## Abstract

We report the measurement of the  $1^1\Sigma \rightarrow 2^1\Sigma$  transition of  $\text{CaH}^+$  by resonance-enhanced photodissociation of  $\text{CaH}^+$  that is co-trapped with laser-cooled  $\text{Ca}^+$ . We observe four resonances that we assign to transitions from the vibrational  $v=0$  ground state to the  $v'=1-4$  excited states based on theoretical predictions. A simple theoretical model that assumes instantaneous dissociation after resonant excitation yield results in good agreement with the observed spectral features except for the unobserved  $v'=0$  peak. The resolution of our experiment is limited by the mode-locked excitation laser, but this survey spectroscopy enables future rotationally resolved studies with applications in astrochemistry and precision measurement.<sup>1</sup>

## 1 Introduction

The spectroscopy of cold trapped ions is an important tool for the determination of molecular species in the interstellar medium [1, 2] and the precise measurement of fundamental physical constants [3, 4, 5]. Application of methods from the laser-cooling of atomic ions has led to new advances in taming both external and internal quantum states of trapped molecular ions. The new techniques have allowed for the sympathetic sideband cooling of motional modes to the ground state [6, 7], preparation of the rotational ground state [8, 9, 10], and the non-destructive probing of rotational states [11]. The large rotational constants

ChemPhysChem, online, (2016), which has been published in final form at DOI: [10.1002/cphc.201600645](https://doi.org/10.1002/cphc.201600645). This article may be used for non-commercial purposes in accordance with Wiley Terms and Conditions for Self-Archiving.

of diatomic hydrides [9, 10, 8, 12] which slows blackbody rethermalization after rotational cooling combined with the availability of atomic coolants of similar masses make these molecular ions particularly well-suited to high precision spectroscopy measurements. Homonuclear diatomic molecular ions allow almost complete decoupling from blackbody radiation and are also a promising route towards tests of fundamental constants [13, 14, 15].

The detection of neutral CaH radicals in sun spots [16] suggests possible solar presence of CaH<sup>+</sup>. However, the spectroscopy vital to the detection of this molecular ion has been absent in contrast to other neutral metal hydrides. Short storage times and weak absorption and dispersion signals [17] pose intrinsic challenges to molecular beam spectroscopy, a limitation that has contributed to the lack of experimental data on CaH<sup>+</sup>. Within the last few decades, new trapping and laser-cooling techniques have made it possible to generate metal hydride ions with quantum state-controlled chemical reactions between laser-cooled trapped atomic ions and molecular hydrogen [18, 19, 20]. These techniques have created a new opportunity for the spectroscopy of CaH<sup>+</sup> with the observation of a dissociative electronic transition [21] and ground state vibrational overtones [22].

Apart from being of astronomical interest, CaH<sup>+</sup> has much potential as a candidate for testing the time variation of fundamental physical constants. Vibrational and rotational transitions in molecules have different dependencies on the electron-to-proton mass ratio,  $\sqrt{m_e/m_p}$  and  $m_e/m_p$ , respectively [23, 24, 25]. By comparing these transitions within one system, many systematic errors can be canceled. It has been previously proposed that the uncertainty in rovibrational frequency measurement in CaH<sup>+</sup> is on the order of the predicted astronomical time variation of  $m_e/m_p$  [26].

Despite the lack of experimental data, CaH<sup>+</sup> spectroscopy has been the subject of many previous theoretical studies. *Ab initio* calculations of vibrational dipole moments of metal hydrides [27] by Abe *et al.*, and subsequent calculations of potential energy curves of the electronic ground and excited states of the CaH<sup>+</sup> [3, 28] have offered theoretical guidance for our experiments. We report our measurement of the  $1^1\Sigma \rightarrow 2^1\Sigma$  vibronic transitions by resonance enhanced dissociation between 370 nm and 421 nm.

## 2 Experiment

The ion trap used in this experiment was previously described in Ref. [29]. The experiment takes place in a spherical octagon vacuum chamber (Kimball Physics MCF800-SphOct-G2C8) with eight viewports used for electrical connections and optical access. Low DC voltages (0 - 10V) applied to all eleven pairs of DC electrodes weakly confine the ions in the axial direction, and a RF voltage of 210 V oscillating at 19.35 MHz traps ions radially. 397 nm and 866 nm lasers Doppler cool the ions axially and radially. Figure 1 outlines the transitions used for Doppler cooling Ca<sup>+</sup> ions.

