Abstract

We report low temperature scanning tunneling microscopy characterization of MoSe₂ crystals, and the fabrication and electrical characterization of MoSe₂ field-effect transistors on both SiO₂ and parylene-C substrates. We find that the multilayer MoSe₂ devices on parylene-C show a room temperature mobility close to the mobility of bulk MoSe₂ (100 cm²V⁻¹s⁻¹ – 160 cm²V⁻¹s⁻¹), which is significantly higher than that on SiO₂ substrate (≈ 50 cm²V⁻¹s⁻¹). The room temperature mobility on both types of substrates are nearly thickness independent. Our variable temperature transport measurements reveal a metal-insulator transition at a characteristic conductivity of e^2/h . The mobility of MoSe₂ devices extracted from the metallic region on both SiO₂ and parylene-C increases up to ≈ 500 cm²V⁻¹s⁻¹ as the temperature decreases to ≈ 100 K,

with the mobility of MoSe₂ on SiO₂ increasing more rapidly. In spite of the notable variation of charged impurities as indicated by the strongly sample dependent low temperature mobility, the mobility of all MoSe₂ devices on SiO₂ converges above 200 K, indicating that the high temperature (> 200 K) mobility in these devices is nearly independent of the charged impurities. Our atomic force microscopy study of SiO₂ and parylene-C substrates further rule out the surface roughness scattering as a major cause of the substrate dependent mobility. We attribute the observed substrate dependence of MoSe₂ mobility primarily to the surface polar optical phonon scattering originating from the SiO₂ substrate, which is nearly absent in MoSe₂ devices on parylene-C substrate.

The successful isolation of two-dimensional (2D) graphene has stimulated research on a broad range of other 2D materials, among which layered transition metal dichalcogenides (TMDs) have attracted particular attention.¹⁻¹⁵ Similar to graphene, atomic layers of covalently bonded chalcogen-metal-chalcogen units can be extracted from bulk TMD crystals by a mechanical cleavage technique due to the relatively weak van der Waals interactions between the layers. The semiconducting members of the TMD family including MoS₂, MoSe₂, WS₂ and WSe₂ have not only demonstrated many of the "graphene like" properties highly desirable for electronic applications such as a relatively high mobility, mechanical flexibility, chemical and thermal stability, and the absence of dangling bonds, but also have a substantial band gap (1 ~ 2 eV depending on the material and its thickness), which is absent in 2D graphene but required for mainstream logic applications.^{1, 16-18} For example, in contrast to the low ON/OFF ratios in graphene field-effect transistors (FETs), an ON/OFF ratio of $> 10^8$ has been reported in monolayer MoS₂.⁵

Despite these recent progress, the mobility values of monolayer and multilayer MoS₂ devices on SiO₂ (the most commonly used substrate for MoS₂ FETs) reported by multiple groups were substantially below the Hall mobility of bulk MoS₂ (100~200 cm²V⁻¹s⁻¹),^{3, 7, 9-10} which greatly hinders their application potential in multifunctional electronic devices. In addition to the intrinsic scattering from phonons in the TMD channel,¹⁵ the carrier mobility of TMD transistors on SiO₂ is expected to be also limited by extrinsic scattering from charged impurities at the channel/substrate interface and charge traps in SiO₂, substrate surface roughness, and remote surface optical phonons originating from SiO₂. Coulomb scattering from charged impurities at the channel/substrate interface has been proposed as the predominant cause of the relatively low

room-temperature mobility in MoS₂.^{7, 19} Although a high- κ dielectric may screen Coulomb scattering from charged impurities, complete recovery of the intrinsic phonon-limited mobility has not been observed in high- κ dielectric encapsulated MoS₂ devices. On the other hand, the presence of a low energy optical phonon mode in SiO₂ (~ 60 meV) may also cause non-negligible surface polar optical scattering²⁰ and significantly reduced the mobility, as suggested by a recent theoretical study.²¹ However, experimental investigations of surface polar optical phonon effects on the channel mobility of TMD FETs are still lacking. In order to tap into the full potential of TMDs as a channel material for high performance FETs, it is crucial to use substrate/dielectric materials that do not further reduce the TMD mobility *via* surface polar optical phonon scattering.

