ABSTRACT

So called scaling relations have the potential to reveal the mass and radius of solar-like oscillating stars, based on oscillation frequencies. In derivation of these relations, it is assumed that the first adiabatic exponent at the surface (Γ_{1s}) of such stars is constant. However, by constructing interior models for the mass range $0.8\text{--}1.6 M_\odot$, we show that Γ_{1s} is not constant at stellar surfaces for the effective temperature range with which we deal. Furthermore, the well-known relation between large separation and mean density also depends on Γ_{1s} . Such knowledge is the basis for our aim of modifying scaling relations. There are significant differences between masses and radii found from modified and conventional scaling relations. However, comparison of predictions of these relations with the non-asteroseismic observations of Procyon A reveals that new scaling relations are effective in determining the mass and radius of stars. In the present study, solar-like oscillation frequencies of 89 target stars (mostly *Kepler* and *CoRoT*) were analysed. As well as two new reference frequencies ($\nu_{\min 1}$ and $\nu_{\min 2}$) found in the spacing of solar-like oscillation frequencies of stellar interior models, we also take into account $\nu_{\min 0}$. In addition to the frequency of maximum amplitude, these frequencies have very strong diagnostic potential for determination of fundamental properties. The present study involves the application of derived relations from the models to the solar-like oscillating stars, and computes their effective temperatures using purely asteroseismic methods. There are in general very close agreements between effective temperatures from asteroseismic and non-asteroseismic (spectral and photometric) methods. For the Sun and Procyon A, for example, the agreement is almost total.

Key words: stars: evolution – stars: interiors – stars: late-type – stars: oscillations – stars: fundamental parameters

1 INTRODUCTION

Many different types of physical processes occur deep inside stars. The standard stellar models (SSMs), however, are constructed by taking into account only the most basic of the most essential physical principles (such as structure equations, matter-matter and matter-radiation interactions). Therefore, it is inevitable that our SSMs will be inadequate in some respects. Progress depends on finding discrepancies between SSMs and stars. Very detailed analysis is required for improvement in stellar physics, and also for discovering new processes occurring inside stars, and only very precise constraints can lead to the discovery of such processes. Helioseismology and asteroseismology of solar-like oscillating stars are able to provide such constraints (see e.g. Kosovichev 2011, Chaplin & Miglio 2013, Christensen-Dalsgaard 2002, 2016).

Oscillation frequencies (ν) of such stars are now available

from the *Kepler* (Borucki et al. 2010) and *CoRoT* (Baglin et al. 2006) space missions, and from ground-based observations (Bedding et al. 2010, Bedding et al. 2007 and Bazot et al. 2012). According to scaling relations, stellar mass (M) and radius (R) can be found from frequency of maximum amplitude (ν_{\max}), the large separation between the oscillation frequencies ($\Delta\nu$) and effective temperature (T_{eff}). $\Delta\nu$ is not constant and therefore its mean value ($\langle\Delta\nu\rangle$) is used in these computations. Furthermore, it has an oscillatory component. We have shown in two recent papers (Yıldız et al. 2014, hereafter Paper I; Yıldız, Çelik Orhan & Kayhan 2015, hereafter Paper II) that there is very strong diagnostic potential in the new reference frequencies ($\nu_{\min 1}$ and $\nu_{\min 2}$) at which $\Delta\nu$ is minimum.

Paper I involved the investigations of models constructed using the ANKİ code for the solar-like oscillating stars with solar composition, revealing for the first time new relations between oscillation frequencies and fundamental stellar parameters. The discovery of new reference frequencies $\nu_{\min 1}$ and $\nu_{\min 2}$ made these

* E-mail: mutlu.yildiz@ege.edu.tr

relations available. In order to derive general relations, the effects of metallicity (Z) and helium abundance (Y) should be clarified. In Paper II, we attempted to generalize the relations for arbitrary M , R , Z and Y values. In the present study, we analyse observed oscillation frequencies, confirm the relations between the reference frequencies, and apply the new methods to the *Kepler* and *CoRoT* target stars. Their T_{eff} , R and M were found using asteroseismic parameters. Such an application is also very important for testing the scaling relations.

In derivation of the scaling relations used to compute M and R in terms of ν_{max} , $\langle \Delta\nu \rangle$ and T_{eff} , it is assumed that the first adiabatic exponent (Γ_{1s}) and mean molecular weight (μ) at stellar surface are constant (Brown et al. 1991; Kjeldsen & Bedding 1995). We test whether these quantities are constant for our purposes and, if not, recommend that the scaling relations should be verified (see Section 3).

The relation between $\langle \Delta\nu \rangle$ and mean density ($\langle \rho \rangle$) has been widely discussed in recent papers. White et al. (2011) state that the $\langle \Delta\nu \rangle$ - $\langle \rho \rangle$ relation depends on T_{eff} and suggest a fitting formula for correction in order to find $\langle \rho \rangle$ from the observed values of $\langle \Delta\nu \rangle$. In addition to the $\langle \Delta\nu \rangle$ - $\langle \rho \rangle$ relation, Belkacem et al. (2013) also discuss the relation between ν_{max} and acoustic cut-off frequency (ν_{ac}), claiming that departure from the observed relation arises from the complexity of non-adiabatic processes. García Hernández et al. (2015), however, derive an observational scaling ($\langle \Delta\nu \rangle$ - $\langle \rho \rangle$) relation for the δ Scuti components in eclipsing binaries. Recently, Sharma et al. (2016) aimed to generalize problems pertaining to the scaling relations for *Kepler* red giants, without considering Γ_{1s} as variable. Our strategy is first to identify whether constants are constant, before attempting to find parameters for $\langle \Delta\nu \rangle$ - $\langle \rho \rangle$ and $\nu_{\text{max}}-\nu_{\text{ac}}$ relations.

For the assessment of the results on fundamental properties of stars, it is crucial to derive the observed values of these parameters by alternative direct methods, for which, the roles of Sun and Procyon A are of key importance. From astrometric observations of Procyon by *Hubble Space Telescope*, the mass of its primary component is determined very precisely, $1.478 \pm 0.012 M_{\odot}$ (Bond et al. 2015). This data enables the testing of new scaling relations (see Section 4). In addition to interferometrically observed solar-like oscillating stars (Huber et al. 2011b, Baines et al. 2014), component stars in eclipsing binaries are benchmark for asteroseismic studies (Gaulme et al. 2013, Rawls et al. 2016), despite the complicating factor of tidally induced oscillations.

This paper is organized as follows. Section 2 is the presentation of the basic asteroseismic and non-asteroseismic properties of the target stars compiled from literature. In this section, we also compare ν_{min1} and ν_{min2} of the models with their observational counterparts. Section 3 is devoted to MESA (Paxton et al. 2011) models and role of Γ_{1s} in new scaling relations. In this section, we also develop new expressions for effective temperature by using oscillation frequencies. In Section 4, the results based on asteroseismic methods are presented and compared with results obtained by conventional methods. Finally, in Section 5, conclusions are drawn.

