Abstract. The first results from p–Pb collisions at $\sqrt{s_{NN}}$ = 5.02 TeV are discussed.

1 Introduction

Proton–lead (p–Pb) collisions are an integral part of the nuclear program at the Large Hadron Collider (LHC). Their study provides the reference for the Pb–Pb data to disentangle initial from final state effects, as well as the potential to address the partonic structure of matter at low parton fractional momenta (small-*x*) [\[1\]](#page-6-0).

The experimental results reported in these proceedings are obtained in a short low-luminosity run performed in September 2012 (with about $1/\mu$ b recorded by each experiment), and a longer high-luminosity run in January/February 2013 (with about 30/nb recorded by AT-LAS and CMS, about 10/nb by ALICE and about 2/nb by LHCb). The setup of the beams, which is constrained by the two-in-one magnet design of the LHC imposing the same magnetic rigidity of the beams, consisted of protons at 4 TeV energy and of $^{208}_{82}$ Pb ions at 82 \times 4 TeV energy. This configuration produced collisions at $\sqrt{s_{NN}}$ = 5.02 TeV in the nucleon–nucleon centre-of-mass system, shifted in rapidity relative to the laboratory system by $\Delta y_{NN} = 0.465$ in the direction of the proton beam. For clarity, the rapidity (y) as well as the pseudorapidity (η) are sometimes denoted as as y_{lab} and y_{cms} , as well as η_{lab} and $\eta_{\rm cms}$.

To investigate the role of nuclear effects in p–Pb collisions it is desirable to study experimental observables as a function of centrality of the collision. In nucleus– nucleus (A–A) collisions this is typically achieved by relating intervals of measured multiplicity (or energy) distributions (that correspond to certain fractions of the inelastic cross-section) to an average number of nucleon– nucleon collisions $(\langle N_{\text{coll}} \rangle)$ via a Glauber model [\[2\]](#page-6-1). In p–Pb collisions, however, the correlation between multiplicity and collision geometry is less strong than in A–A collisions, and more importantly dynamical biases introduced by the multiplicity estimation can strongly affect the observables under study [\[3\]](#page-6-2). Therefore, so far, the experimental results are either reported for minimum-bias collisions (where $\langle N_{\text{coll}} \rangle = 208 \sigma_{\text{pp}}/\sigma_{\text{pPb}} = 7.0 \pm 0.6$, with interpolated σ_{pp} = 70 ± 5mb [\[4\]](#page-6-3) and measured σ_{ppb} = $2.07 \pm 0.07b$ [\[5,](#page-6-4) [6\]](#page-6-5)), or as a function of multiplicity, i.e. in selected intervals of a measured multiplicity or energy distribution without relating to centrality explicitly. In the latter case, the selected intervals are typically characterized by the corresponding average charged-particle multiplicity at midrapidity. Potential biases introduced by the event selection can be studied by varying the underlying multiplicity or energy distribution.

The results presented at the conference include the measurements of the charged-particle pseudorapidity [\[4\]](#page-6-3) and transverse momentum (p_T) distributions [\[7\]](#page-6-6), results on dijet [\[8\]](#page-6-7) and J/ψ [\[9,](#page-6-8) [10\]](#page-7-0) production, multiple results on long-range correlations of charged particles using twoparticle [\[11–](#page-7-1)[13\]](#page-7-2) and four-particle [\[14,](#page-7-3) [15\]](#page-7-4) correlation analysis techniques, as well as results on identified particle p_T distributions [\[16,](#page-7-5) [17\]](#page-7-6). These, complemented by recent measurements on identified two-particle correlations [\[18\]](#page-7-7), as well as the measurement of the average p_T of charged particles as a function of multiplicity at midrapidity [\[19\]](#page-7-8), will be discussed in the following.