In this article, we present a detailed temperature dependent electrical study of ultrahigh crystalline quality multilayer MoSe₂ FETs of varying thickness (5-15 nm) on SiO₂ and parylene-C substrates. Parylene-C, a cross-linkable polymer widely used as a passivation layer and gate dielectric, is an excellent candidate for substrate because its lowest energy optical phonon mode of 130 meV (corresponding to the vibrational stretch of C-Cl bond) cannot be easily excited at room temperature.²²⁻²³ WSe₂ FETs with parylene top gate dielectric have demonstrated high room temperature mobility up to 500 cm²/Vs.²⁴ Moreover, parylene-C is insoluble in common solvents such as acetone and isopropanol and thus comparable with the standard device fabrication process. Our four-terminal electrical measurements of multiple MoSe₂ FETs on SiO₂ reveal that the room temperature mobility is nearly thickness independent with an average value of ≈ 50 cm²V⁻¹s⁻¹ in good agreement with previously reported results from MoSe₂ and MoS₂ on SiO₂ substrates.²⁵⁻²⁶ However, a two to three-fold mobility improvement is consistently observed

in MoSe₂ FETs on parylene-C substrate compared to MoSe₂ devices on SiO₂. To elucidate the origin of the strong substrate dependence of mobility, we measured the electrical characteristics of MoSe₂ on both types of substrates between 77 K and 295 K. As the temperature decreases, the temperature dependence of the mobility for MoSe₂ FETs on both types of substrates behave as $\mu \sim T^{-\gamma}$, indicating that the charge transport is dominated by phonon scattering in both cases. However, the mobility of MoSe₂ FETs on SiO₂ substrate increases more rapidly (larger γ) than the devices on parylene-C substrate with decreasing temperature, before eventually merging at $\mu \approx 500 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}$ and $T \approx 100 \text{ K}$. The stronger temperature dependence of MoSe₂ devices on SiO₂ than on parylene-C can be primarily attributed to an additional surface polar optical phonon scattering contribution originating from the SiO₂ substrate, which is consistent with the substantially lower room temperature mobility in MoSe₂ devices on SiO₂ than on parylene-C. Our study reveals the important role of surface polar phonon scattering in carrier mobility and demonstrates parylene-C as an excellent substrate for TMD FETs.

RESULTS AND DISCUSSIONS

MoSe₂ crystals were synthesized by chemical vapor transport using iodine as transport agent. The as grown crystals were phase pure as determined by x-ray diffraction. To further characterize the quality of the MoSe₂ crystals, scanning tunneling microscopy (STM) measurements were performed on freshly cleaved surfaces of MoS₂ crystals inside an ultra-high vacuum (UHV) chamber at 4.5 K without any additional thermal treatment to avoid any possible thermally induced surface reconstruction. Figure 1a shows a representative STM topographic image of cleaved MoSe₂ surface measured by 10 nm × 10 nm, where the atomically resolved

honeycomb structures bare close resemblance to other layered systems such as MoS₂ and graphene. The 1×1 unit cell is shown as a rhombus in the high resolution image (Figure 1b) with a lattice distance of 3.3 Å expected for MoSe₂.²⁷ Remarkably, the surface within a relatively large scan area of 10 nm by 10 nm is surprisingly clean and nearly defect/impurity free (see Figure 1a). Since defects and/or impurities reduce the mean free path of the charge carriers and thus the mobility by serving as scattering centers for charge transport, the extremely low impurity level and high crystalline quality of our MoSe₂ is critical to achieving its ultimate materials and device performance.^{14, 28}