2 ASTEROSEISMIC AND NON-ASTEROSEISMIC PROPERTIES OF *Kepler* AND *CoRoT* SOLAR-LIKE OSCILLATING STARS

The basic data of certain *Kepler* (79 stars) and *CoRoT* (7 stars) target stars, compiled from the literature, are listed in Table A1. Oscillation frequencies of three stars (Procyon A, HD 2151 and

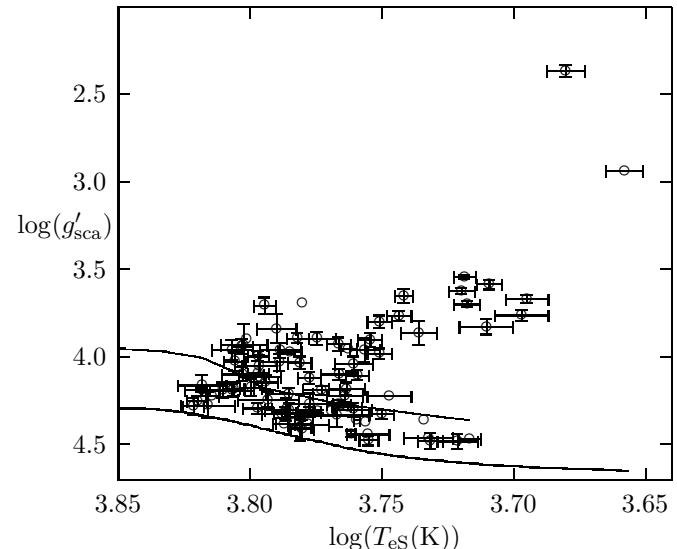

Figure 1. $\log(g'_{\text{sca}})$ of the target stars, computed from $\nu_{\text{max}} T_{\text{eS}}^{0.5}$, is plotted with respect to $\log(T_{\text{eS}})$. The thin and thick solid lines represent ZAMS and TAMS lines taken from Yıldız (2015), respectively.

HD 146233) were obtained from ground-based observations (Bedding et al. 2010, Bedding et al. 2007 and Bazot et al. 2012, respectively). These stars are also listed in this table, with data for the Sun for comparison. For most stars, we provide $B-V$ and $V-K$ colours (SIMBAD database) from photometric, and surface gravity ($\log(g)$), effective temperature (T_{eS}) and metallicity ([Fe/H]) from spectroscopic observations.

Observational oscillation frequencies are obtained from the *Kepler* and *CoRoT* light curves, and from the radial velocity curves. For most stars, frequencies (ν_{nl}) of modes with low degrees (l) and high order (n) are available, allowing the computation of ν_{max} , $\Delta\nu$ and small separation between oscillation frequencies ($\delta\nu_{02} = \nu_{n0} - \nu_{n-1,2}$). Mean values of $\Delta\nu$ ($\langle \Delta\nu \rangle$) and $\delta\nu_{02}$ ($\langle \delta\nu_{02} \rangle$) are used in scaling relations. Furthermore, two minima are seen in the $\Delta\nu$ - ν graph of the majority of stars. For a few stars, there are more than two minima, allowing the consideration of the effect of He II ionization zone on the oscillation frequencies, and the assessment of their diagnostic potential if any. High frequency minima (minH) and low frequency minima (minL) are referred to as ν_{minH} and ν_{minL} , respectively.

These stars are plotted on a $\log(g'_{\text{sca}})$ - $\log(T_{\text{eS}})$ diagram in Fig. 1. g'_{sca} is computed from conventional scaling relation ($g'_{\text{sca}}/g_{\odot} = \nu_{\text{max}}/\nu_{\text{max}\odot}(T_{\text{eS}}/T_{\text{eff}\odot})^{0.5}$). Uncertainties in g'_{sca} are computed from uncertainties in ν_{max} and T_{eS} in the standard way: $\Delta g'_{\text{sca}}/g'_{\text{sca}} = \Delta\nu_{\text{max}}/\nu_{\text{max}} + 0.5\Delta T_{\text{eS}}/T_{\text{eS}}$. Also seen in Fig. 1 are zero-age main-sequence (ZAMS) and terminal-age main-sequence (TAMS) lines taken from Yıldız (2015). Nearly half are main-sequence (MS) stars while the other half are evolved as far as the red giant phase. T_{eS} of the hottest and coolest stars are about 6630 K (KIC 11081729) and 4550 K (KIC 8219268), respectively. T_{eS} of the coolest MS star (KIC 11772920) is 5209 K. Therefore, the effective temperature range for the models that are used to derive relations between asteroseismic and non-asteroseismic quantities is set as 5200-6650 K (see Section 3).

The colours $B-V$ and $V-K$ derived from atmospheric models (Lejeune, Cuisinier & Buser 1998) were fitted to the observed colours, in order to find the effective temperatures T_{eBV} and T_{eVK} ,

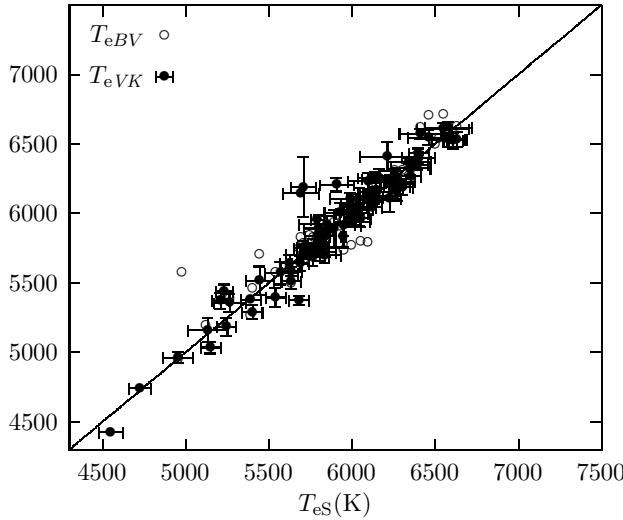

Figure 2. Effective temperatures of the target stars derived from fitting model colours to the observed colours $B - V$ (T_{eBV}) and $V - K$ (T_{eVK}) are plotted with respect to T_{eS} .

respectively. In Fig. 2, these effective temperatures are plotted with respect to T_{eS} . The three effective temperatures are in good agreement. Only in the case of two stars, namely KIC 10920273 and HD 146233, there is a large difference between T_{eVK} and T_{eS} . For most stars, the difference between T_{eVK} and T_{eS} , $\delta T_{eVK} = T_{eVK} - T_{eS}$, is as $-100 \text{ K} < \delta T_{eVK} < 100 \text{ K}$; few are out of this range. The results for T_{eBV} , $-150 \text{ K} < \delta T_{eBV} < 150 \text{ K}$, are similar, showing that T_{eVK} is in better agreement with T_{eS} than T_{eBV} .

We have already confirmed the presence of $\nu_{\min 1}$ and $\nu_{\min 2}$ in the observed oscillation frequencies of the Sun (BiSON data; Chaplin et al. 1999). It was unexpected to find two such minima in the oscillation frequencies of most of *Kepler* and *CoRoT* target stars. As an example $\Delta\nu$ - n diagram of 16 Cyg A (Metcalfe et al. 2012) is plotted for degrees $l = 0$ and 1 in Fig. 3. From data of both degrees, it was seen that $\min L$ corresponds to the mode with order $n = 16$. The order of the minima with high frequency for $l = 0$ is 21, and 20 for $l = 1$.

In Fig. 4, $\nu_{\min H}$ and $\nu_{\min L}$ from the observed oscillation frequencies of the target stars are plotted with respect to ν_{\max} . The most striking result is that for most, $\nu_{\min H}$ is greater than ν_{\max} while $\nu_{\min L}$ is lower than ν_{\max} . For the ANKI models (Paper I and II), the situation was found to be different: $\nu_{\min 1}$ is less than ν_{\max} if $M < 1.2M_{\odot}$, otherwise $\nu_{\min 1} > \nu_{\max}$. This inconsistency may arise from mismatch of the minima, i.e. $\min H$ may not be $\min 1$, and similarly $\min 2$ may not be $\min L$. Another possibility is that the ordering of these frequencies according to their values is model dependent (see below).

In $\Delta\nu$ - ν graph for the ANKI models (see figure 3 of Paper I), the depth around $\nu_{\min 1}$ is deeper than that of around $\nu_{\min 2}$ for $1.0 M_{\odot}$ models, and comparable to that of $\nu_{\min 2}$ for $1.2 M_{\odot}$ models. We notice considerable difference in the depths of $\min H$ and $\min L$ in $\Delta\nu$ - ν graph for observed oscillation frequencies. The depth of $\min H$ is in general much shallower than that of $\min L$. In figure 3 of Paper I, very clear shallow minima are seen in the high frequency ($\nu > \nu_{\min 1}$) range for the models with 1.1 and $1.2 M_{\odot}$.