2 Unidentified charged particles

The measurement of the charged-particle density provides constraints to improve the understanding of particle production and the role of initial state effects in QCD at small*x* [\[4\]](#page-6-3). The data are normalized to non-single diffractive collisions and reported in the laboratory system (Fig. [1\)](#page-1-0). The systematic uncertainty of the measurement is about 3.8%. It is dominated by the uncertainty on the normalization, which is obtained by requiring that not all of the nucleon–nucleon collisions (as for example modeled in the DPMJET [\[20\]](#page-7-9) generator) are single-diffractive. The charged-particle pseudorapidity density at midrapidity in the laboratory system ($|\eta_{lab}| < 0.5$) is found to be 17.4 \pm 0.7, while the corresponding density in the nucleon–nucleon centre-of-mass system ($|\eta_{\rm cms}|$ < 0.5) to be 16.8 \pm 0.7. The measured distribution is compared to various model predictions (references can be found in [\[4\]](#page-6-3)) that broadly can be characterized as either two-component or saturation models. The two-component models combine perturbative QCD processes with soft interactions, and may include nuclear modification of the initial parton distributions. The saturation models typically employ coherence

Figure 1. Pseudorapidity density of charged particles measured in the laboratory system (η_{lab}) for non-single diffractive p–Pb collisions at $\sqrt{s_{NN}}$ = 5.02 TeV compared to model predictions [\[4\]](#page-6-3).

Figure 2. Nuclear modification factor for charged particles as a function of p_T in $|\eta_{\rm cms}| < 0.3$ in non-single diffractive p-Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV compared to data in $|\eta| < 0.8$
in central (0.5%) and peripheral (70.80%) Pb. Pb collisions at in central $(0-5\%)$ and peripheral $(70-80\%)$ Pb–Pb collisions at $\sqrt{s_{NN}}$ = 2.76 TeV [\[7\]](#page-6-6).

effects to reduce the number of soft gluons available for particle production below a given energy scale. The comparison with the data shows that most of the calculations predict the measured distribution to within 20%, with a tendency that the the saturation models exhibit a steeper η_{lab} dependence than the data (see also [\[21\]](#page-7-10)).

Further information on particle production are provided by the charged particle p_T distributions, which are measured in $0.5 < p_T < 20 \text{ GeV}/c$ for 3 ranges of η_{cms} near midrapidity normalized to non-single diffractive (NSD) collisions [\[7\]](#page-6-6). The systematic uncertainty of the measurement is about 8–10% including the uncertainty on the normalization. The spectra seem to soften with increasing pseudorapidity, although the effect is of the similar magnitude as the systematic uncertainty. It is found that most models that describe the η_{lab} distribution, like the DP-

Figure 3. Dijet properties measured from jet pairs selected by requiring $p_{T1} > 120 \text{ GeV}/c$ for the leading and $p_{T2} > 30 \text{ GeV}/c$ for the subleading jet, as well as an azimuthal angular difference of $\Delta\varphi_{1,2} > 2\pi/3$ for jets reconstructed with the anti- k_T algorithm with $R = 0.3$ in $\eta_{\text{lab}} < 3$ [\[8\]](#page-6-7). The results are presented as a function of forward energy in p–Pb collisions, compared to PYTHIA+HIJING p–Pb as well as minimum bias PYTHIA pp simulations (shown as a blue band) at $\sqrt{s_{NN}} = 5.02$ TeV.