Photoionization of sublimed neutral Ca allows the trapping of a few hundred

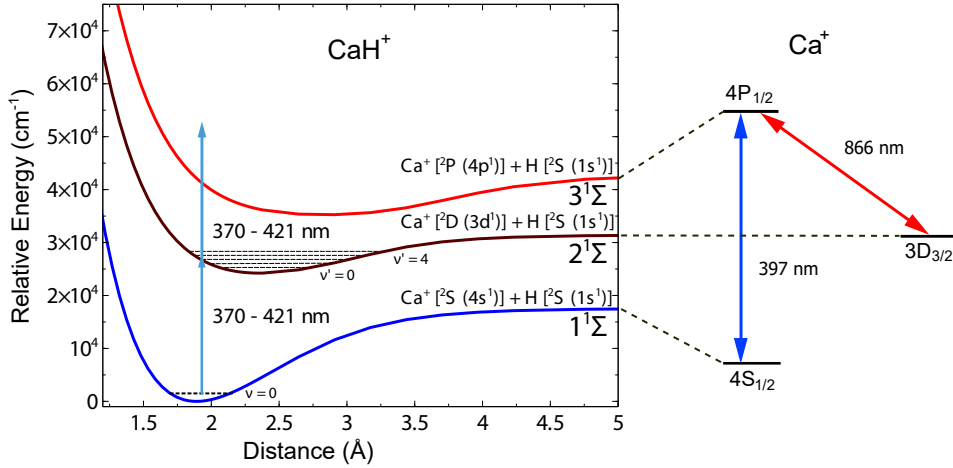

Figure 1: The three lowest  $1^1\Sigma$  potential energy curves for  $\text{CaH}^+$  are shown [3]. We measure vibrational lines using resonance enhanced dissociation. The first photon excites the molecules on the  $1^1\Sigma \rightarrow 2^1\Sigma$  transition. A second photon could then dissociate the ion. The atomic asymptotes of the plotted molecular potentials lead to  $\text{Ca}^+$  in different electronic states and H in the ground state. A simplified  $\text{Ca}^+$  energy level diagram shows the states involved in Doppler cooling and how they correspond to the limits of the molecular states (energy not to scale). The 397 nm laser is the main Doppler cooling laser and the 866 nm laser repumps the metastable  $D_{3/2}$  state.

$\text{Ca}^+$  ions. Addition of  $\text{H}_2$  gas to the vacuum chamber through a manual leak valve promotes the formation of  $\text{CaH}^+$  through photo-activated reactions between  $\text{Ca}^+$  and  $\text{H}_2$ . Upon addition of hydrogen gas, the pressure in the chamber goes from  $1.2 \times 10^{-10}$  Torr to around  $3 \times 10^{-8}$  Torr. At these pressures, decrease in fluorescence on the photomultiplier tube (PMT) (Hamamatsu H7360-02) accompanied by the darkening of a large part of the Coulomb crystal on the CCD camera (Princeton Instruments Cascade 1K) indicates 50 to 100 reactions within a few minutes. The molecular ions are excited using a frequency-doubled Ti:sapphire laser. We achieve a 10% efficiency in laser power after doubling the IR beam through a 0.1 mm thick Foctek BBO crystal. The doubled beam enters along the trap axis, and dissociation of the molecular ions is detected by the increase in fluorescence, as well as the reappearing of the bright  $\text{Ca}^+$  ions.

The frequency-doubled Ti:sapphire is tuned between 370 and 421 nm. Theoretical calculations predicted [3, 28] that the  $1^1\Sigma \rightarrow 2^1\Sigma$  transition would occur in this range, Figure 1. The bandwidth of pulses is measured for different wavelengths by an Ocean Optics spectrometer (model HR2000+) and corresponds to a pulse length of 300 fs. The power is maintained at 20 mW for all wavelengths.