Although the solar models constructed by using the ANKI code are in good agreement with the helioseismic data of the Sun, there are significant differences between asteroseismic data of the

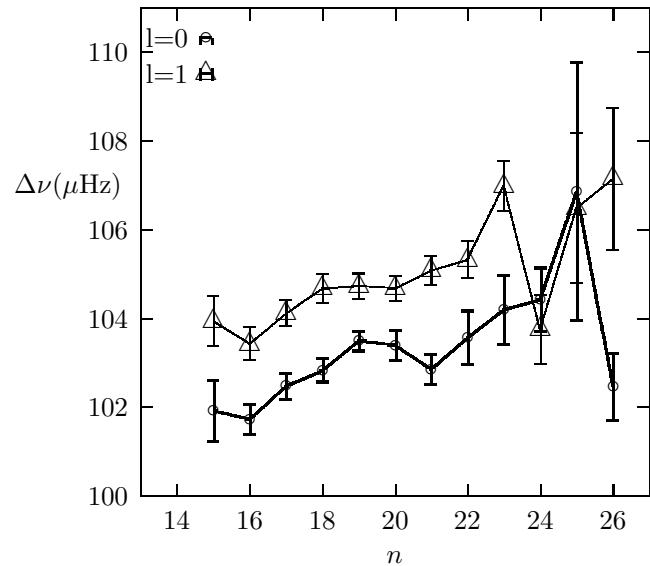

Figure 3. $\Delta\nu$ is plotted with respect to order n for the observed oscillation frequencies of 16 Cyg A (Metcalfe et al. 2012). The circle and triangle show the modes with $l = 0$ and $l = 1$, respectively. $\Delta\nu$ for $l = 1$ is shifted up $1.25 \mu\text{Hz}$ for a clear appearance. Two minima appear for $l = 0$; one is about $n = 16$ and the other is about $n = 21$. Notice that there are large scattering for the modes with $n > 23$. A similar scattering is seen in the early helioseismic data (see e.g. Grec, Fossat & Pomerantz 1983).

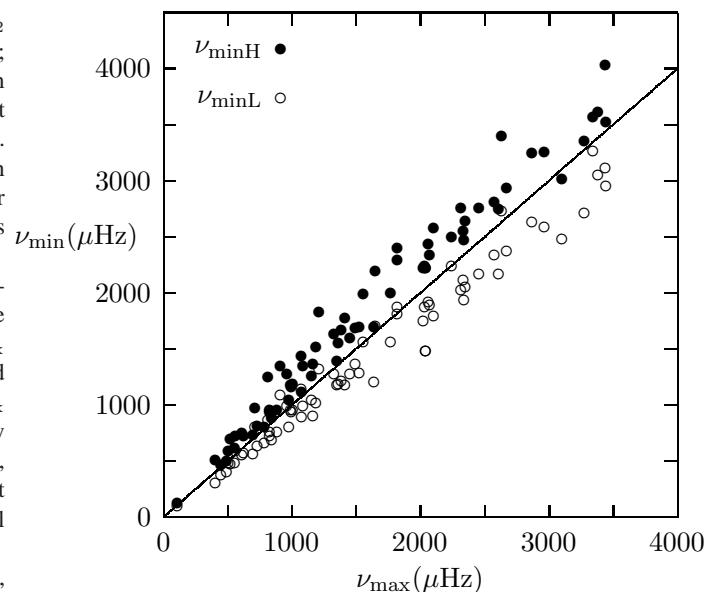

Figure 4. $\nu_{\min H}$ (filled circles) and $\nu_{\min L}$ (circles) of the observed frequencies are plotted with respect to ν_{\max} .

solar-like oscillating stars and models, at least for $\nu_{\min 1}$, $\nu_{\min 2}$ and ν_{\max} . Therefore, we construct new models using a different code, to make a comparison between their asteroseismic properties and the observed ones.

3 PROPERTIES OF MESA MODELS AND ROLE OF Γ_{1s} IN SCALING RELATIONS

Our results presented in Paper I and II are based on the ANKI models. It is important to test whether these results are code dependent. Furthermore, as emphasized above, there are large differences between models and the observed oscillation frequencies in terms of the relations between ν_{\max} and frequencies of minima. Therefore, we construct models by using the MESA evolution code (Paxton et al. 2011, 2013). As in the case of the ANKI models, we obtain solar values by fitting interior model to the Sun, then use these values to construct stellar models. The solar values for the MESA code for initial hydrogen abundance (X), Z and the mixing-length parameter (α) are $X = 0.70358$, $Z = 0.0172$ and $\alpha = 2.175$. As in the case of the ANKI models, we also construct models by using MESA for the mass range $0.8 M_\odot \leq M \leq 1.6 M_\odot$ and compute their adiabatic oscillation frequencies when the central hydrogen abundance (X_c) is approximately $X_c = 0.7, 0.53, 0.35$ and 0.17 .

In the construction of interior models with MESA, standard mixing-length theory (Böhm-Vitense 1958) was derived for convection treatment, whereas the effects of convective overshooting were not considered. MESA EOS tables were selected for equation-of-state, and OPAL opacity tables (Iglesias & Rogers 1993, 1996) were used in the high temperature region supplemented by the low-temperature tables of Ferguson et al. (2005). Nuclear reaction rates were taken from Angulo et al. (1999) with significant updates (Kunz et al. 2002; Cyburt et al. 2010). The element diffusion is used in MESA default option (see in detail Paxton et al. 2011) for the solar model only. As stellar atmosphere, we choose `simple_photosphere` in our models. Adiabatic oscillation frequencies were computed using ADIPLS oscillation package (Christensen-Dalsgaard 2008) in the MESA module.

It is important first to clarify which of the minima found in observed oscillation frequencies ($\nu_{\min H}$ and $\nu_{\min L}$) matches min1 or min2. In Fig. 5, both model (min1 and min2) and observed (minH and minL) frequencies of minima are plotted with respect to ν_{\max} . We notice that while $\nu_{\min 1}$ and $\nu_{\min 2}$ do not exactly match $\nu_{\min H}$ and $\nu_{\min L}$, $\nu_{\min L}$ and $\nu_{\min 1}$ are in good agreement for the majority of the data. Revisiting the $\Delta\nu-\nu$ graph of some models, we find the frequencies of shallower minima (see e.g. fig. 3 in Paper I). Frequencies ($\nu_{\min 0}$) of these minima (called as min0, in accordance with min1 and min2) are also plotted in Fig. 5. We confirm that $\nu_{\min H}$ corresponds $\nu_{\min 0}$, for most of the stars.