MJET or HIJING models, have difficulties in describing the p_T distributions. One exception is a calculation from EPOS v3 [\[22\]](#page-7-11), which includes parton saturation and a hydrodynamical evolution. Nuclear effects are usually quantified by the ratio of the yield extracted in p–Pb collisions relative to that in pp scaled by $\langle N_{\text{coll}} \rangle$, which is expected to be unity in absence of nuclear effects. Since there are no pp data at \sqrt{s} = 5.02 TeV, the pp reference is con-
structed by interpolating pp data at 2.76 and 7.TeV [23] structed by interpolating pp data at 2.76 and 7 TeV [\[23\]](#page-7-12). Using this reference, the nuclear modification factor, R_{pPb} , at $|\eta_{\rm cms}| < 0.3$ is found to be consistent with unity for p_T above 2 GeV/*c*, showing that there are no strong nuclear effects present in NSD ($\langle N_{\text{coll}} \rangle \approx 7$) p–Pb collisions (Fig. [2\)](#page-1-1). Consequently, the measurement demonstrates that the high- p_T suppression observed in central $(0-$ 5%, $\langle N_{\text{coll}} \rangle \approx 1700$) and peripheral (70–80%, $\langle N_{\text{coll}} \rangle \approx 16$) $Pb-Pb$ collisions at $\sqrt{s_{NN}}$ = 2.76 TeV [\[24\]](#page-7-13) is not due
initial-state but rather due to final-state interactions. It is initial-state, but rather due to final-state interactions. It is interesting to note that the suppression in Pb–Pb is present already in 70–80% collisions, where $\langle N_{\text{coll}} \rangle$ is only twice as large as in NSD p–Pb collisions. Therefore, final state effects could indeed play a role in more central p–Pb collisions (see Sections [5](#page-3-0) and [6\)](#page-4-0).

3 Dijet production

Complementary information is provided by a measurement of dijet production using an integrated luminosity of ¹⁸.5/nb [\[8\]](#page-6-7). High-energy jets are reconstructed with the anti- k_T algorithm [\[25\]](#page-7-14) for a resolution parameter of $R =$ 0.3 in η_{lab} < 3, using combined information from tracking and calorimetry. Dijet pairs are selected by requiring $p_{T,1} > 120 \text{ GeV}/c$ for the leading and $p_{T,2} > 30 \text{ GeV}/c$ for the subleading jet. Then, the azimuthal angle correlations between the two jets ($\Delta\varphi_{1,2}$), the dijet momentum balance $(p_{T,1}/p_{T,2})$, and the mean and width of the dijet pseudorapidity distributions $(\frac{\eta_1 + \eta_2}{2})$ are measured for $\Delta\varphi_{1,2} > 2\pi/3$ as a function of forward calorimeter transverse energy (approximately spanning a range of $\langle N_{\text{coll}} \rangle$ between 5 to 15). The data are compared to PYTHIA simulations representing pp collisions, and to p–Pb simulations using HIJING, where dijet pp events from PYTHIA are embedded (Fig. [3\)](#page-1-2). The width of the azimuthal angle difference distribution and the dijet momentum ratio is not sensitive to the forward activity of the collision, and comparable to the same quantity obtained from the simulations, confirming that the observed dijet asymmetry in Pb–Pb collisions [\[26,](#page-7-15) [27\]](#page-7-16) is not originating from initial state effects. The pseudorapidity distribution of the dijet system, however, changes strongly with increasing forward calorimeter activity in the nucleus direction, which indicates that the hard scattering process and the underlying event are strongly correlated. The effects are much stronger than expected from the depletion of low-*x* partons in nuclear Parton Distribution Functions (nPDFs) [\[28\]](#page-7-17), which are found to describe the minbias p–Pb collisions reasonably well[\[29\]](#page-7-18).

4 J/ψ **production**

 J/ψ production in proton–nucleus collisions is expected to be sensitive to several initial and final state effects related to the presence of cold nuclear matter, such as the suppression of low-*x* gluons and initial state energy loss [\[21\]](#page-7-10). Results in p–Pb collisions are available for inclusive J/ ψ in 2 < $y_{\rm cms}$ < 3.5 and $-4.5 < y_{\rm cms} < -3.0$ using about 10.8/nb [\[9\]](#page-6-8) and for the first time separately for prompt J/ψ and J/ψ from b hadron decays in 1.5 < $y_{\rm cms}$ < 4.0 and $-5.05 < y_{\rm cms} < -2.5$ using about 1.6/nb [\[10\]](#page-7-0). To obtain the nuclear modification factor, the pp reference at forward rapidity is constructed by interpolating available lower and higher beam energy data with various functional forms [\[30\]](#page-7-19).

