Abstract

Nuclear shell model predictions for the proton spectroscopic factor of the 1^+ , $E_x = 5.68$ MeV level in ²⁶Si are about fifty times smaller than the value suggested by the measured $(\alpha^3 \text{He})$ cross section for the $E_x = 5.69 \text{ MeV}$ mirror level in ²⁶Mg, assuming purely single-particle transfer. Given that the 5.69 MeV level has been very weakly, if it all, populated in previous studies of the simpler ²⁵Mg(d,p) reaction, it is unclear if the (α^3) He) result is a true singleparticle spectroscopic factor. If we assume the $(\alpha^3 \text{He})$ result, the thermonuclear rate of the ²⁵Al(p, γ)²⁶Si reaction would increase by factors of $\approx 6 - 50$ over stellar temperatures of $T \approx 0.05 - 0.2$ GK. We examine the implications of this enhanced rate for model predictions of nucleosynthesis in classical nova explosions.

Significant progress has been made in recent years to better determine charged-particle thermonuclear reaction rates involved in classical nova explosions. As a result, most of these rates can be specified with experimentally based uncertainties over the relevant stellar temperatures [\[1\]](#page-2-0). The thermonuclear rate of the ²⁵Al(p, γ)²⁶Si reaction $(Q = 5513.78(48)$ keV [\[2\]](#page-2-1)) is considered to be one of the few remaining rates with an uncertainty large enough to significantly affect model predictions of nucleosynthesis in classical nova explosions (see, e.g., Ref. [\[3\]](#page-2-2)). Over temperatures involved in novae ($\approx 0.01 - 0.4$ GK) this rate is dominated by contributions from direct capture, a 1^+ resonance at $E_x(^{26}\text{Si}) = 5.68 \text{ MeV}$, and a 3⁺ resonance at 5.92 MeV. As well, a 0^+ resonance at 5.95 MeV is a minor contributor for $T > 0.2$ GK. These contributions to the total rate, as tabulated in Ref. [\[4\]](#page-2-3), are shown in Fig. [1.](#page-2-4) We note that recent recommended rates [\[1,](#page-2-0) [4](#page-2-3)[–6\]](#page-2-5) all agree to a factor of \approx 3 over the relevant temperatures.

The uncertainty in this rate is difficult to quantify since direct measurements of the strengths of the 1^+ and 3^+ resonances are not yet possible. Instead, shell model calculations, information from the β -decay of ²⁶P, and information from mirror states in ²⁶Mg have been used to estimate and constrain the proton and γ -ray partial widths of these two states. These quantities can then be used to determine resonance strengths and the corresponding resonant contributions of these states to the total thermonuclear rate, as in Fig. [1.](#page-2-4) The 1^+ , 5.69 MeV and 3^+ , 6.13 MeV levels in 26 Mg are the most likely mirror states of the two important resonances in ²⁶Si due to the lack of other candidates in this energy region of ^{26}Mg [\[7\]](#page-2-6).

Recent determinations of the ²⁵Al(p, γ) rate have used proton spectroscopic factors S_l to estimate the required proton partial widths [\[1,](#page-2-0) [4](#page-2-3)[–6\]](#page-2-5). These quantities have been cal-culated using the shell model [\[5,](#page-2-7) [6,](#page-2-5) [9\]](#page-2-8), and, for the 3^+ resonance, adopted from the mirror state [\[8,](#page-2-9) [9\]](#page-2-8). Uncertainties of a factor of three have been assumed for proton partial widths estimated using quantities calculated though the shell model [\[4,](#page-2-3) [10\]](#page-2-10). More recently, Ref. [\[6\]](#page-2-5) found that a $\approx 20\%$ uncertainty in their theoretical spectroscopic factors accounts for the spread in values determined using different sd-shell Hamiltonians.

Experimental neutron spectroscopic factors determined in the ${}^{25}Mg(\alpha,{}^{3}He)^{26}Mg$ measurement of Yasue et al. (1990) [\[11\]](#page-2-11) have not been considered, to our knowledge, in any determination of the ${}^{25}\text{Al}(p,\gamma){}^{26}\text{Si}$ rate. These measured values are of interest as they are in good agreement with shell model predictions for most of the states populated, including the 3^+ and 0^+ states of concern here. For example, for the 3^+ , ²⁶Si state at $E_x = 5.92$ MeV, shell model calculations give $S_{l=0} = 0.14$ and $S_{l=2} = 0.33$ [\[6,](#page-2-5)9]; Yasue et al. measured $S_{l=0} = 0.14$ and $S_{l=2} = 0.30$ for the mirror state at $E_x(^{26}Mg) = 6.13 \text{ MeV}$ [\[11\]](#page-2-11). For the $0^+,$ ²⁶Si state at E_x $= 5.95$ MeV, shell model calculations give $S_{l=2} = 0.047$ [\[9\]](#page-2-8) and $S_{l=2} = 0.039$ [\[6\]](#page-2-5); Yasue et al. measured $S_{l=2} = 0.054$ for the likely mirror state at $E_x(^{26}Mg) = 6.26 \text{ MeV}$ [\[11\]](#page-2-11). Curiously, for the 1^+ , ²⁶Si state at $E_x = 5.68$ MeV, shell model calculations give $S_{l=2} = 0.0040$ [\[9\]](#page-2-8), $S_{l=2} = 0.0048$ [\[5\]](#page-2-7), and $S_{l=2} = 0.0035$ [\[6\]](#page-2-5); while Yasue et al. measured $S_{l=2} = 0.20$ for the mirror state at $E_x(^{26}Mg) = 5.69$ MeV [\[11\]](#page-2-11).