We measured the spectrum by repeatedly exciting the ions for 400  $\mu\text{s}$  before

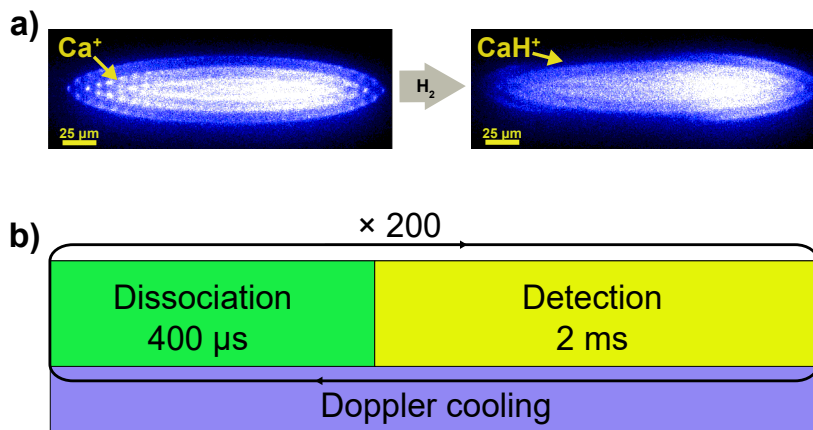

Figure 2: a) Coulomb crystal containing a few hundred  $\text{Ca}^+$  ions react with  $\text{H}_2$  to make 50 to 100  $\text{CaH}^+$  ions. The reaction is indicated by the darkening of the left side of the crystal. The asymmetry seen in the Coulomb crystal is due to the 397 nm radiation pressure on  $\text{Ca}^+$  ions. b) The pulse sequence used to dissociate the molecular ions is shown. The Doppler cooling lasers remain on to avoid ion heating and losses. An AOM switches the dissociation beam.

detecting the fluorescence on the PMT for 2 ms as shown in Figure 2. The photon count is recorded as a function of time and the data is fit to a first order reaction rate equation to deduce the dissociation rate:

$$A_t = A_\infty - (A_\infty - A_0)e^{-\Gamma(\lambda)t}, \quad (1)$$

where  $A_t$  is the fluorescence at time  $t$ ,  $A_\infty$  is the steady-state fluorescence after dissociation,  $\Gamma(\lambda)$  is the wavelength dependent rate, and  $A_0$  is the initial fluorescence. An acoustic-optical modulator (AOM) switches the excitation beam on and off, but the wavelength is scanned manually. Figure 3 shows example fluorescence data for two different excitation wavelengths.

### 3 Results and discussion

The spectrum acquired is based on the dissociation rate and we measured the four vibronic transitions shown in Figure 4. Every single point is an average of five measurements. These rates are repeatable for every wavelength with low standard deviation between experiments as shown in the plot. To avoid variations in raw fluorescence data, we preferred using larger crystals than ion chains with the dissociation beam aligned along the axis of the trap for more homogeneous dissociation across the crystal. Future single-molecule experiments could be performed in the same fashion as in Ref. [22].

Figure 3: The measured fluorescence recovery curves for excitation at 395.5 nm and 397 nm are shown. The data is fit with a single exponential (Equation 1) and the fluorescence is normalized to the steady-state fluorescence parameter,  $A_\infty$ , from the fit.

$v'$	CASPT2 [30]	$\nu_{0v'}$ CPP-CI [31]	Experiment
0	23887	23826	(23828)
1	24674	24594	$24624 \pm 13$
2	25449	25330	$25399 \pm 19$
3	26206	26067	$26156 \pm 14$
4	26942	26782	$26891 \pm 6$

Table 1: Comparison of experimentally measured vibronic transition frequencies,  $1 \ ^1\Sigma(v = 0) \rightarrow 2 \ ^1\Sigma(v')$ , and theoretical calculations. Experimental peaks were assigned based on agreement with theoretical predictions. With this assignment, the transition to  $v' = 0$  was not measured and the experimental value is extrapolated from the measured peaks (Equation 5)

Figure 4: The dissociation rate as a function of excitation wavelength. The error bars are standard deviations over the five measurements. A model that assumes the dissociation rate is limited by the absorption of the first photon is used to plot the theoretical curves and to find the experimental fit. The theory model is based on CASPT2 [31] but all peaks are red shifted by a constant  $50 \text{ cm}^{-1}$ .