3.1 Why Γ_{1s} is important in scaling relations?

In asteroseismic studies, ν_{\max} (Brown et al. 1991) is taken as

$$\nu_{\max} \propto \frac{g}{\sqrt{T_{\text{eff}}}}. \quad (1)$$

ν_{\max} is assumed to be proportional to ν_{ac} (Lamb 1909; Balmforth & Gough 1990), given as

$$\nu_{\text{ac}} \sim \frac{c}{H} \left(1 - \frac{dH}{dr} \right), \quad (2)$$

where c and H are sound speed and pressure scale height at the stellar surface, respectively. dH/dr , gradient of H , has order about 10^{-4} and henceforth is negligibly small. If we insert the usual expressions for c and H in equation (2), we obtain

$$\nu_{\text{ac}} = \frac{g}{\sqrt{\mathfrak{R}T_{\text{eff}}}} \sqrt{\Gamma_{1s}\mu}. \quad (3)$$

where \mathfrak{R} is the multiplication of Boltzmann constant and Avagadro's number. It is clear that equation (1) is valid if Γ_{1s} and μ are

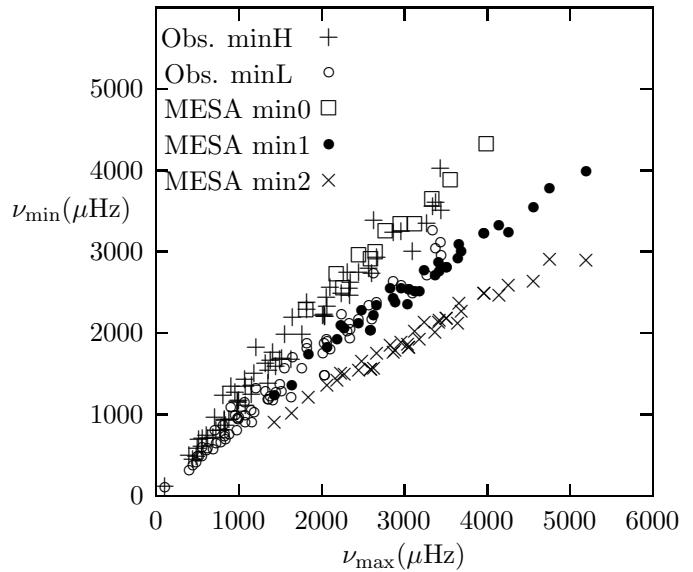

Figure 5. Comparison of model and observational frequencies of minima in $\Delta\nu-\nu$ graph. + and circle show observed oscillation frequencies of minH and minL, respectively. Square, filled circle and cross are for min0, min1 and min2 of model frequencies, respectively.

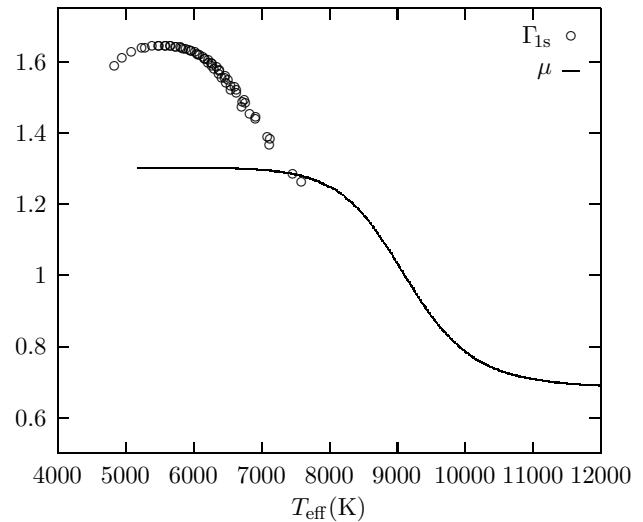

Figure 6. Γ_{1s} (circle) and μ (line) at the surface of interior models with respect to T_{eff} .

constant for the solar-like oscillating stars. We confirm below that this is the case.

In Fig. 6, Γ_{1s} and μ at the surface of interior models are plotted with respect to T_{eff} . For the cool stars, both hydrogen and helium are neutral and μ is about 1.3. μ decreases as hydrogen and helium are ionized. For the solar-like oscillating stars ($T_{\text{eff}} < 6900$ K), μ is constant in great extent. However, this is not the case for Γ_{1s} . Its maximum value is about 1.64 at about $T_{\text{eff}} = 5500$ K and it decreases for higher or lower T_{eff} values. The value of Γ_{1s} for the hottest solar-like oscillating stars is 1.25, nearly 30 per cent below the maximum value. Therefore, to improve the accuracy of the scaling relation, it is important to take into account variation of Γ_{1s} .

Γ_{1s} is a function of T_{eff} . We fit a parabolic function for $1/\Gamma_{1s}$

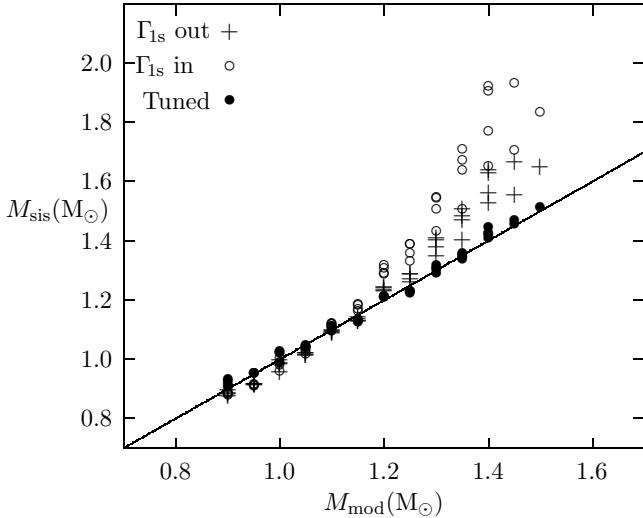

Figure 7. Comparison of asteroseismic masses computed from the customary scaling relation (+) and the new scaling relation (equation 5) with Γ_{1s} (circle). M_{sca} is plotted with respect to model mass in units of solar mass. For the tuned scaling relation (filled circle), see below (equation 9).

to the data shown in Fig. 6. The derived function is as

$$\frac{1}{\Gamma_{1s}} = 1.6 \left(\frac{T_{\text{eff}}}{T_{\text{eff}\odot}} - 0.96 \right)^2 + 0.607. \quad (4)$$

Equation (4) is very effective in representing Γ_{1s} for the cool stars in the (T_{eff}) range under consideration in this study. For red giants, for example, there might be a deviation. If we adopt that Γ_{1s} is not constant, we obtain new scaling relations for stellar mass (M''_{sca}) as

$$\frac{M''_{\text{sca}}}{M_{\odot}} = \frac{(\nu_{\text{max}}/\nu_{\text{max}\odot})^3}{(\langle \Delta\nu \rangle / \langle \Delta\nu_{\odot} \rangle)^4} \left(\frac{T_{\text{eff}}}{T_{\text{eff}\odot}} \frac{\Gamma_{1s\odot}}{\Gamma_{1s}} \right)^{3/2} \quad (5)$$

and for radius (R''_{sca}) as

$$\frac{R''_{\text{sca}}}{R_{\odot}} = \frac{(\nu_{\text{max}}/\nu_{\text{max}\odot})}{(\langle \Delta\nu \rangle / \langle \Delta\nu_{\odot} \rangle)^2} \left(\frac{T_{\text{eff}}}{T_{\text{eff}\odot}} \frac{\Gamma_{1s\odot}}{\Gamma_{1s}} \right)^{1/2}. \quad (6)$$

In Fig. 7, M''_{sca} and mass from conventional scaling relation (M'_{sca}) are plotted with respect to the model mass (M_{mod}) in solar units. Despite the substantial difference between M'_{sca} and M_{mod} in particular for the models with $M > 1.2 M_{\odot}$, the inclusion of Γ_{1s} has the effect of increasing the difference, contrary to expectations.

We also test the scaling relation for stellar radius in Fig. 8, in which R''_{sca} and radius from conventional scaling relation (R'_{sca}) are plotted with respect to R_{mod} in solar units. There is a significant difference between R'_{sca} and R_{mod} if $R > 1.2 R_{\odot}$, and the greater difference appears between R''_{sca} and R_{mod} . This implies that the inclusion of Γ_{1s} in equation (3) itself does not result in improvement in scaling relations, highlighting the need for a much more general approach (see below).

$\Gamma_{1s\odot}$, the solar value of Γ_{1s} , is taken as 1.639. The other solar quantities used in equations (4)-(6) are given at the end of Table A1.

In scaling relations, we use T_{es} in place of T_{eff} . In our analysis, we use T_{evk} for those seven stars for which no T_{es} is available in the literature.