For electrical transport studies, thin MoS₂ crystals (5 nm - 15 nm thick) were produced by repeated splitting of bulk crystals using a mechanical cleavage method, and subsequently transferred to degenerately doped silicon substrates covered either by 290 nm SiO₂ or by 130 nm parylene-C vapor deposited on top of 290 nm SiO₂.^{3-4, 29} Optical microscopy was used to identify thin MoSe₂ crystals, which were further characterized by non-contact mode atomic force microscopy (AFM). We chose 5 nm - 15 nm thick MoSe₂, because multilayer MoSe₂ of this thickness range has a much high yield of sufficiently large flakes (for patterning multiple electrodes) than thinner samples and a relatively smaller *c*-axis interlayer resistance compared to thicker samples.³⁰ MoSe₂ FET devices were fabricated using standard electron beam lithography and electron beam deposition of 5 nm of Ti and 50 nm of Au.³¹ To eliminate electrical contact contributions, we also patterned voltage probes in between drain and source electrodes to facilitate four-terminal measurements. A schematic illustration and an AFM image of typical MoSe₂ devices are shown in Figure 1c and 1d, respectively. Electrical properties of the devices were measured by a Keithley 4200 semiconductor parameter analyzer in a Lakeshore Cryogenic probe station under high vacuum ($\sim 1 \times 10^{-6}$ Torr).

Figure 2a and 2b depict the room temperature transfer characteristics of two ~ 12 nm MoSe₂ devices on SiO₂ and parylene-C, respectively. Both devices exhibit highly asymmetric ambipolar behavior, with the ON/OFF current ratio exceeding 10^6 for electrons and less than 10^3 for holes at a drain-source voltage of 1 V. The asymmetry between electron and hole transport may be attributed to 1) a relatively large Schottky barrier height for the hole channel as the Fermi level of the contact metal (Ti) tends to line up much closer to the conduction band edge than the valence band edge in MoSe₂, and 2) small amount of intrinsic *n*-doping in the transport channel.³² The hysteresis in the transfer characteristics is likely due to the charge injection from the adsorbates (such as moisture and oxygen) on the channel surfaces and/or at the interfaces between the channel and the substrate.³³ The hysteresis could be reduced by sweeping the gate voltage in a smaller range as discussed below. In future studies, the observed hysteresis could also be removed using a glove box as achieved by multiple groups.³⁴⁻³⁶ As shown in Figure 2c and 2d, the drain-source current of both devices is linear at low drain-source voltages. As V_{ds} increases, the drain-source current starts to saturate in the low gate voltage range ($V_{bg} < 10$ V and < 30 V for devices on SiO₂ and parylene-C, respectively), while remaining linear at higher gate voltages. The current saturation at low gate voltages is likely caused by the reduction of the effective V_{bg} and V_{ds} due to the relatively large parasitic series drain/source contact resistance (R_C) given by $V_{bg_eff} = V_{bg} - R_C I_{ds}$ and $V_{ds_eff} = V_{ds} - 2R_C I_{ds}$.¹⁵ At higher V_{bg} , the contact resistance is lowered by the reduction of the effective Schottky barrier height through band bending, leading to more linear I_{ds} - V_{ds} behavior signifying near Ohmic contacts.³⁷

To investigate the true channel-limited electronic performance of MoSe₂ devices and understand the charge transport mechanisms, particularly the role of the substrate, we measured the back gate dependence of conductivity σ for MoSe₂ devices both on SiO₂ and on parylene-C

in a four-terminal configuration. The four-terminal conductivity is defined as $\sigma = I_{ds} \times \frac{L}{W} / V_{inn}$, where L and W are the separation between the voltage probes (the inner contacts) and sample width, respectively; and V_{inn} is the measured voltage difference between the voltage probes (kept below 50 mV in all measurements). Field-effect mobility is extracted from the V_{bg} dependence of σ using the expression $\mu = 1/C_{bg} \times d\sigma/dV_{bg}$ in the linear region of the σ vs V_{bg} curves, where C_{bg} is the back-gate capacitance per unit area. Based on a simple parallel plate capacitor model, C_{bg} is determined to be 1.2×10^{-8} F cm⁻² for 290 nm SiO₂ ($C_{bg} = 3.9 \times \epsilon_0 / 290$ nm) and 7.6×10^{-9} F cm⁻² for 130 nm parylene-C on 290 nm SiO₂ ($C_{bg} = \frac{3.9 \times 3.12 \times \epsilon_0}{130 \text{ nm} \times 3.9 + 290 \text{ nm} \times 3.12}$), respectively.²⁹

Figure 3a shows the room temperature conductivity as a function of back gate voltage for two representative MoSe₂ devices: a 10 nm thick MoSe₂ on SiO₂ and a 12 nm thick MoSe₂ on a parylene-C. In spite of the qualitatively similar transfer and output characteristics between devices on SiO₂ and parylene-C (Figure 2), the mobility of the MoSe₂ device on parylene-C (≈ 118 cm²V⁻¹s⁻¹) is significantly larger than that on SiO₂ (≈ 50 cm²V⁻¹s⁻¹).

