Abstract

In view of the LHC upgrade phases towards HL-LHC, the ATLAS experiment plans to upgrade the Inner Detector with an all-silicon system. The n-in-p silicon technology is a promising candidate for the pixel upgrade thanks to its radiation hardness and cost effectiveness, that allow for enlarging the area instrumented with pixel detectors. We report on the development of novel n-in-p edgeless planar pixel sensors fabricated at FBK (Trento, Italy), making use of the active edge concept for the reduction of the dead area at the periphery of the device. After discussing the sensor technology and fabrication process, we present device simulations (pre- and post-irradiation) performed for different sensor configurations. First preliminary results obtained with the test-structures of the production are shown.

Keywords: Fabrication technology, TCAD simulations, Planar silicon radiation detectors

1. Introduction

In the next decade the CERN Large Hadron Collider (LHC) will be upgraded to extend its physics reach; by 2022 the collider should be capable of a peak luminosity of $10^{35} \text{cm}^{-2} \text{s}^{-1}$, the so-called High Luminosity LHC (HL-LHC) [1]. By then the ATLAS collaboration will be equipped with a completely new Pixel Detector. The innermost layer of the new pixel detector will integrate a fluence of about $10^{16} \text{1 MeV}_{\text{neq}}/\text{cm}^2$ for an integrated luminosity of 3000fb^{-1} (~ 10 years of operation). These harsh conditions demand radiation-hard devices and a finely segmented detector to cope with the expected high occupancy.

The new pixel sensors will need to have high geometrical acceptance: the future material budget restrictions and tight mechanical constraints require the geometric inefficiency to be less than 2.5% [2].

In conventional sensor designs there is a relatively large un-instrumented area at the edge of the sensor to prevent the electric field from reaching the rim, where a large number of defects are present due to the wafer cutting; for example the current ATLAS pixel sensor has an un-instrumented region of 1.1 mm at the edge [3], including Guard Rings (GRs) and providing a suitable safety margin. GRs, placed all around the pixel area, can help to improve the voltage-handling capability.

One way to reduce or even eliminate the insensitive region along the device periphery is offered by the “active edge” technique, in which a deep vertical trench is etched along the device periphery throughout the entire wafer thickness, thus performing a damage free cut (this requires using a support wafer, to prevent the individual chips from getting loose). The trench is then heavily doped, extending the ohmic back-contact to the lateral sides of the device: the depletion region can then extend to the edge without causing a large current increase. This is the technology we have chosen for realizing n-on-p pixel sensors with reduced inactive

42 zone.

43 In Section 2 the active edge technology chosen
 44 for a first production of n on p sensors is pre-
 45 sented. Studies performed with TCAD simulation
 46 tools (Section 3) helped in defining the layout and
 47 making a first estimation of the charge collection
 48 efficiency expected after irradiation. In Section 4
 49 some preliminary results from the electrical charac-
 50 terization of the sensors will be shown.

51 2. The active edge sensor production at 52 FBK

53 The sensors are fabricated on 100 mm diameter,
 54 high resistivity, p-type, Float Zone (FZ), <100>
 55 oriented, 200 μm thick wafers. The active edge
 56 technology [4] is used, which is a single sided pro-
 57 cess, featuring a doped trench, extending all the
 58 way through the wafer thickness, and completely
 59 surrounding the sensor. For mechanical reasons,
 60 a support wafer is therefore needed, making the
 61 back inaccessible after wafer-bonding. Several ap-
 62 proaches to eventually remove the support wafer
 63 are under evaluation; for more details see [5]. After
 64 a uniform high-dose boron implant has been per-
 65 formed on the back side, the wafers have then been
 66 wafer-bonded to a 500 μm thick silicon substrate.
 67 Both homogeneous (“p-spray”) and patterned (“p-
 68 stop”) implants have been used to insulate the n-
 69 type pixels; the process splittings adopted in the
 70 fabrication batch concern the presence and the
 71 doses of these implants.

72 Two patterned high dose implants are then per-
 73 formed: a phosphorus implant forming the pixel
 74 and GR junctions and a boron implant for the
 75 ohmic contact to the substrate (“bias tab”).

76 The etching of the trench is accomplished by a
 77 Deep Reactive Ion Etching (DRIE) machine (Alcatel
 78 AMS-200), the same used for the fabrication of
 79 3D detectors [6].

80 After the trench is etched, its walls are boron-
 81 doped in a diffusion furnace. Thus, a continuous
 82 ohmic contact to the substrate is created, covering
 83 the trench wall and to the backside. FBK technol-
 84 ogy can routinely obtain very uniform, well defined
 85 and narrow trenches.