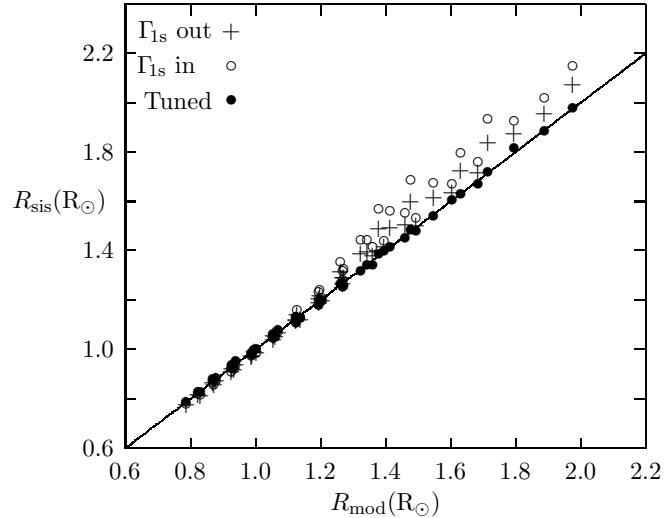

Figure 8. Comparison of asteroseismic radii computed from the customary scaling relation (+) and the new scaling relation (equation 6) with Γ_{1s} (circle). R_{sca} is plotted with respect to model radius in units of solar radius. For the tuned scaling relation (filled circle) for radius, see below (equation 10).

3.2 Tuning the scaling relations

It is reported in some studies (see e.g. White et al. 2011 and Sharma et al. 2016) that the relation between $\langle \Delta\nu \rangle$ and $\langle \rho \rangle^{1/2}$ deviates from a linear relation. In Fig. 9, the ratio of $\langle \Delta\nu \rangle / \langle \rho \rangle^{1/2}$ is plotted with respect to Γ_{1s} in solar units. There is a very clear linear relation between $\langle \Delta\nu \rangle / \langle \rho \rangle^{1/2}$ and Γ_{1s} . The fitting line is found as

$$\frac{\langle \Delta\nu \rangle / \langle \Delta\nu_{\odot} \rangle}{(\langle \rho \rangle / \langle \rho_{\odot} \rangle)^{1/2}} = f_{\Delta\nu} = 0.430 \frac{\Gamma_{1s}}{\Gamma_{1s\odot}} + 0.570, \quad (7)$$

where $f_{\Delta\nu}$ is defined as the ratio $\langle \Delta\nu \rangle / \langle \rho \rangle^{1/2}$ in solar units. The range of $f_{\Delta\nu}$ is about [0.95, 1.01]. In derivation of equation (7), we adopt $\langle \Delta\nu_{\odot} \rangle = 136 \mu\text{Hz}$. Thus, we obtain its solar value as unity: $f_{\Delta\nu\odot} = 1$. There are two important indicators for $\langle \Delta\nu_{\odot} \rangle = 136 \mu\text{Hz}$: i) The solar oscillation frequencies in Broomhall et al. (2009) yield the same value; ii) the maximum value of $\Delta\nu$ in between min1 and min2 is very close to 136 μHz . The latter point is important because this mode is the least effected, if not completely unaffected, by the He II ionization zone.

Understanding of the underlying physics of Γ_{1s} dependence of $\langle \Delta\nu \rangle / \langle \rho \rangle^{0.5}$ ratio can be achieved by comparing the solar model with a modified solar model (MSM). Suppose that Γ_{1s} in the most outer region of MSM is lower than $\Gamma_{1s\odot}$, otherwise identical to the solar model. In the outer region of MSM, sound travels more slowly than in the solar model. As speed is decreased in a part of the model, frequencies of all the modes decrease in accordance with the dispersion relation for sound waves. Radial nodes of MSM come to closer in the modified outer region and move away from each other in the unchanged interior regions. Although these two models have the same mean density, their oscillation frequencies are different. Oscillation frequency of MSM for a given mode (ν'_{nl}) is always less than that of the solar model ($\nu_{nl\odot}$): $\nu'_{nl} = q\nu_{nl\odot}$, where q is less than 1, depending on ratio of modified Γ_{1s} to $\Gamma_{1s\odot}$. Then, the large separation of MSM ($\Delta\nu'$) can be written as

$$\Delta\nu' = \nu'_{nl} - \nu'_{n-1,l} = q(\nu_{nl\odot} - \nu_{n-1,l\odot}) = q\Delta\nu_{\odot}.$$

This states that the ratio of $\Delta\nu'/\Delta\nu_{\odot}$ for the models with the same density is a function of the ratio ($\Gamma_{1s}/\Gamma_{1s\odot}$): $q = q(\Gamma_{1s}/\Gamma_{1s\odot})$.

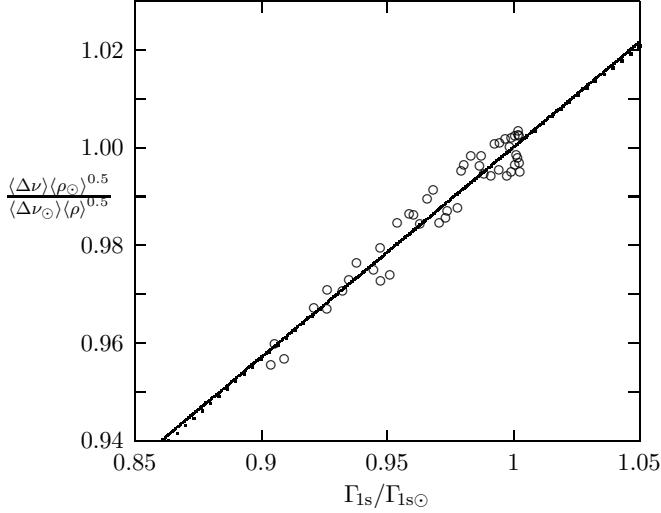

Figure 9. $\langle \Delta\nu \rangle / \langle \rho \rangle^{0.5}$ (in solar units) is plotted with respect to Γ_{1s} . The solid line is the fitted line $f_{\Delta\nu} = 0.43 \frac{\Gamma_{1s}}{\Gamma_{1s\odot}} + 0.57$. The fitted curve (dotted line) is $\left(\frac{\Gamma_{1s}}{\Gamma_{1s\odot}}\right)^{0.42}$. These two functions are equivalent to each other.

We know that ν_{ac} is also a function of Γ_{1s} . However, there is another underlying assumption for derivation of the scaling relations, which states that ν_{ac}/ν_{max} is constant. However, it seems reasonable to assume that

$$\nu_{max} = f_{\nu} \nu_{ac}, \quad (8)$$

where f_{ν} is a parameter to be determined. Then, we derive new scaling relations for mass (M_{sca}) and radius (R_{sca}) as

$$\frac{M_{sca}}{M_{\odot}} = \frac{(\nu_{max}/\nu_{max\odot})^3}{(\langle \Delta\nu \rangle / \langle \Delta\nu_{\odot} \rangle)^4} \left(\frac{T_{eff}}{T_{eff\odot}} \frac{\Gamma_{1s\odot}}{\Gamma_{1s}} \right)^{3/2} \frac{f_{\Delta\nu}^4}{f_{\nu}^3} \quad (9)$$

and

$$\frac{R_{sca}}{R_{\odot}} = \frac{(\nu_{max}/\nu_{max\odot})}{(\langle \Delta\nu \rangle / \langle \Delta\nu_{\odot} \rangle)^2} \left(\frac{T_{eff}}{T_{eff\odot}} \frac{\Gamma_{1s\odot}}{\Gamma_{1s}} \right)^{1/2} \frac{f_{\Delta\nu}^2}{f_{\nu}}, \quad (10)$$

respectively. If we plot f_{ν} in equation (9) by taking $M_{sca} = M_{mod}$, we find a linear relation between f_{ν} and $\Gamma_{1s\odot}/\Gamma_{1s}$:

$$f_{\nu} = 0.470 \frac{\Gamma_{1s\odot}}{\Gamma_{1s}} + 0.530. \quad (11)$$

If we plot f_{ν} in equation (10) by taking $R_{sca} = R_{mod}$, we find a very similar f_{ν} : $f_{\nu} = 0.456 \Gamma_{1s\odot}/\Gamma_{1s} + 0.543$. In our computations, equation (11) is used for f_{ν} . The maximum difference between R_{sca} (equation 10) and R_{mod} is about 1 per cent if f_{ν} is taken as in equation (11). The maximum difference between M_{sca} (equation 9) and M_{mod} is about 2 per cent. The range of f_{ν} is about [0.94, 1.0].