To eliminate any possible sample-to-sample variations, we systematically measured 11 MoSe₂ devices on SiO₂ and 5 MoSe₂ devices on parylene-C in the four-terminal configuration. Figure 3b plots room temperature field-effect mobility as a function of channel thickness for all measured MoSe₂ FETs devices, with thickness ranging from ~ 5 nm to 14 nm. The mobility of our SiO₂-supported MoSe₂ devices slightly fluctuates around an average value of ≈ 50 cm²V⁻¹s⁻¹ without showing any noticeable thickness dependence, consistent with previous results from SiO₂-supported multilayer MoS₂.²¹ In spite of the extremely high crystalline quality of our MoSe₂ samples (as shown in Figure 1a), the average room temperature mobility of our MoSe₂ devices on SiO₂ substrate is rather low compared to the Hall mobility of bulk MoSe₂ (about 100

$\text{cm}^2\text{V}^{-1}\text{s}^{-1} - 200 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}$), but similar to that observed in SiO_2 -supported MoS_2 devices fabricated from commercially available MoS_2 crystals.^{28,26} This suggests that the room temperature mobility of our MoSe_2 devices on SiO_2 is likely limited by extrinsic scattering mechanisms. In contrast, the room temperature mobility of all five MoSe_2 devices on parylene-C ranges from $\approx 100 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}$ to $\approx 150 \text{ cm}^2\text{V}^{-1}\text{s}^{-1}$, which is close to the bulk values.²⁸ Since the error bars in the mobility data are mainly caused by the uncertainties in the channel length between the voltage probes due to their finite width, the greater absolute fluctuations in the mobility on parylene-C is directly related to the higher mobility on parylene-C.

To understand the substrate/dielectric dependent mobility in our MoSe_2 devices, we consider various mobility-limiting scattering mechanisms as formulated by Mathiessen's rule $\mu^{-1} = \mu_{INT}^{-1} + \mu_{SD}^{-1} + \mu_{CI}^{-1} + \mu_{SR}^{-1} + \mu_{SPP}^{-1}$. Here μ_{INT}^{-1} represents the mobility limited by intrinsic scattering from lattice phonons, μ_{SD}^{-1} presents mobility limited by structural defects, and μ_{CI}^{-1} , μ_{SR}^{-1} and μ_{SPP}^{-1} represent mobility limited by extrinsic scattering from Coulomb impurities (CI), the surface roughness (SR), and the dielectric surface polar optical phonons (SPP), respectively. The intrinsic mobility μ_{INT} and mobility limited by structural defects μ_{SD} are expected to be similar for MoSe_2 FETs both on SiO_2 and on parylene-C, since all our devices are fabricated from the same MoSe_2 crystal. We also exclude structural defects as a major source of scattering given the extremely high crystalline quality of our MoSe_2 crystals. Next, we consider the effects of surface roughness scattering on the mobility of our MoSe_2 devices. Figure 3c and 3d show AFM topographic images acquired in the vicinity of MoSe_2 samples on SiO_2 and parylene-C, respectively, from which the RMS surface roughness is determined to be 0.3 nm for SiO_2 and 0.6 nm for parylene-C. The observation of higher mobility on rougher parylene-C substrate rules out surface roughness scattering as a major cause of the substrate dependent mobility in our

MoSe₂ devices. Therefore, we can safely deduce that the lower mobility in MoSe₂ devices on SiO₂ is likely due to additional Coulomb and/or interfacial surface polar optical phonon scattering.