86 The trenches are then oxidized and filled with
 87 polysilicon. The remaining processing, arriving at
 88 the final device, whose cross-section is sketched in
 89 Figure 1, is quite standard, and includes the fol-
 90 lowing steps: contact opening; metal deposition

91 and patterning; deposition of a passivation layer
 92 (PECVD oxide) and patterning of the same in the
 93 pad and bump-bonding regions.

Figure 1: Schematic section of the pixel sensor. The region close to the sensor’s edge is portrayed, including the pixel closest to the edge, the edge region, including GRs (when present), the bias tab (present only on one edge of the device), the vertical doped trench, and the support wafer.

94 An additional layer of metal is deposited over
 95 the passivation and patterned into stripes, each of
 96 them shorting together a row of pixels, contacted
 97 through the small passivation openings foreseen for
 98 the bump bonding. This solution has already been
 99 adopted for the selection of good 3D FE-I4 [7] sen-
 100 sors for the ATLAS IBL [8]. After the automatic
 101 current-voltage measurement on each FE-I4 sensor,
 102 the metal will be removed by wet etching, which
 103 does not affect the electrical characteristics of the
 104 devices.

105 Wafer layout

106 Nine FE-I4 compatible pixel sensors can be ac-
 107 commodated in a 100 mm wafer. The nine FE-I4
 108 sensors differ in the pixel-to-trench distance (100,
 109 200, 300, and 400 μm) and in the number of the
 110 guard rings (0, 1, 2, 3, 5, and 10) surrounding the
 111 pixel area (see Figure 1). The sensor with 3 GRs
 112 and a 200 μm pixel-to-trench distance features two
 113 different GR designs, and each of them is repeated
 114 twice. A list of the different FE-I4 sensor versions
 115 is reported in Table 1.

116 The wafer layout also includes sensors compatible
 117 with the FE-I3 read-out chip [9], sensors compatible
 118 with the OmegaPIX readout chip [10] and many
 119 test structures. More details can be found in [5].

Multiplicity	Number of GRs	pixel-to-trench distance (μm)
1	0	100
1	1	100
1	2	100
4	3	200
1	5	300
1	10	400

Table 1: List of FEI4 sensors. The number of the sensors (first column) is reported for each combination of number of GRs and pixel-to-trench distance. Two different designs are envisaged for the sensor with 3 GRs and 200 μm pixel-to-trench distance. See text for more details.

3. TCAD simulation

In order to explore and compare the properties of the design variations considered, numerical simulations were performed with TCAD tools from SILVACO [11]. 2D structures analogous to the one sketched in Figure 1 have been simulated, varying parameters like the number of GRs and the pixel-to-trench distance. The break down (BD) behaviour of the devices and the charge collection efficiency (CCE) were studied, for simulated unirradiated and irradiated sensors, with a fluence $\phi = 1 \times 10^{15} n_{\text{eq}}/\text{cm}^2$; this is the expected fluence for the outer pixel layers of the new tracker at the end of the HL-LHC phase.

Each of the doped regions (n^+ for the pixel and the GRs, p^+ for the backside, p-stop, p-spray, bias tab and the trench walls) have been modeled with simple functions, depending on a set of parameters like the peak concentration and the reference concentration, *i.e.* the concentration value at a specified “rolloff” distance from the peak position.

Oxide fixed charge density (with surface density $N_f = 10^{11} \text{ cm}^{-2}$ before irradiation, and $N_f = 3 \times 10^{12} \text{ cm}^{-2}$ after), generation-recombination lifetimes and surface recombination velocity have been set according to measured IV and CV characteristics of diodes from previous n-on-p CiS^1 productions.

The defects at the edge have been modeled with a 1 μm wide region in which the generation-recombination lifetime was set to a very small value (10^{-12} s; for comparison, before irradiation the corresponding value for the bulk is of 10^{-5} s). If the

¹Forschungsinstitut für Mikrosensorik und Photovoltaik GmbH

trench doping were not effective, a large current would appear as soon as the electric field reaches the edge area.

To describe the radiation damage, an effective model based on three deep levels in the forbidden gap was used [12]. Each of these deep levels is defined as either donor or acceptor, and is characterized by its energy (with respect to the closest energy band), its capture cross-sections for electrons (σ_e) and holes (σ_h) and its introduction rate η , which is the proportionality term between defect concentration and radiation fluence.

Radiation-induced interface traps at the Si-SiO₂ interface are also included in the simulation, as described in [13].

The structure shown in Figure 1 has been slightly modified in the simulations: the support wafer was not present and the backside p^+ implant was metallized. This was done in order to simulate a sensor ready for use.