This indicates that Γ_{1s} is a hitherto neglected, but key factor in determining relations between asteroseismic and non-asteroseismic quantities. The parameters $f_{\Delta\nu}$ and f_{ν} , appearing in new scaling relations, are plotted in Fig. 10 with respect to T_{eff} . We insert expression (4) for Γ_{1s} in equations (7) and (11). This gives expressions for $f_{\Delta\nu}$ and f_{ν} as functions of T_{eff} . We notice that Γ_{1s} , $f_{\Delta\nu}$ and f_{ν} are approximately unity for the range 5200–5800 K. Outside this range, all deviate from unity, making conventional scaling relations much more uncertain.

M_{sca} and R_{sca} computed from equations (9) and (10) are also

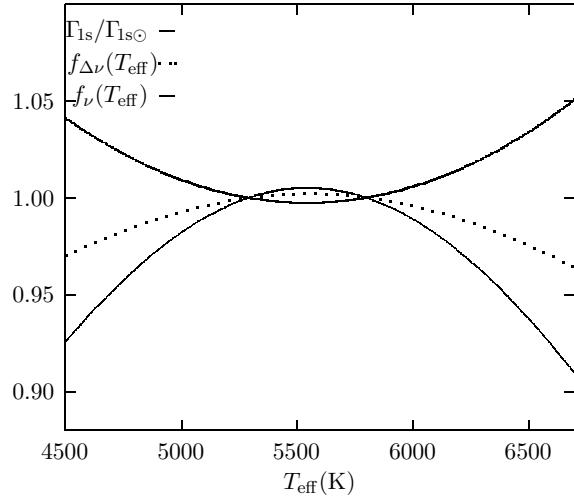

Figure 10. $\Gamma_{1s}/\Gamma_{1s\odot}$ (thin solid line), $f_{\Delta\nu}$ (dotted line) and f_{ν} (thick solid line) are plotted with respect to T_{eff} . Around $T_{eff} = 5500$ K, they all are about unity.

plotted in Figs. (7) and (8), respectively. Both of M_{sca} and R_{sca} are in very good agreement with model values.

Uncertainty in M_{sca} can be computed from uncertainties in ν_{max} , $\Delta\nu$ and T_{eff} :

$$\frac{\Delta M_{sca}}{M_{sca}} = 3 \frac{\Delta \nu_{max}}{\nu_{max}} + 4 \frac{\Delta \langle \Delta\nu \rangle}{\langle \Delta\nu \rangle} + 1.5 \frac{\Delta T_{eff}}{T_{eff}}. \quad (12)$$

Similarly, uncertainty in radius can be obtained from

$$\frac{\Delta R_{sca}}{R_{sca}} = \frac{\Delta \nu_{max}}{\nu_{max}} + 2 \frac{\Delta \langle \Delta\nu \rangle}{\langle \Delta\nu \rangle} + 0.5 \frac{\Delta T_{eff}}{T_{eff}}. \quad (13)$$

ΔM_{sca} and ΔR_{sca} are computed for the target stars are given in the second row of the two lines for each star in Table A1.

3.3 T_{eff} from model frequencies

In Paper I, for the first time, ANKI models were used to derive a relation between T_{eff} and $\Delta n_{x1} = (\nu_{max} - \nu_{min1})/\langle \Delta\nu \rangle$. Now we compute ν_{max} of the MESA models not from equation (1) but from the following new relation

$$\frac{\nu_{max}}{\nu_{max\odot}} = f_{\nu} \left(\frac{T_{eff\odot}}{T_{eff}} \frac{\Gamma_{1s\odot}}{\Gamma_{1s}} \right)^{1/2} \frac{g}{g_{\odot}}. \quad (14)$$

For the MESA models, the relation between T_{eff} and Δn_{x1} is plotted in Fig. 11. From this relation, we obtain

$$\frac{T_{sis1}(\Delta n_{x1})}{T_{eff\odot}} = 1.157 - 1.093 \times 10^{-9} (\Delta n_{x1} + 15)^{6.4}. \quad (15)$$

The maximum difference between T_{sis1} from equation (15) and model T_{eff} is generally less than 100 K.

Similarly, we derive fitting formula for effective temperatures in terms of $\min0$ (T_{sis0}) and $\min2$ (T_{sis2}) frequencies (see Fig. 11), more precisely, $\Delta n_{x0} = (\nu_{max} - \nu_{min0})/\langle \Delta\nu \rangle$ and $\Delta n_{x2} = (\nu_{max} - \nu_{min2})/\langle \Delta\nu \rangle$;

$$\frac{T_{sis0}(\Delta n_{x0})}{T_{eff\odot}} = 1.127 - 3.339 \times 10^{-9} (\Delta n_{x0} + 20)^6 \quad (16)$$

and

$$\frac{T_{sis2}(\Delta n_{x2})}{T_{eff\odot}} = 1.179 - 4.049 \times 10^{-9} (\Delta n_{x2} + 10)^6. \quad (17)$$

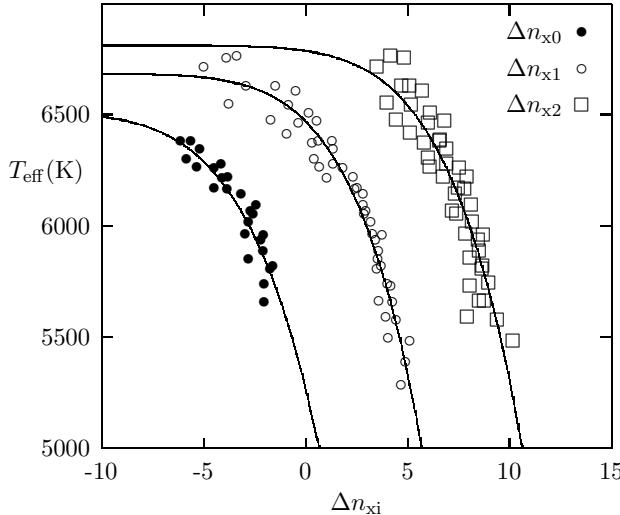

Figure 11. Effective temperature is plotted with respect to Δn_{x0} (filled circles), Δn_{x1} (circles) and Δn_{x2} (squares). The fitting curves are given in equations (15)-(17).

Expression for typical uncertainty in $T_{\text{sis}0}$ can be obtained from equation (16) as

$$\frac{\Delta T_{\text{sis}0}}{T_{\text{eff} \odot}} = 2.0 \times 10^{-8} (\Delta n_{x0} + 20)^5 \frac{\Delta \nu_{\max} + \Delta \nu_{\min 0}}{\langle \Delta \nu \rangle}. \quad (18)$$

In a similar manner, expressions for uncertainties in $T_{\text{sis}1}$ and $T_{\text{sis}2}$ are derived from equations (15) and (17), respectively.