Charged impurities present at the interface between the semiconducting channel and substrate have been generally considered as the primary cause of low room-temperature mobility in TMD devices.^{7, 38} Radisavljevic *et al.* recently showed significantly improved mobility in monolayer MoS₂ devices with a high- κ HfO₂ top-gate dielectric, which was attributed to effective damping of Coulomb scattering on charged impurities.⁷ However, the mobility observed in their MoS₂ devices (up to 60 cm²V⁻¹s⁻¹ at 260K) is still much lower than the theoretical values or experimental results from bulk samples.^{19, 28} A possible cause of this discrepancy is surface polar optical phonon scattering from substrate and gate dielectric. Indeed, the temperature-dependent mobility curve in reference ⁷ was recently reproduced by a Monte Carlo method taking into account both the charged impurity scattering and surface polar optical phonon scattering.²¹ Considerable mobility improvement was also reported in multiplayer MoS₂ on PMMA dielectric in comparison with MoS₂ on SiO₂, which was attributed to the reduced short-range disorder and long range disorder at the channel/PMMA interface than at the channel/SiO₂ interface.²¹ However, the lack of temperature dependent mobility data makes it difficult to further elucidate the origin of substrate dependent mobility in these devices.

To shed additional light on the origin of the significant mobility difference between MoSe₂ devices on SiO₂ and on parylene-C, we systematically measured the temperature dependence of four-terminal conductivity *vs* gate voltage. Figures 4a and 4b show the temperature dependence of four-terminal conductivity as a function of back gate voltage for two representative MoSe₂ devices: one on SiO₂ and one on parylene-C. At low gate voltages, both

devices show typical insulating or semiconducting behavior with the conductivity increasing with temperature. At high gate voltages, the conductivity decreases with increasing temperature, characteristic of metallic behavior. To further examine the crossover from an insulating or semiconducting state to a metallic state, we plot the conductivity as a function of temperature at various gate voltages in Figure 4c and 4d. It is apparent that a metal-insulator transition occurs at a critical gate voltage between 30 and 35 V, corresponding to a critical carrier density of $\sim 1 \times 10^{12} \text{ cm}^{-2}$ and $\sim 7 \times 10^{11} \text{ cm}^{-2}$ for the SiO_2 and parylene-C substrates, respectively. Above this critical carrier density, the conductivity decreases with increasing temperature, corresponding to a metallic behavior. Below this critical carrier density, the conductivity increases with increasing temperature, characteristic of insulating or semiconducting behavior. More interestingly, this metal-insulator transition is associated with a critical conductivity of e^2/h , consistent with metal-insulator transitions (MITs) observed in monolayer, bilayer and multilayer MoS_2 as well as theoretical expectations for 2D semiconductors.^{7, 8, 11} To rule out the possible hysteresis effects on the observed MIT, we also measured the four-terminal conductivity as a function of gate voltage in both the "up" and "down" gate-sweep directions. As shown in Figure 5b, hysteresis is nearly absent in the four-terminal conductivity, while the two terminal conductivity of the same device shows substantial hysteresis. The significantly reduced hysteresis in our four-terminal conductivity data is likely due to the smaller gate sweep range of our four-terminal measurement than two-terminal measurement. Since all our four-terminal conductivity results were consistently measured in a relatively small gate voltage range ($-10 \text{ V} < V_{\text{bg}} < 60 \text{ V}$) where the hysteresis is negligibly small, these results were unlikely influenced by possible hysteresis effects.