The sensors were simulated under reverse bias, applying a negative voltage to the back contact while keeping the pixel at ground potential; the bias tab was left floating. Different geometries were simulated, varying the number of GRs and the pixel-to-trench distance; see Table 2 for the list of simulated geometries. If present, the GRs were left floating during the simulations.

# of GRs	pixel-to-trench distance (μm)
0	100
1	100
2	100
0	200
1	200
2	200

Table 2: List of simulated sensor layouts.

Simulation results

Figure 2 shows the current-voltage curves of all the simulated designs, before irradiation. The depletion voltage has been estimated using the AC analysis in the simulations, and determining the depletion voltage value from the fit to the $\log(C) - \log(V)$ curve; the result was checked against the aforementioned measurements on n-on-p diodes from a former production. A sensor with a design compatible with the current ATLAS pixel modules was also simulated; it features a pixel-to-trench distance of 1.1 mm and 16 GRs.

Figure 2: Simulated IV curves for the pixel closest to the edge, for several sensor designs before irradiation (see text for details). The simulated current has been scaled to reproduce the behaviour of a $50 \mu\text{m}$ wide pixel in the edge direction. The depletion voltage is indicated by the arrow.

From Figure 2 it can be seen that before irradiation the BD voltage exceeds by at least 100 V the depletion voltage for all the designs we considered. The ATLAS-like sensor shows higher BD voltage with respect to those predicted for our edgeless detectors, but all sensors are largely over-depleted before BD. Increasing the pixel-to-trench distance yields a higher bulk-generated current, since the depleted volume can further extend laterally. Adding more GRs greatly helps in increasing the value of BD voltage, extending the operability range of the sensors. The best performance is obtained from a device with 2 GRs and a $100 \mu\text{m}$ pixel-to-trench distance.

As reported in the literature by different groups (*e.g.* [14]), after irradiation the BD voltage increases to much larger values. Our simulations of irradiated devices confirm this observation.

To study charge collection efficiency (CCE) after irradiation, charge creation in irradiated sensors was simulated. The most interesting case is when the charge is released in the gap between the pixel and the trench, when no GRs are present. If a significant amount of charge can be collected after irradiation in that region, the edgeless concept would be verified to work.

Our sensor was illuminated from the front side with a simulated 1060 nm laser beam, setting its power in order to generate the same charge that would be released by a minimum ionizing particle

(MIP) traversing $200 \mu\text{m}$ of silicon ($\sim 2.6 \text{ fC}$). The laser beam was originating above the front side of the detector, with a $2 \mu\text{m}$ wide gaussian beamspot. The duty cycle of the laser was 50 ns, with the power ramping up in 1 ns, remaining constant for 10 ns and ramping down in the next nanosecond.

The CCE was studied as a function of the bias voltage for the detector with no GRs and a $100 \mu\text{m}$ trench-to-pixel distance. Two incidence points of the laser beam have been considered: one within the pixel and the other in the edge region, at $50 \mu\text{m}$ distance from the pixel. In the following they will be identified as “Pixel” and “Edge”, respectively.

Based on the properties of the laser beam and of the target material, the simulation program determined the charge of carriers photogenerated inside the device by one pulse. The charge collected by the pixel was defined as the integral over the laser duty cycle of the current flowing through the pixel, once the stable leakage current had been subtracted. Finally, the CCE was obtained by dividing this collected charge by the total photogenerated charge.

In Figure 3 the simulated CCE of an irradiated sensor is presented as a function of the bias voltage for the two incidence points of the laser beam.

Figure 3: Simulated charge collection efficiency as a function of bias voltage for an irradiated device at a fluence $\phi = 10^{15} \text{ n}_{\text{eq}}/\text{cm}^2$. The laser is entering the detector either in the pixel region (“Pixel”) or in the un-instrumented region (“Edge region”). The sensor has no GRs, and a $100 \mu\text{m}$ distance between edge and pixel.

At a fluence $\phi = 10^{15} \text{ n}_{\text{eq}}/\text{cm}^2$ more than 50 % of the signal is collected in the “Edge” region at a bias voltage of 500 V; as a comparison, 70 % of the signal is retained in the “Pixel” region. In both

252 cases the effect of trapping can be observed: the
 253 collected charge reaches a *plateau* at high voltage,
 254 but there the CCE is not of 100 %. No charge is
 255 collected from the “Edge” region below 100 V: in-
 256 deed at 100 V bias the electric field is negligible
 257 in that region. It can be seen that while the maxi-
 258 mum CCE for a charge created in the pixel region
 259 is reached at a bias voltage above ~ 400 V, in the
 260 “Edge” region a bias voltage of 500 V is needed:
 261 this is consistent with the depletion zone extending
 262 laterally.