4 RESULTS AND DISCUSSIONS

4.1 Effective temperatures of the target stars

In the previous section, effective temperature was shown to be a function of order difference between the minima in $\Delta\nu$ - ν graph and ν_{\max} . Computations of $T_{\text{sis}0}$, $T_{\text{sis}1}$ and $T_{\text{sis}2}$ of the target stars using equations (15)-(17) are listed in Table A1. $T_{\text{sis}0}$, $T_{\text{sis}1}$ and $T_{\text{sis}2}$ are plotted with respect to T_{eS} in Fig. 12. In general, there is a very close agreement between asteroseismic $T_{\text{eff}S}$ ($T_{\text{sis}0}$, $T_{\text{sis}1}$ and $T_{\text{sis}2}$) and T_{eS} . However, a discrepancy occurs between T_{eS} and $T_{\text{sis}1}$ in the case where $T_{\text{eS}} < 5500$ K. $\text{min}2$ is only seen in $\langle \Delta \nu \rangle$ - ν graph of very hot solar-like oscillating stars. Therefore, it was only possible to find $T_{\text{sis}2}$ for 15 stars.

For some stars, there is a systematic difference between asteroseismic and non-asteroseismic $T_{\text{eff}S}$. In some cases, such as KIC 3427720, KIC 3544595 and KIC 5866724, T_{eS} is greater than both $T_{\text{sis}0}$ and $T_{\text{sis}1}$, therefore, the values of ν_{\max} should be decreased to fit $T_{\text{sis}0}$ to T_{eS} . For some targets (for example KIC 3424541, KIC 6679371 and KIC 7799349), however, T_{eS} is less than both of $T_{\text{sis}0}$ and $T_{\text{sis}1}$. In this case, ν_{\max} might be increased to fit $T_{\text{sis}0}$ to T_{eS} . This method will be considered in the next paper of this series.

For the Sun, the results are very impressive; the mean effective temperature from $\text{min}0$, $\text{min}1$ and $\text{min}2$ was obtained as 5804 ± 60 K. This value is very close to observed effective temperature of the Sun (5777 K), with very low standard deviation. Since there is no calibration of asteroseismic relations for effective temperature (equations 15-17), this finding alone shows the great value of asteroseismic tools.

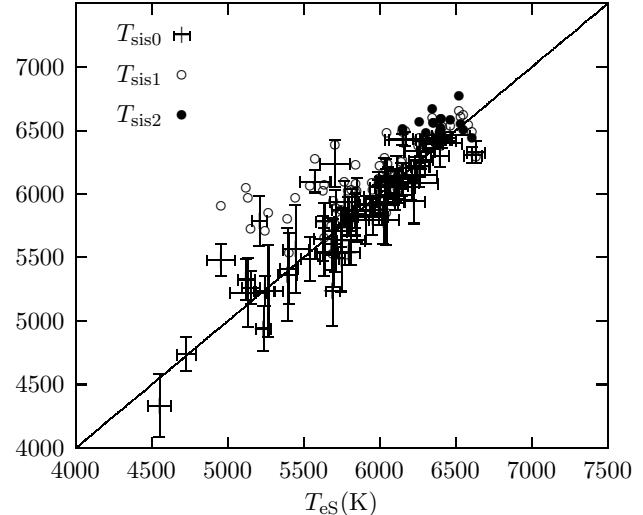

Figure 12. Effective temperatures of the target stars obtained by using oscillation frequencies are plotted with respect to T_{eS} .

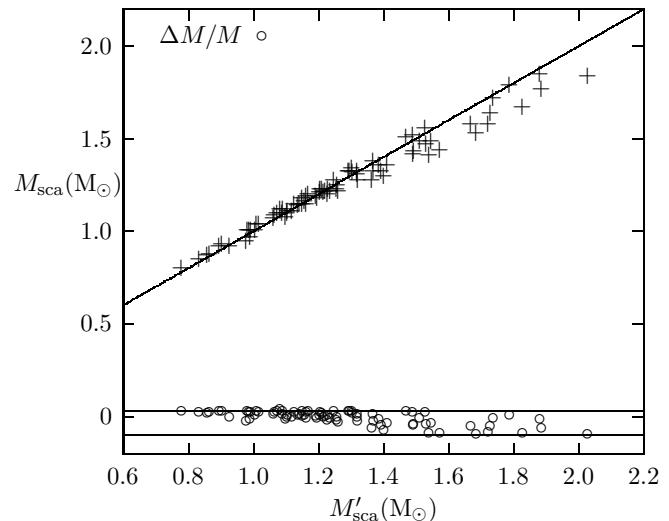

Figure 13. Mass of target stars computed by using the tuned scaling relation (equation 9) is plotted with respect to mass from the conventional scaling relation.

4.2 Masses and radii

In Fig. 13, M_{sca} (equation 9) is plotted with respect to M'_{sca} . Also shown in Fig. 13 is the fractional difference between M_{sca} and M'_{sca} . The horizontal solid lines are for 0.03 and -0.10. For $M < 1.3 M_{\odot}$, M_{sca} is nearly 3 per cent greater than M'_{sca} . For $M > 1.3 M_{\odot}$; however, the difference between M_{sca} and M'_{sca} does not rise above 10 per cent.

M_{sca} , M'_{sca} , R_{sca} and R'_{sca} are listed in Table A1, together with the masses (M_{lit}) and radii (R_{lit}) of the target stars compiled from the literature. M_{lit} and R_{lit} were found by constructing interior models of the target stars, except Procyon A. The mass and radius of Procyon A given in Table A1 were obtained from observations (see Section 4.3). In Fig. 14, fractional mass difference between mass found from new scaling relation and mass from the literature, $\Delta M/M = (M_{\text{lit}} - M_{\text{sca}})/M_{\text{sca}}$, is plotted with respect to fractional radius difference, $\Delta R/R = (R_{\text{lit}} - R_{\text{sca}})/R_{\text{sca}}$. This figure shows that the maximum difference between R_{sca} and R_{lit}

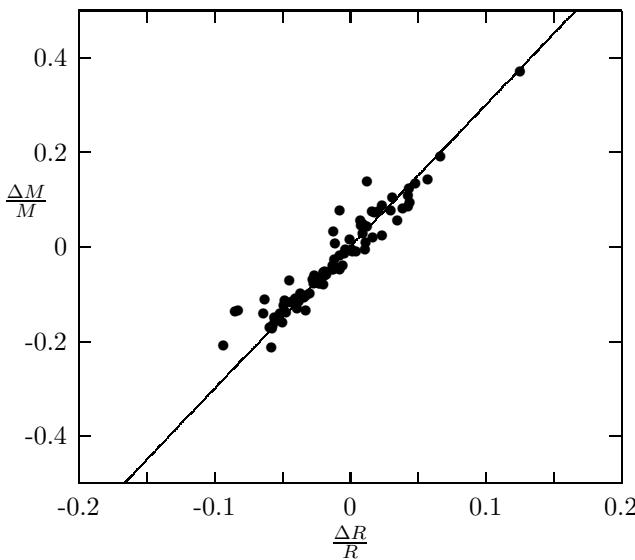

Figure 14. Fractional mass difference is plotted with respect to fractional radius difference. The solid line represents $\Delta M/M = 3\Delta R/R$.