This large disagreement for the 1^+ resonance may be attributed, in part, to the difficulty in separating the doublet at $E_x(^{26}Mg) = 5.69$ and 5.72 MeV when obtaining angular distributions from the ${}^{25}Mg(\alpha,{}^{3}He)$ measurement. This is supported by how differential cross sections for the combined doublet are given at twelve angles between $\theta_{CM} \approx$ 5 − 60◦ , but cross sections for each member of the doublet are given at only seven angles between $\theta_{CM} \approx 5 - 25^{\circ}$ [\[11\]](#page-2-11). A more pressing issue may lie in the suitability of using the $(\alpha,^3\text{He})$ reaction to study the relevant single-particle properties: Yasue et al. themselves suggest that multi-step processes may be responsible for larger $(\alpha,^3\text{He})$ yields for 1^+ states [\[11\]](#page-2-11). Furthermore, the 5.69 MeV state of ^{26}Mg has been very weakly, if it all, populated in previous studies with a simpler neutron-transfer reaction $(^{25}Mg(d,p))$ and sufficient energy resolution to separate the doublet (e.g., Refs. [\[12,](#page-2-12) [13\]](#page-2-13)). As such, it is not clear whether the Yasue et al. result for the 1^+ resonance is a true single-particle spectroscopic factor. With regard to the thermonuclear rate of the ²⁵Al(p, γ) reaction, a spectroscopic factor of $S_{l=2} = 0.20$ for the important 1^+ resonance would lead to a total rate that is $\approx 6 - 50$ times larger than recently recommended rates at $T \approx 0.05 - 0.2$ GK (see Fig. [1\)](#page-2-4).

New high resolution measurements of the $^{25}Mg(d,p)$ and ${}^{25}Mg(\alpha,{}^{3}He)$ reactions, used in conjunction with improved theoretical treatments of the reaction mechanisms, could help to clarify this possible discrepancy. To assess the astrophysical motivation for such measurements, we first use some simple calculations to gain some insight into the possible impact in classical nova explosions of the enhanced ²⁵Al(p, γ) rate in Fig. [1.](#page-2-4) At T = 0.1 GK, the tabulated total rate of Ref. [\[4\]](#page-2-3) is 3.0×10^{-11} cm³ s⁻¹ mol⁻¹, with the resonant contribution of the 1⁺ state accounting for $\approx 99\%$ of this value. Use of the Yasue et al. [\[11\]](#page-2-11) spectroscopic factor for the 1^+ resonance would lead to a total rate (at 0.1) GK) of 1.5×10^{-9} cm³ s⁻¹ mol⁻¹. If we then assume a density of $\approx 10^3$ g cm⁻³ and a hydrogen mass fraction of ≈ 0.4 (i.e., after mixing), we would obtain a ²⁵Al half life for proton capture of $\approx 10^6$ s. Similarly, at T = 0.2 GK, use of the Yasue et al. spectroscopic factor for the 1^+ resonance would lead to a ²⁵Al half life for proton capture of ≈ 200 s. These values may be compared to the half life for the β-decay of ²⁵Al: $t_{1/2} = 7.2$ s. These rough estimates imply that even the enhanced rate of Fig. [1](#page-2-4) would not be expected to compete effectively with the β -decay of ²⁵Al at the relevant temperatures.

To investigate this issue in more detail, we performed two hydrodynamic simulations to test the impact of an increased ${}^{25}\text{Al}(p,\gamma)$ rate on predictions of nucleosynthesis in classical nova explosions. The two simulations were identical except for the rate of the ²⁵Al(p, γ) reaction employed: one used the tabulated reaction rate of Ref. [\[4\]](#page-2-3), while the other used an enhanced rate determined using $S_{l=2} = 0.20$ for the 1⁺ resonance (instead of $S_{l=2} = 0.0040$, as used in Ref. [\[4\]](#page-2-3)). These two rates are shown in Fig. [1.](#page-2-4) We have adopted a typical nova scenario consisting of a 1.25 M[⊙] oxygen-neon white dwarf accreting solar material at a rate of 2×10^{-10} M_☉ yr⁻¹ [\[14\]](#page-2-14). Mixing at a level of 50%

Figure 1: The thermonuclear rate of the 25 Al(p, γ)²⁶Si reaction over typical nova temperatures. Contributions to the total rate of Wrede (2009) (thick black line) by direct capture (thin black line) and the 1^+ , 3^+ and 0^+ resonances (dashed lines) are indicated [\[4\]](#page-2-3). Also shown is an enhanced rate (grey line) determined using a spectroscopic factor for the 1^+ resonance that is fifty times larger [\[11\]](#page-2-11) than that used in Ref. [\[4\]](#page-2-3) (see text).

 Al(p, \gamma)
 (10) 0+ between accreted material and the outermost layer of the white dwarf was assumed. We found no appreciable differences in the nucleosynthesis of the two models; predicted yields were in agreement to better than $\approx 5\%$. As may be expected from the simple calculations mentioned earlier, even the enhanced 25 Al(p, γ) rate is not large enough to compete effectively with the β -decay of any ²⁵Al produced in nova explosions for $T < 0.2$ GK. For completeness, we performed a third simulation using a 25 Al(p, γ) rate determined from a spectroscopic factor for the 1^+ resonance that is 50 times lower than the shell model value of $S_{l=2} \approx 0.004$. Again, as expected, the calculated yields did not differ significantly from those determined using the tabulated rate of Ref. [\[4\]](#page-2-3).

Nucleosynthesis in the adopted nova model is not very sensitive to variations by a factor of ≈ 50 of the theoretical proton spectroscopic factor of the 1^+ resonance of the 25 Al(p, γ)²⁶Si reaction. As such, experimental efforts to improve this rate for models of classical nova explosions should probably focus on better contraining the resonant contribution of the key 3^+ resonance.