We assigned peaks based on theoretical predictions in the literature using a complete-active-space approach (CASPT2) [30] and a core pseudopotential - configuration interaction approach (CCP-CI) [31]. The CASPT2 transition frequencies are blue-shifted and the CCP-PI transition frequencies are red-shifted relative to the data, Table 1. The CASPT2 predicted transition frequencies differed from the measured transition frequencies by a consistent  $\approx 50 \text{ cm}^{-1}$ , which is well within the expected theoretical error based on differences between the calculated asymptotes and the measured atomic spectra of  $\approx 100 \text{ cm}^{-1}$  [32]. The difference between the CPP-CI transitions and the measured transitions was less consistent and varied between 30 and  $110 \text{ cm}^{-1}$ . Using this assignment, the  $1^1\Sigma, \nu = 0 \rightarrow 2^1\Sigma, \nu' = 0$  transition was not observed. The experimental peaks showed the expected asymmetry for a system with a smaller rotational constant in the excited state.

### 3.1 Theoretical model for estimation of experimental parameters

In order to determine the bare vibrational frequency, we modeled our predicted spectra assuming the ion starts in the ground electronic and vibrational state, but a thermal distribution of rotational states. We truncate the rotational states at  $J = 15$  which is expected to only have a population of 0.003% at room temperature. We then calculate the excitation rate using Einstein B coefficients and the spectral density of the doubled Ti:Sapphire. The molecular ion is assumed to instantaneously dissociate after it is excited to the  $2^1\Sigma$  state.

The rate is calculated as the sum of individual rotational absorption rates multiplied by the thermal probability of being in that state:

$$\Gamma(\lambda) = \sum_{J,v',J'} B_{0,J,v',J'}(\lambda)p(0, J) \quad (2)$$

where  $B$  is the Einstein stimulated absorption coefficient when the laser is at wavelength  $\lambda$  and  $p(0, J)$  is the probability of being in the ground vibrational state with the rotational state  $J$  assuming a Boltzmann distribution. The Einstein B coefficient is given by:

$$B_{0,J,v',J'}(\lambda) = \frac{I_\lambda(f)}{c} \frac{A_{x,0}}{8\pi\hbar f^3}, \quad (3)$$

where  $I_\lambda(f)$  is the intensity of laser at frequency  $F$ ,  $f$  is the transition frequency from  $1^1\Sigma, v = 0, J \rightarrow 2^1\Sigma, \nu', J'$ , and  $A_{v',J',0,J}$  is the Einstein A coefficient. Each Einstein A is calculated as:

$$A_{v',J',0,J} = \frac{16\pi^3 S(J, J')}{3\epsilon_0\hbar} f^3 \mu_{v',0}^2, \quad (4)$$

where  $J$  is the ground state rotational quantum number,  $S(J, J')$  is Hönl-London factor for a rotational transition  $J \rightarrow J'$ , and  $\mu$  is the transition dipole moment.

The data for the laser profile was determined by measurement and fitting to a Gaussian profile. The rotational constants for the excited vibronic levels were calculated using the LEVEL8.2 program [33] and the potential energy surfaces of Ref. [30]. All other constants were provided by [30]. Initially, nearly all molecular ions are in the vibronic ground state which means only the  $\nu = 0$  vibrational state is needed for calculations.

Figure 4 shows the expected theoretical plots for the CASPT2 with a  $50 \text{ cm}^{-1}$  red shift. One observes quantitative agreement with the experimental peak positions and almost quantitative agreement with the peak heights with the notable exception of the  $\nu' = 0$  state. Our hypothesis is that this is due to the second part of the dissociation process which needs to be further investigated.

To find our experimental fit, we set the rotational constants to the theoretical values and allow the vibrational transition frequency and dipole matrix element (which controls the peak height) to vary. The nonlinear regression was done by applying Nelder-Mead Minimization Algorithm [34] to the  $\chi^2$  value using a C++ library [35]. This yields our experimentally determined transition frequencies (Table 1).