At forward rapidity the inclusive J/ψ production is suppressed (with a mild rapidity dependence), compared to the backward rapidity (Fig. [4\)](#page-2-0). The uncertainties related to tracking and trigger efficiency are regarded to be alled to tracking and trigger emerency are regarded to be \sqrt{s} dependence of pp reference and $\langle N_{\text{coll}} \rangle$ to be fully correlated (gray bar), and those related to the y dependence of the pp reference and the signal extraction to be partially correlated (open boxes). The data are compared to various calculations (see the legend of Fig. [4](#page-2-0) for references). Within the uncertainties, the models including

at $\sqrt{s_{\text{NN}}} = 5.02$ TeV compared to calculations [\[9\]](#page-6-8).

Figure 5. Forward-to-backward ratio for inclusive J/ψ as a function of y_{cms} in $0 < p_{\text{T}} < 15$ GeV/*c* in NSD p–Pb collisions at $\sqrt{g_{\text{esc}}} = 5.02$ TeV compared to calculations [0] $\sqrt{s_{NN}}$ = 5.02 TeV compared to calculations [\[9\]](#page-6-8).

Figure 6. Forward-to-backward ratio for inclusive J/ψ as a function of p_T in 3.0 < y_{cms} < 3.5 in NSD p–Pb collisions at $\sqrt{g_{\text{ctx}}}-5.02 \text{ TeV}$ compared to calculations [0] $\sqrt{s_{NN}}$ = 5.02 TeV compared to calculations [\[9\]](#page-6-8).

shadowing or coherent energy loss are able to reproduce the data, while the prediction based on the Color Glas Condensate (CGC) overestimates the observed suppression.

EPJ Web of Conferences

Figure 7. Per-trigger particle associated yield in Δφ and Δη for pairs of charged particles with 2 < $p_{\text{T,trig}}$ < 4 GeV/*c* and 1 < $p_{\text{T,assoc}}$ < 2 **GeV/***c* in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV for the 0–20% event class, selected in ZNA (left panel), V0M (middle panel) and SPL (right panel) after subtraction of the vield obtained in the corresponding 60–100% eve SPD (right panel), after subtraction of the yield obtained in the corresponding 60–100% event class [\[12\]](#page-7-20).

To be independent of the non-measured pp reference the ratio (R_{FB}) of J/ ψ produced symmetrically around $y_{\rm cms} = 0$ in a forward over a backward rapidity interval is taken. In this way, the uncertainties which are uncorrelated between backward and forward rapidity enter quadratically combined in the ratio, while for signal extraction the uncertainty can be directly calculated on the ratio of the number of signal events. For the forward-tobackward ratio, the main contribution to the uncertainty originates from the tracking efficiency. Models including shadowing or coherent energy loss are qualitatively able to reproduce the R_{FR} measurement, either versus y_{cms} or versus p_T (Figs. [5](#page-2-1) and [6;](#page-2-2) references for models can be found in the respective legends).

The measurements from [\[10\]](#page-7-0) indicate that cold nuclear matter effects are less pronounced for non-prompt than for prompt J/ ψ , and are in agreement [\[30\]](#page-7-19) for inclusive J/ ψ with those from [\[9\]](#page-6-8).

The results in p–Pb indicate that the J/ψ suppression observed in Pb–Pb collisions at $\sqrt{s_{NN}}$ = 2.76 TeV [\[31,](#page-7-21) [32\]](#page-7-22)
can not be attributed to cold nuclear matter effects. Howcan not be attributed to cold nuclear matter effects. However, firm conclusions will have to be drawn from model calculations.