Figure 5a shows the temperature dependence of field-effect mobility for six MoSe₂ devices on SiO₂ (solid symbols) and three MoSe₂ devices on parylene-C (hollow symbols) extracted from the linear region of the conductivity curves in the metallic state ($35 < V_{bg} < 45V$), using the expression for field-effect mobility $\mu = 1/C_{bg} \times d\sigma/dV_{bg}$. The mobility values of all three devices on parylene-C follow a $\mu \sim T^{-\gamma}$ dependence with $\gamma \approx 1.2$ for the entire measured temperature range. This is consistent with the theoretical modeling of phonon-limited mobility in layered TMD materials such as MoS₂ and MoSe₂, which shows $\mu \sim T^{-\gamma}$ dependence where the exponent γ depends on the dominant phonon scattering mechanism with $\gamma \sim 2.4$ in bulk MoSe₂ samples and lower for carriers in 2D.^{19, 28} The relatively low γ in our devices suggests that the charge carriers are likely confined in 2D and behave as a 2D electron gas, which is consistent with the recent finding of Li *et al.* that the carriers in a 14 layer MoS₂ FET (about 10 nm thick) are largely confined within 1-2 nm range near the interface of the gated dielectric.³⁰ A similar $\mu \sim T^{-\gamma}$ dependence with a higher $\gamma \approx 1.7$ is observed in two of the six MoSe₂ devices on SiO₂ (5.2 nm and 14 nm thick, respectively), indicating that their mobility is also predominantly limited by phonon scattering. The mobility of other four MoSe₂ device on SiO₂ also follows the same phonon limited behavior (with the same power exponent $\gamma \approx 1.7$) at temperatures above 160 K. As the temperature decreases from 160 K to 77 K, their mobility starts to saturate, likely limited by Coulomb scattering due to the varying amount of charged impurities at the MoSe₂/SiO₂ interface as previously observed in MoS₂ devices.^{7, 10} Higher γ value for MoSe₂ devices on SiO₂ than on parylene-C suggests additional temperature dependent scattering mechanism(s) in SiO₂-supported MoSe₂ devices.

A likely scenario is that the mobility in MoSe₂ on SiO₂ is further reduced by additional polar optical phonon scattering from the underlying SiO₂. The SiO₂ surface polar optical phonon

mode with an energy of ≈ 60 meV can be easily excited by thermal energy at room temperature, while such a soft surface polar optical phonon mode is absent in parylene-C.^{20, 22} At about 100 K, the phonon limited mobility values for MoSe₂ devices on both SiO₂ (those with lower level of charged impurities) and parylene-C merge, which is expected as the mobility undergoes a transition from being dominated by optical phonon scattering (including surface polar optical phonons) to being dominated by acoustic phonon scattering at ~ 100 K.¹⁹ Another possible source of stronger temperature dependence of the mobility observed in MoSe₂ devices on SiO₂ is the presence of greater amount of charged impurities at the SiO₂/MoSe₂ interface than at the parylene/MoSe₂ interface. Recently, Ong and Fischetti showed theoretically that the increase of mobility with decreasing temperature (behaving as $\mu \sim T^\gamma$), which is commonly interpreted to be a signature of phonon-limited electron transport, could also be limited by CI scattering due to the weakening of charge screening within the TMD channel as the temperature increases.³⁹ Although CI scattering could contribute to the temperature dependence of the mobility as a separate term, we believe that the lower room temperature mobility and larger γ in our MoSe₂ devices on SiO₂ than on parylene-C substrate is unlikely to be chiefly caused by stronger CI scattering for the following reasons. Firstly, the mobility of all six MoSe₂ devices on SiO₂ converges above 200 K in spite of the notable variation of charged impurities as indicated by the strongly sample dependent low temperature mobility (Figure 5), indicating that the high temperature (> 200 K) mobility in these devices is nearly independent of the charged impurities. Secondly, the mobility values of our devices on both SiO₂ and parylene-C are significantly higher than the CI limited mobility from the calculations of Ong and Fischetti, suggesting that CI scattering plays a less significant role in our devices compared to the theory.³⁹ At carrier densities comparable to the lower end of the carrier density range for the calculation of

CI/phonon-limited mobility of bear MoS₂ devices in reference [39] ($\approx 10^{12}$ cm⁻²), the mobility of our devices is at least an order of magnitude higher than the calculated mobility. As the carrier density increases, the field-effect mobility in our devices slightly decreases (as indicated by the slight decrease of the slope in the conductivity-gate voltage curves shown in Figure 4a and 4b), while the CI/phonon-limited mobility in reference [39] increases. Thirdly, the temperature dependence of mobility in our devices is qualitatively different from the previously reported CI scattering limited field-effect mobility of MoS₂ devices, in which case the mobility decreases with decreasing temperature below 200 K.⁷

