six principal axis. We see that we have an EW > 0.02 Å everywhere. The 0.1 area covering fraction line is falling monotonically with b, whereas the 0.01 and 0.001 lines show noisy distortions at $b > 1.5 R_y$.

simulations. However, due to the special transfer behaviour of Ly α mentioned at the end of section 4 the Ly α emission is not only an indicator of cold streams. Therefore the results have to be taken with caution. Our strongest metal absorption lines, Si II and C II, have both a maximum line depth of ~ 0.015 with $\eta \sim 350 \text{ km s}^{-1}$ for the 10 – 41 kpc bin. This appears tiny compared to the corresponding lines presented in figures 18 or 19 of S10 having a line depth of

ion	λ_0 [Å]	S10's W ₀ [Å]	our MLD	$\begin{array}{c} \text{our} \\ \eta \\ [\text{km s}^{-1}] \end{array}$	our W_0 [Å]
$Ly\alpha$	(1216)	4.7	0.61	550	2.3
C II	(1334)	2.61	0.016	350	0.025
SiII	(1260)	2.01	0.012	400	0.019
ΟI	(1302)		0.0080	400	0.013
SiII	(1526)	1.96	0.0038	400	0.0072
Si 11	(1304)		0.0030	400	0.0047
CIV	(1548)	3.90	0.0013	350	0.0023
Si IV	(1393)	2.04	0.00081	350	0.0013
CIV	(1550)	3.90	0.00068	350	0.0012
SiIV	(1402)		0.00041	350	0.00064

FeII	(2383)		0.0062	400	0.019

Table 3. Comparison of maximum line depths (MLD), FWHM η and EW W_0 in the background geometry between S10's observations (their Table 4, second line) and our predictions from the simulations (the "10 – 41 kpc" line in our figures 24 and 25).

0.2 and $\eta \sim 1000 \text{ km s}^{-1}$. Detailed comparisons between our values and the observed values by S10 are given in Table 3.

Figure 24 as well as the upper middle panel of figure 25 can be compared to figure 13 of F11. For Ly α , in the 10 – 41 kpc bin, the maximum line depth is 0.61 and 0.55 respectively, and the FWHM η is 550 and 400 km s⁻¹ respectively. For Si II (1260 Å), in the same 10–41 kpc bin, the maximum depth is 0.013 and 0.05 respectively, and $\eta \sim 350$ km s⁻¹ in both. These results are similar. The upper left panel of figure 25 can be compared to the right panel of figure 3 in Kimm et al. (2011), where for C II the maximum line depth is ~ 0.65 with a FWHM η of 550 km s⁻¹. We identified three possible reasons for these differences: First Kimm et al. (2011) used a simulation² having a much lower

MareNostrum

simulation

Figure 23. Same area covering fraction g_c as in figure 22, this time for the metal line absorption lines. Peak EWs go as high as 0.1 Å and the minimal values are well below 10^{-6} Å. In all cases the EWs are decreasing mainly monotonic. The decrease goes over five orders of magnitude and more. We see some noisy distortions in the high b, low g_c regime. Over all the strongest lines are C II and Mg II.

Figure 24. Absorption line profiles for the background geometry for Ly α . The data are averaged over three different impact parameter bins, three different galaxies and six different viewing directions in the background geometry. Note the different x-and y-scales in this figure in comparison to Figure 25. This figure agrees with the results of F11 (their figure 13). A qualitative comparison to the observation is presented in table 3.

resolution than we do. Second, the haloes they analysed are in a very different (much higher) mass range $(M_v > 10^{12} M_{\odot})$ than the haloes we use. Third and most importantly they use a different prescription for the Gaussian velocity distribution as described earlier. We conclude that stacking of the absorption lines from a background source tends to wash out the cold filament absorption signal (compare figure 18 with figures 24 and 25). Unlike the case of a central source, in the case of a background source the absorption by inflowing gas is not well separated from the absorption by outflowing gas.

6 CONCLUSIONS

Theory, including hydrodynamical cosmological simulations, tells us that massive galaxies at high redshifts were fed by cold gas streams, inflowing into dark-matter haloes at high rates along the filaments of the cosmic web (Keres et al. 2005; Dekel & Birnboim 2006; Dekel et al. 2009; Danovich et al. 2012), but observing this process is not straightforward. Here we addressed the expected absorption signature from these cold streams. We "observed" simulated galaxies for Ly α absorption as well as metal lines from low and medium ionisation ions. We focused on the absorption line profiles as observed by Steidel et al. (2010), using their set of ten different lines and mimicking their way of stacking data from several galaxies, for sources that

(Ocvirk, Pichon & Teyssier 2008) with a maximum resolution of 1 kpc

are either in the background or at the centre of the absorbing halo itself. The simulations used are zoom-in cosmological simulations with a maximum resolution of 35-70 pc (Ceverino, Dekel & Bournaud 2010). Self-shielding was accounted for by a simple density criterion.

We showed a variety of example absorption line profiles, as well as averaged absorption line profiles, both for a central source and a background source, which are directly comparable to the observations of S10. We computed the resulting EWs and their sky covering fractions for the two geometries. We found in agreement with Kimm et al. (2011) that when observations are averaged the absorption signatures of the low-ionisation metals from the cold streams are overwhelmed by the noise of other absorption processes in the host galaxy. This has the following reasons: First, since the infalling gas has compared to the ISM of the host galaxy so low densities and so low metallicities that subsequently compared to other absorption processes in the host galaxy the low-ionisation transitions of the cold streams also have tiny optical depths. Second, the difference in redshift between the absorption signal of the cold streams and that of the ISM is too small. The general absorption signature of the ISM still overwhelms the one from the cold streams even in the very redshifted part of the line. Last but not least, the flows have a radial, narrow stream geometry, which makes them only very occasionally aligned with the line of sight for a high optical depth. To show this we computed the probabilities of detecting an inflow of a given speed with a given signal.