5 Two- and four-particle correlations

The study of angular correlations (in ϕ and η) of two or more particles provides important information for the characterization of the underlying mechanism of particle production in collisions of hadrons and nuclei at high energy. For example, it is well known that in minimumbias pp collisions the correlation at ($\Delta \varphi \approx 0$, $\Delta \eta \approx 0$), the "near-side" peak, and at $\Delta \varphi \approx \pi$, the "away-side" structure, originates from particle production correlated to jets. In A–A collisions additional long-range structures along the $\Delta \eta$ axis emerge on the near- and awayside, whose shape in $\Delta\varphi$, typically quantified by Fourier coefficients v_n , can be related to the collision geometry and density fluctuations of the colliding nuclei in hydrodynamic models (see [\[33\]](#page-7-23) for a review). In pp collisions ay name models (see [55] for a review). In pp comsions at a centre-of-mass energy $\sqrt{s} = 7$ TeV a similar long-

Figure 8. The p_T differential $v₂$ (left panels) and $v₃$ (right panels) values in Pb–Pb collisions at $\sqrt{s_{NN}}$ = 2.76 TeV (top pan-
els) values in Pb–Pb collisions at $\sqrt{s_{NN}}$ = 2.76 TeV (top panels) and p–Pb collisions at $\sqrt{s_{NN}}$ = 5.02 TeV (top panels)
for one multiplicity interval. The results from CMS [15] are for one multiplicity interval. The results from CMS [\[15\]](#page-7-4) are v_2 {2, $|\Delta \eta| > 2$ } and v_3 {2, $|\Delta \eta| > 2$ } (filled circles) before and after subtracting the $N_{\text{trk}}^{\text{offline}}$ < 20 (70–100%) data (dashed curves), as
well as $v_2/4$ (filled squares) for the 120 < N^{offline} < 150 (0) well as v_2 {4} (filled squares) for the 120 < $N_{\text{trk}}^{\text{offline}}$ < 150 (0–
2%) event class obtained with $|v_1| < 2.4$ and 0.3 < n^{ref} 2%) event class obtained with $|\eta_{\text{lab}}| < 2.4$ and $0.3 < p_{\text{T}}^{\text{ref}}$
3 GeV/c. The results from ALICE [12] are $n\cdot/2$ $|\Delta n| > 0.81$ $T_{\rm B}$ 3 GeV/*c*. The results from ALICE [\[12\]](#page-7-20) are v_2 (2, $|\Delta \eta| > 0.8$ } and v_2 (2, $|\Delta \eta| > 0.8$) (open cross) obtained in $|v_1| < 2$ for the 0–20% $v_3\{2, |\Delta\eta| > 0.8\}$ (open cross) obtained in $|\eta_{\text{lab}}| < 2$ for the 0–20% subtracted by 60–100% event class selected using forward-andbackward multiplicity (V0M). The results from ATLAS [\[13,](#page-7-2) [14\]](#page-7-3) are v_2 {2, $|\Delta \eta| > 2$ } (open circle) and v_2 {4} (open squares) for the 0–2% subtracted by the 50–100% event class selected using the transverse energy on the Pb side ($\Sigma T_{\text{p}}^{\text{Pb}}$) obtained in $|\eta_{\text{lab}}| < 2.5$
and 0.3 < $n^{\text{ref}} > 5$ GaV/c. The measurements [11, 14] use 2/*u*b and $0.3 < p_{\rm T}^{\rm ref} < 5 \text{ GeV}/c$. The measurements [\[11–](#page-7-1)[14\]](#page-7-3) use $2/\mu$ b, while [15] uses $31/\text{nb}$ while [\[15\]](#page-7-4) uses 31/nb.

range (2 < $|\Delta \eta|$ < 4) structure, so called ridge, emerges on the near-side in events with significantly higher-thanaverage particle multiplicity [\[34\]](#page-7-24). Its origin has been attributed either to initial-state effects (such as gluon saturation and colour connections forming along the longitudinal direction) or to final-state effects (such as parton-induced

Figure 9. interactions, and collective effects arising in a high-density system (see [\[35\]](#page-7-25) for a review).