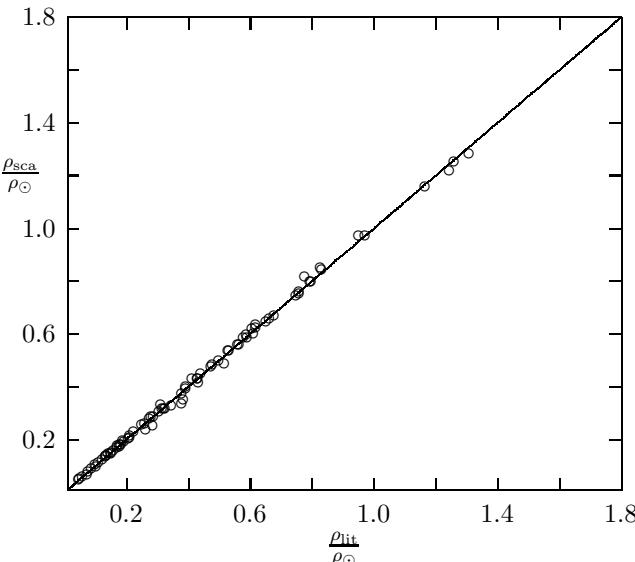

Figure 15. ρ_{sca} is plotted with respect to ρ_{lit} .

is about 10 per cent, and is about 25 per cent for the mass. More crucially, it can be seen that there is a linear relation between the fractional mass and radius: $\Delta M/M = 3\Delta R/R$, implying that the density of the models are the same as that of given by $M_{\text{sca}}/R_{\text{sca}}^3$. This result arises from the fact that oscillation frequency of a given mode depends on mean stellar density, and may imply that density is indeed the fitted parameter in the calibration process of model frequencies to the observed oscillation frequencies. In that case, it is possible that different combinations of M and R yield the same density. In Fig. 15, $\rho_{\text{sca}}/\rho_{\odot} = M_{\text{sca}}/R_{\text{sca}}^3$ is plotted with respect to $\rho_{\text{lit}}/\rho_{\odot} = M_{\text{lit}}/R_{\text{lit}}^3$ (masses and radii are in solar units). Despite the significant differences between the masses and the radii (Fig. 14), the densities ρ_{sca} and ρ_{lit} are in very good agreement. Therefore, our further research will address the need for further constraints, such as frequencies of minimum $\Delta\nu$, when applying asteroseismic methods for finding fundamental properties of stars.

4.3 Comparison with masses and radii from non-asteroseismic measurements

Asteroseismic and non-asteroseismic effective temperatures of the Sun are compared above. Among the stars focused on, Procyon A is only star for which mass and radius are found by non-asteroseismic methods. Its mass was obtained by Bond et al. (2015) as $1.478 \pm 0.012 M_{\odot}$, and its radius was found as $2.03 \pm 0.013 R_{\odot}$ (Audouze, Ludwig & Kervella, 2005). Conventional scaling relations give mass and radius as $1.63 M_{\odot}$ and $2.14 R_{\odot}$, respectively. Results from the new scaling relations for these two quantities are $1.46 M_{\odot}$ and $2.03 R_{\odot}$, respectively, very close to the observed values, showing the effectiveness of these new relations.

Another non-asteroseismic observational result for testing asteroseismic methods of the present study pertains to HD 181907. Its radius, found by interferometric methods, is $12.1 \pm 0.5 R_{\odot}$ (Baines et al. 2014), and its literature value is $12.93 \pm 0.95 R_{\odot}$ (Ghezzi & Johnson 2015). The old and new scaling relations, however, yield 12.91 and $12.42 R_{\odot}$, respectively. Again, the radius from the new scaling relation is in very good agreement with the interferometric radius.

5 CONCLUSIONS

Asteroseismology of solar-like oscillating stars provides information about fundamental properties of these stars through the scaling relations. In these relations it is assumed that the first adiabatic exponent Γ_{1s} is constant. However, analysis of our models constructed by the MESA code shows that Γ_{1s} significantly changes through the surfaces of solar-like oscillating stars, depending on effective temperature. Furthermore, the ratio of the mean large separation $\langle \Delta\nu \rangle$ to $\langle \rho \rangle^{0.5}$, which is customarily assumed to be constant, is a linear function of Γ_{1s} . Thus, it seems that Γ_{1s} is the factor in scaling relation that has previously been overlooked.

In contrast to the literature, we do not consider the ratios of $\nu_{\text{ac}}/\nu_{\text{max}}$ and $\nu_{\text{ac}}/(g/T_{\text{eff}}^{0.5})$ as constant. We show that these ratios can also be taken as functions of Γ_{1s} . Then, we revise the scaling relations and obtain new relations for stellar mass and radius (equations 9 and 10), and then compute mass and radius of *Kepler* and *CoRoT* targets (89 stars + the Sun) using their asteroseismic properties. A difference of up to 10 per cent exists between the masses from new and old scaling relations. However, the great part of the uncertainties in mass and radius found from scaling relations comes from uncertainty in ν_{max} .

When mass and radius obtained from scaling relations are compared with those available in the literature, significant differences are seen. The fractional differences between the masses are up to $\Delta M/M = 0.25$ and $\Delta R/R = 0.10$. Particularly noteworthy, however, is the linear relation between $\Delta M/M$ and $\Delta R/R$: $\Delta M/M = 3\Delta R/R$ (see Fig. 14), highlighting that the fitted parameter is indeed mean density when oscillation frequencies of interior models are fitted to the observed oscillation frequencies.

We also computed effective temperatures of these stars using purely asteroseismic methods. In our previous paper (Paper I), the effective temperature of models was shown to be a function of Δn_{x1} , which is approximately the order difference between the frequencies of maximum amplitude and min1 in the $\Delta\nu - \nu$ graph. Taking into account the effect of Γ_{1s} , we derive new relations between T_{eff} and Δn_{x1} by using the MESA models. Similar expressions are obtained for Δn_{x0} and Δn_{x2} . This allows us in principle to use three different methods to compute T_{eff} in terms of the

oscillation frequencies of the target stars. These effective temperatures ($T_{\text{sis}0}$, $T_{\text{sis}1}$ and $T_{\text{sis}2}$; see equations 15-17) are in general in very good agreement within themselves and with T_{eff} from conventional methods. A significant difference appears between $T_{\text{sis}1}$ and T_{eS} for cool stars, but not for the Sun, for example. The value of these new approaches lies in the increased number of methods they allow for computing the effective temperature of a solar-like oscillating star. The six methods consist of three asteroseismic, one spectroscopic and two photometric methods.

In principle, we can compute the fundamental stellar parameters by purely asteroseismic quantities, provided that the oscillation frequencies are precisely determined. The solar effective temperature is found as 5742, 5831 and 5840 K from frequencies of min0, min1 and min2, respectively. All of these values are very close to $T_{\text{eff}\odot}$. Another key result we obtain is about Procyon A. Its mass is determined by using astrometric data from *Hubble Space Telescope* as $1.478 \pm 0.012 M_{\odot}$. While the conventional scaling relation yields $1.63 M_{\odot}$, the new scaling relation gives a much more accurate figure, $1.46 M_{\odot}$.

However, in some cases, we confirm that there are systematic differences between asteroseismic and non-asteroseismic effective temperatures. These differences can be reduced or eliminated by increasing or decreasing ν_{max} . Such a modification, critical for obtaining more precise mass and radius from the scaling relations, will be the subject of our next paper.

APPENDIX A: BASIC ASTEROSEISMIC AND NON-ASTEROSEISMIC PROPERTIES OF KEPLER AND COROT TARGETS

Table A1: Basic properties of target stars. Columns are organized as star name, frequency of maximum amplitude, reference frequencies for min0, min1 and min2, mean large and small separations between oscillation frequencies, effective temperatures (from spectra, $V - K$ and $B - V$ colours (see Section 2) and from minima min0, min1 and min2 (see Section 3), respectively), masses and radii (from new and conventional scaling relations (see Section 3) and from literature, respectively), surface gravities (from new and conventional scaling relations (see Section 3), and from spectra, respectively), and numbers of references. Second row describes uncertainties of these basic properties. Unlike others, for Procyon A, mass and radius are the observed values, not the model values in the literature. Since T_{eS} , T_{eVK} and T_{eBV} of KIC 11771760 are not available, we use T_{sis0} in scaling relations. The Sun is given at the end of the table.