In the insulating (or semiconducting) region ($V_{bg} < 35V$), the temperature dependence of conductivity shows a thermally activated behavior as depicted in Figures 6a and 6b for devices on SiO₂ and parylene-C, respectively. Since the conductivity was measured in a four-terminal configuration, we exclude Schottky barriers as a possible explanation. An activation energy E_a can be extracted using the express $\sigma \sim \exp(-\frac{E_a}{k_B T})$, where k_B is the Boltzmann constant. As shown in Figure 6c, the activation energy E_a decreases with the gate voltage, which can be attributed to the decrease of energy gap between the Fermi level E_F and conduction band edge E_C as the Fermi level is tuned toward the conduction band by the gate voltage. The slope of the curves at low gate voltages (when the devices are in the fully depleted region) can be expressed as $\frac{dE_a}{dV_{bg}} = -\frac{dE_F}{dV_{bg}} = -\frac{eC_{bg}}{(C_{bg} + e^2 D(E))}$, where $D(E)$ represents the density of trap states at the interface between the MoSe₂ channel and substrate. The density of trap states is found to be $\approx 7.6 \times 10^{12}$ cm⁻² and $\approx 4.9 \times 10^{12}$ cm⁻² for MoSe₂ on SiO₂ and parylene-C, respectively, in excellent agreement with the $D(E)$ of multiplayer MoS₂ on SiO₂ reported by Ayari *et. al* (7.2×10^{12} cm⁻²).⁴⁰ The rather similar $D(E)$ for SiO₂ and parylene-C substrates further indicates that CI

scattering is unlikely the limiting factor of the drastically different mobility in our MoSe₂ devices on SiO₂ and parylene-C.

High- κ HfO₂ has been favored as a dielectric material for TMD transistors due to its capability to screen charged impurities and its effectiveness in tuning the charge carriers.^{5, 7} However, the presence of a soft polar phonon vibration mode in HfO₂ along with its high dielectric constant may lead to severe surface polar optical phonon scattering.²¹ A thin layer of parylene may be used as a buffer layer between the TMD channel and HfO₂ to reduce the surface polar phonon scattering from HfO₂ while taking advantage of its high dielectric constant to effectively screen the charged impurities and tune the charge density in the TMD channel.

CONCLUSIONS

In conclusion, we demonstrated that the room temperature mobility in multilayer MoSe₂ FETs fabricated on parylene-C approaches its bulk value and is significantly higher than that in MoSe₂ devices on SiO₂. We attribute the observed mobility difference primarily to the additional surface polar optical phonon scattering originating from the SiO₂ substrate but nearly absent in parylene-C. The additional polar optical phonon scattering from SiO₂ substrate at the MoSe₂/SiO₂ interface also leads to a stronger temperature dependence of the mobility in MoSe₂ on SiO₂ than on parylene-C. At sufficiently low temperatures where acoustic phonons dominate, the mobility of MoSe₂ devices both on SiO₂ and parylene-C merge. Our variable temperature study of the substrate dependence of the mobility in MoSe₂ further demonstrates that substrate surface polar phonons may be a significant limiting factor of room temperature mobility in TMD FETs.

Methods

Parylene-C was deposited on degenerately doped silicon substrate with 290 nm thermal oxide at room temperature using di-para-xylylene (DPX) as the precursor in a commercially available parylene coating system (PDS 2010). Multilayer MoSe₂ flakes were produced by mechanical exfoliation of high quality MoSe₂ crystals and subsequently transferred to Si/SiO₂ substrates with and without 130 nm of parylene-C. Optical microscopy and Park-Systems XE-70 noncontact mode atomic force microscopy (AFM) were used to identify and characterize thin MoSe₂ flakes. MoSe₂ FET devices were fabricated using standard electron beam lithography and subsequent electron beam deposition of 5 nm of Ti covered by 50 nm of Au. Electrical properties of the devices were measured by a Keithley 4200 semiconductor parameter analyzer in a lakeshore Cryogenic probe station under high vacuum (1×10^{-6} Torr).