Similar to our work, F11 studied the absorption characteristics of the gas in galaxies and streams, in order to compare with the statistics of observed absorption-line systems. Like us they postprocessed high-resolution simulated galaxies for determination of the ionisation states of the gas. To compute those however we used the combined effects of electron-impact collisional ionisation and photoionisation together with a distinction between UV-shielded gas (where collision-ionisation equilibrium was assumed) and UV-unshielded gas (where photo-ionisation equilibrium was assumed). F11 on the other hand used a full radiative transfer approach. Since both analyses use the same data, the high resolution CDB simulations, direct comparisons to F11 gives us a good handle to estimate the strengths and weaknesses of our simplifying procedure. We compared the distributions by volume of the neutral hydrogen fractions $x_{\rm HI}$ and total hydrogen gas densities $n_{\rm H}$ in the circumgalactic environment (our figure 2). We also compared the HI area covering fractions (our figure 17) as well as the average EW as a function of impact parameter b for Ly α and the SiII (1260 Å) lines (our figure 21) both for the background geometry. We finally compared the absorption line profiles for the background geometry in Ly α and SiII (1260 Å) (our figures 24 and 25). The differences from our results are small, justifying the assumptions made in our simplifying model.

Both F11 and Faucher-Giguere & Keres (2011) analysed the sky covering fractions of neutral hydrogen column densities, and came up with similar results to ours. Kimm et al. (2011) predicted CII absorption line profiles similar to ours. Certain differences emerge from the fact that Kimm et al. (2011) deploy a Gaussian profile instead of a Voigt profile. Also, while we used thermal Doppler broadening that depends on the temperature of the cell, they used

Figure 25. Same absorption line profiles for the background geometry as in figure 24, this time for the metal lines. Note the changing y-scales from row to row as well as the different x- and y-scales with respect to figures 24. The Si II (1260Å) panel of this plot agrees with the results of F11 (their figure 13) the C II panel of this plot disagrees with the results of Kimm et al. (2011, their figure 3) due to different line computing algorithms. The lines with the deepest signals are C II and Si II (1260 Å). A more detailed qualitative comparison to the observation is presented in table 3.

turbulent Doppler broadening that depends on the velocity differences with respect to the 26 neighbouring cells. F11, like us, concluded that cold streams are unlikely to produce the large EWs of low-ion metal absorption around massive galaxies. If the average equivalent widths reported by S10 are confirmed (e.g. with higher resolution observations), more precise feedback models must be included in the simulations, which are capable of causing winds with the right densities and temperature range, since only such winds are able to produce these high equivalent widths of low-ion metal absorption lines.

We mention three potential limitations of our analysis. A limitation of our simulations may arise from the artificial pressure floor imposed in order to properly resolve the Jeans mass. This may have an effect on the temperature and density of the very dense and cold parts of the streams, with potential implications on the computed absorption. Still, the AMR code is the best available tool for recovering the stream properties. With 35-70 pc resolution, and with proper cooling below 10^4 K, these simulations provide the most reliable description of the cold streams so far.

S10 and others observed strong signatures of metals at distances as large as 200 kpc from the galaxy centre, that are interpreted as massive outflows. Such massive and cold outflows are not reproduced in our current simulations, which incorporate supernova feedback, but not yet strong radiative feedback and other processes that are capable of driving sufficiently massive outflows. Our studies of absorption from the simulated inflows are valid only if one could assume that the outflows do not drastically affect the inflowing streams. The strong outflows produced in the simulations of Shen et al. (2012) indeed avoid the incoming dense narrow streams, and find their way out in a wide solid angle through the dilute medium between the streams. The same is true for the weaker and hot outflows that are produced in our simulations, with a mass loading factor of about a third. Therefore our analysis is reliable.

The ionisation states should ideally be coupled to the hydrodynamical calculations using radiative transfer, but in our current analysis they are computed in postprocessing. The analysis distinguished between UV-shielded gas, where collision-ionisation equilibrium was assumed, and UV-unshielded gas, where photo-ionisation equilibrium was assumed. An additional source of local ionising radiation is the Lyman continuum from newly born stars. This could be a non-negligible source of ionisation, which is neglected in our calculations so far.

We conclude that the signatures of cold inflows are subtle, and when stacked are overwhelmed by the outflow signatures. Our predicted Ly α line absorption profiles agree with the observations, while the stacked metal line absorption from the inflows is much weaker than observed in the outflows. The single-galaxy line profiles predicted here will serve to compare to single-galaxy observations.

ACKNOWLEDGEMENTS

The computer simulations were performed in the astro cluster at HU Jerusalem, at the National Energy Research Scientific Computing Centre (NERSC), Lawrence Berkeley National Laboratory, at NASA Advanced Supercomputing (NAS), at NASA Ames Research Centre and at CCRT and TGCC under GENCI allocation 2011-GEN2192. The analysis was performed on TGCC Curie under Prace project number ra0317. We acknowledge stimulating discussions with Michele Fumagalli, Alexander Knebe, Steffen Knollmann, Jonty Marshall, Crystal Martin and Chuck Steidel.