263 Calculations based on trapping time experimen-
 264 tal data [15] for our sensor thickness and our target
 265 fluence produce CCE estimations in agreement with
 266 our simulations.

267 4. First results on real sensors

268 The first wafers have been recently received and
 269 the electrical characterization of the production has
 270 just started. Test structures consisting of an array
 271 of 6×30 FE-I4-like pixel cells have been measured
 272 first. All the pixels were shorted together and the
 273 current voltage characteristics for these sensors is
 274 reported in Figure 4, top; the sensor were inversely
 275 polarized via the bias tab, the innermost GR was
 276 kept at ground (as well as the pixels), and the cur-
 277 rent flowing through the GR itself is reported. As
 278 it can be seen, adding more GRs increase the BD
 279 voltage and a wider edge-to-pixel distance corre-
 280 sponds to more bulk generated-current; all sensors
 281 can be operated in over-depletion. The simulations
 282 reproduce very well these measurements.

283 For a test structures consisting of an array of
 284 9×13 FE-I4-like pixel cells, in Figure 4, bottom,
 285 the capacitance between the central pixel and all
 286 the other ones is presented as a function of the bias
 287 voltage. It can be seen that the presence of a field-
 288 plate increases the interpixel capacitance; the cou-
 289 pling is particularly important due to the presence
 290 of the uniform p-spray implant. The level of capac-
 291 itative coupling, even with a field-plate, is accept-
 292 able in term of electronic noise for the read-out.

293 5. Conclusions and outlook

294 In view of the upgrade of the ATLAS Inner De-
 295 tector for HL-LHC runs, FBK Trento and LPNHE
 296 Paris developed new planar n-on-p pixel sensors,
 297 characterized by a reduced inactive region at the
 298 edge thanks to a vertical doped lateral surface at

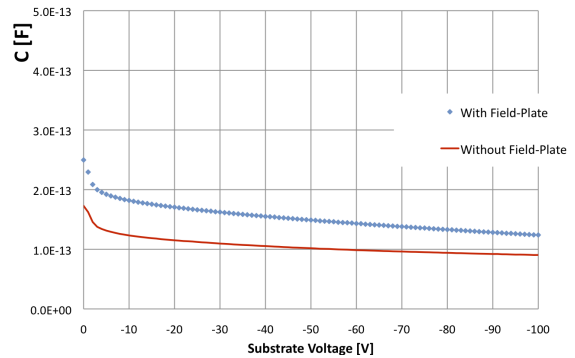

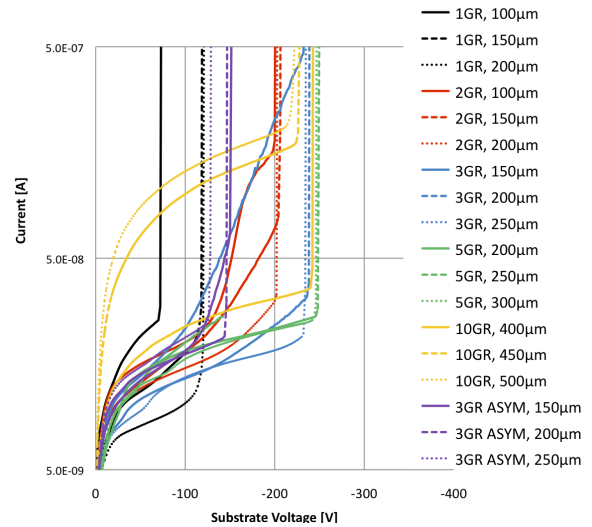

Figure 4: (Top) IV curves for several test structures, differing by pixel-to-trench distance and by the number of GRs. (Bottom) Interpixel capacitance for test structure with FEI4-like cells; the capacitance between the central pixel and all the other pixels surrounding it in the test structure is reported as a function of the bias voltage for pixel cells with a field plate (points), and without it (solid line).

299 the device boundary, the “active edge” technology.
 300 Simulation studies show the effectiveness of this
 301 technique in reducing the dead area, even after sim-
 302 ulated fluences comparable to those expected at
 303 the end of the HL-LHC phase for the external layers.

304 The first, preliminary measurements on real sen-
 305 sors look promising. Functional tests of the pixel
 306 sensors with radioactive sources and eventually in
 307 a beam test, after having bump bonded a number
 308 of pixel sensors to the FE-I4 read out chips, will
 309 follow.