A qualitatively similar ridge, but with stronger correlation strength than in pp, also appears on the nearside in high-multiplicity p–Pb collisions at $\sqrt{s_{NN}}$ = ⁵.02 TeV [\[11\]](#page-7-1). Subsequent measurements [\[12,](#page-7-20) [13\]](#page-7-2), which removed jet-induced correlations by subtracting the correlations extracted from low-multiplicity events, reveal that the near-side ridge is accompanied by essentially the same ridge on the away-side (Fig. [7\)](#page-3-2). Due to a bias on the jet production or fragmentation the subtraction of the jet peak is less complete, when the event selection is performed at midrapidity (SPD) than at forward-and-backward rapidity (V0M) or at beam rapidity (ZNA). The p_T dependence of the extracted v_2 and v_3 coefficients from twoparticle correlations is found to be similar to that measured in Pb–Pb collisions (Fig. [8\)](#page-3-1). This is in particular the case for v_3 , where the p_T -integrated v_3 turns out to be the same in p–Pb collisions and in Pb–Pb collisions at the same multiplicity (Fig. [9\)](#page-4-1). Differences between the two systems become apparent for v_2 {4}, which is obtained by extracting the genuine four-particle correlations using cu-mulants [\[36\]](#page-7-26). The integrated v_2 {4}, as well as v_2 {2}, are smaller (by up to about 35%) than in Pb–Pb collisions at the same multiplicity (Fig. [10\)](#page-4-2).

It is interesting to note that v_2 {4} and v_3 {2} set in at about the same multiplicity ($N_{\text{trk}}^{\text{offline}} \approx 50$ for $|\eta| < 2.4$),

which only is slightly larger than the average value for minimum bias p–Pb collisions. The interpretation of the correlation data focuses on two different approaches: either quantum interference between rapidity-separated gluons enhanced by gluon saturation in the CGC model [\[37,](#page-7-27) [38\]](#page-7-28), or collective dynamics induced by strong final-state interactions [\[39–](#page-7-29)[41\]](#page-7-30), as commonly applied in hydrodynamical models of A–A collision data. So far, the interpretation of the v_3 data is only achieved with the hydrodynamical approaches, and it is argued that the observed effects result from rare fluctuations of the nucleon density [\[42\]](#page-7-31). The similarity of the v_2 {4} and v_3 {2} data at fixed multiplicity in the p–Pb and Pb–Pb systems can be explained as the collective response to the fluctuations of clusters, when the geometrical contribution from the reaction plane in v_2 {4} is factorized out [\[43\]](#page-7-32). However, the application of hydrodynamics to a small system such as p–Pb is complicated due to a significant model dependence on the initial state geometry and its fluctuations and due to viscous corrections, which may be too large for hydrodynamics to be reliable [\[44\]](#page-7-33).

6 Identified particles

Further experimental information expected to clarify whether final state effects play a role in high-multiplicity p–Pb collisions is provided by the measurement of identified particles. So far, two measurements are available:

- the *p*_T spectra of π^{\pm} , K^{\pm} and p(\bar{p}) measured by CMS via the energy loss in the silicon tracker using 1/*u*b for via the energy loss in the silicon tracker using $1/\mu$ b for $|y_{lab}| < 1$ in the p_T ranges of 0.1-1.2, 0.2-1.05 and 0.4-1.7 GeV/*c*, respectively, as a function of corrected track multiplicity (N_{tracks}) in $|\eta_{\text{lab}}| < 2.4$ [\[16\]](#page-7-5);
- the *p*_T spectra of π^{\pm} , K^{\pm}, K⁰_s, p(\bar{p}) and $\Lambda(\bar{\Lambda})$ measured
by AJ ICE via the energy loss in the barrel tracking sysby ALICE via the energy loss in the barrel tracking systems and via the time-of-flight information using $15/\mu b$ for $0 < y_{\text{cms}} < 0.5$ in the p_{T} ranges of 0.1-3, 0.2-2.5, 0-8, 0.3-4 and 0.6-8 GeV/*c*, respectively, as a function of midrapidity d*N*ch/dη selected in intervals of forward multiplicity (V0A) [\[17\]](#page-7-6).

To obtain the integrated yield and average p_T , the spectra are fitted for the extrapolation to zero and high p_T in the unmeasured p_T region. In the case of CMS, a Tsallis-Pareto distribution is used with the unmeasured fraction of yield of about 15–30% for π^{\pm} , 40–50% for K^{\pm}, and 20–35% for p(\overline{p}). In the case of ALICE a blast-wave func-20–35% for $p(\bar{p})$. In the case of ALICE, a blast-wave function is used with the unmeasured fraction of yield of about $8-9\%$ for π^{\pm} , 10-12% for K^{\pm} , 7-13% for p(\overline{p}) and 17-30% for $\Lambda(\overline{\Lambda})$. The measured *n*_r spectra become harder for for $\Lambda(\bar{\Lambda})$. The measured p_T spectra become harder for increasing multiplicity, with the change being most pronounced for $p(\bar{p})$ and $Λ(Λ)$ (see Fig. 6 in [\[16\]](#page-7-5) and Fig. 1 in [\[17\]](#page-7-6)). This evolution is strongly reflected in the extracted average p_T , which is found to increase with particle mass and the charged multiplicity of the event (Fig. [11](#page-5-0) and Fig. [12\)](#page-5-1). ^{[1](#page-4-3)}This effect, called "radial flow" in a hydrodynamic scenario [\[45\]](#page-7-34), is well known in A–A collisions (e.g.

¹The comparison of the average p_T between the CMS and ALICE results is not straight forward because of the different selection bias and η ranges, as well as the different way the results are presented and ex-

see [\[46\]](#page-7-35) for Pb–Pb at $\sqrt{s_{NN}}$ = 2.76 TeV). Comparisons with calculations of Monte Carlo event generators reveal that EPOS LHC [\[47\]](#page-7-36), which (unlike HIJING or AMPT) includes an hydrodynamic evolution of the created system, is able to reproduce the trend of the data (Fig. [11\)](#page-5-0).

However, a qualitatively similar mass and multiplicity dependence of the identified-particle average p_T has been also found in pp collisions at the LHC [\[48\]](#page-7-37). It has been demonstrated that color string formation between final partons from independent hard scatterings, called "color reconnection" (CR) [\[49\]](#page-7-38), can mimic the "flow-like" trends seen in the pp data [\[50\]](#page-7-39). Unlike hydrodynamics, the CR mechanism acts on a microscopic level, and therefore does not require the formation of a (partially) thermalized medium in a small system.

Similar conclusions can be drawn from a measurement of the average p_T for charged particles with $0.15 < p_T$ 10 GeV/ c in $|\eta_{\rm cms}| < 0.3$ as a function of the number of charged particles with $p_T > 0$ in $|\eta_{\rm cms}| < 0.3$ ($N_{\rm ch}$), compared between pp, p–Pb, and Pb–Pb collisions at the same N_{ch} (Fig. [13\)](#page-5-2). The CR mechanism describes the increase of the average p_T with N_{ch} in pp collisions. Mod-

Figure 13. Average transverse momentum as a function of N_{ch} measured in pp (top panel), p–Pb (middle panel) and Pb–Pb (bottom panel) collisions compared to model calculations [\[19\]](#page-7-8).

els that are only based on a superposition of independent nucleon–nucleon collisions fail to describe the average p_T in p–Pb (and Pb–Pb) collisions. It is argued [\[51,](#page-7-40) [52\]](#page-7-41) that the dependence of average p_T for identified particles in pp and p–Pb collisions with multiplicity can be generally described using geometric scaling and the dependence on the transverse interaction area with multiplicity as computed in the CGC framework. However, this scaling is found to hold less well in the case of unidentified particles [\[19\]](#page-7-8).

Additional information is obtained by comparing the K/ π , p/ π and Λ/π ratios as a function of p_T between p–Pb and Pb–Pb collisions for two event classes (Fig. [14\)](#page-6-9). The p/π and Λ/π ratios exhibit a significant enhancement at intermediate $p_T \approx 3$ GeV/*c*, qualitatively similar to what is observed in Pb–Pb collisions [\[46,](#page-7-35) [53\]](#page-7-42). The magnitude of the observed effects, however, differs between the p–Pb and Pb–Pb systems, with peripheral Pb–Pb collisions roughly resembling the highest multiplicity class in p–Pb. The observations in Pb–Pb are typically attributed to collective flow or quark recombination [\[54\]](#page-7-43), while similar observations in pp could originate from the CR mechanism [\[50\]](#page-7-39).

In Pb–Pb collisions, the v_2 for identified particle species exhibits a characteristic particle-mass dependent splitting, with the v_2 of lighter identified particles found to be larger than that of heavier particles at the same p_T [\[55\]](#page-7-44). The splitting can be understood in the presence of a collective expansion, as for example predicted by hydrodynamic model calculations [\[56\]](#page-7-45). In p–Pb collisions a similar mass dependent splitting of the v_2 coefficients is observed, with the v_2 of p(\overline{p}) being significantly lower than that of π^{\pm} and K^{\pm} (Fig. 15). The v_2 values are extracted from the per- K^{\pm} (Fig. [15\)](#page-6-10). The v_2 values are extracted from the per-

trapolated. If one nevertheless compares the data by taking N_{tracks} = $4.8 dN_{ch}/d\eta_{lab}$, it turns out that $p(\bar{p})$ agrees within uncertainties except for first and last common data points, while the π^{\pm} (K^{\pm}) are systematically different between the two measurements cally different between the two measurements.

classes [17] The p Pb event classes are determined using V0A classes [\[17\]](#page-7-6). The p–Pb event classes are determined using V0A, while the Pb–Pb classes using V0M.

trigger yield of identified associated particles relative to charged trigger particles in symmetric intervals of p_T in the 0–20% event class (selected with V0A) after subtracting the per-trigger yields from the 60–100% event class using $50/\mu b$. As in the case of Pb–Pb, the splitting can be described by hydrodynamical model calculations [\[57,](#page-7-46) [58\]](#page-7-47). It should be noted that a microscopic mechanism as the fore-mentioned CR might create a similar effect, which however has not yet been investigated.

7 Summary

The first results [\[4,](#page-6-3) [7](#page-6-6)[–19\]](#page-7-8) from p–Pb collisions at $\sqrt{s_{NN}}$ = 5.02 TeV are discussed. The strong hadron suppression and dijet momentum imbalance seen for (central) Pb–Pb collisions at $\sqrt{s_{NN}} = 2.76$ TeV can not be attributed to
modification of the initial state alone. The data on $1/h$ modification of the initial state alone. The data on J/ψ production are reproduced by models including shadowing or coherent energy loss. At similar multiplicity, the p–Pb spectra and azimuthal correlation data, as well as the p -Po spectra and azimuthal correlation data, as well as the pp spectra at \sqrt{s} = 7 TeV, exhibit characteristic features that are qualitatively similar to those from Pb–Pb collision at $\sqrt{s_{NN}}$ = 2.76 TeV. These features can all be understood

Figure 15. The v_2 values extracted from two-particle correla-**Eighter 15.** The v_2 values extracted from two-particle correlations in p–Pb collisions at $\sqrt{s_{NN}} = 5.02$ TeV for hadrons (black squares), pions (red triangles), kaops (green stars) and protons squares), pions (red triangles), kaons (green stars) and protons (blue circles) as a function of p_T in the 0–20% after subtraction of the 60–100% event class (selected with V0A) [\[18\]](#page-7-7). The data are plotted at the average- p_T for each p_T interval.

assuming the presence of final state interactions, as maximally realized in hydrodynamical models, which were originally developed to explain the Pb–Pb data. A microscopic approach such as the color reconnection mechanism relevant for the pp data may provide an alternative explanation without having to rely on hydrodynamics. Some of observations are also described by quantum interference effects computed in the CGC framework.

Acknowledgements

I would like to thank the members of the ALICE, ATLAS, CMS and LHCb collaborations for the use of their data, and the CERN accelerator team for the excellent p–Pb operations.