### 3.2 Experimental spectroscopic constants

From our experimental calculation, we determine the anharmonicity constant ( $\omega_e x_e$ ) of the molecular ion in the  $2^1\Sigma$  state. We fitted both the theoretical vibronic frequencies and our measured spectra to the following equation to determine  $\omega_e x_e$  as shown in Figure 5:

$$\nu_{0\nu'} = \nu_{00} + \omega_e \nu' - \omega_e x_e \nu'(\nu' + 1), \quad (5)$$

where  $E(n)$  is the total vibronic energy, and  $\nu_{00}$  is the energy of the  $\nu = 0 \rightarrow \nu' = 0$  transition; and  $\omega_e$  is the harmonic constant for the  $2^1\Sigma$  state. The theoretical vibronic frequencies used in the fit are from Ref. [30]. Table 2 shows our calculated value for the  $\omega_e x_e$  and how it compares to the CASPT2 theoretical results. The fit in Figure 5 yielded a value of  $10.0 \pm 0.2 \text{ cm}^{-1}$  for the anharmonicity constant, which is similar to the deduced theoretical prediction of  $8.6 \pm 0.3 \text{ cm}^{-1}$ . The harmonic constant turned out to be  $815.8 \pm 1.3 \text{ cm}^{-1}$ ; comparable to the theoretical value of  $807 \pm 1.7 \text{ cm}^{-1}$ . This value also matches the most recent calculations by Aymar and Dulieu [28]. Furthermore, the fit in Figure 5 predicts the  $\nu_{00}$  frequency to be  $23828 \pm 1.2 \text{ cm}^{-1}$  but we did not observe a signal at this frequency.

Our results are a step closer to the implementation of rotational cooling on  $\text{CaH}^+$  as well as quantum logic spectroscopy on rovibrational transitions in the molecule.

## 4 Conclusions

We have measured the vibronic spectrum of the  $1^1\Sigma \rightarrow 2^1\Sigma$  transition in  $\text{CaH}^+$  using resonance enhanced dissociation. The observed peaks were assigned based

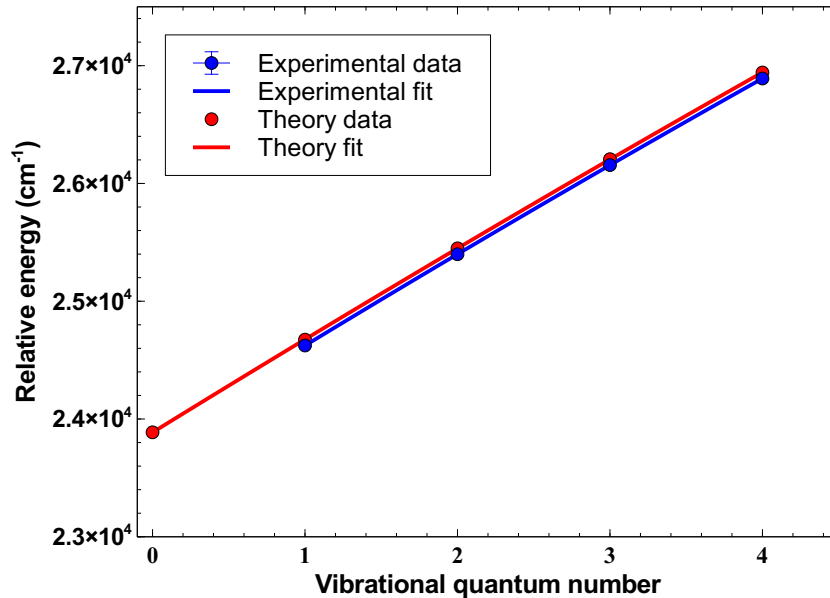

Figure 5: The plot used to determine both the theoretical and experimental values for  $\omega_e x_e$  and  $\omega_e$  for the the  $2^1\Sigma$  state of  $\text{CaH}^+$  is shown. The *ab initio* theoretical energies are taken from ref. [30]

Constant	Experiment	CASPT2 [30]
$\omega_e x_e$	$10.0 \pm 0.2 \text{ cm}^{-1}$	$8.6 \pm 0.3 \text{ cm}^{-1}$
$\omega_e$	$815.8 \pm 1.3 \text{ cm}^{-1}$	$807 \pm 1.8 \text{ cm}^{-1}$
$\nu_{00}$	$23828 \pm 1.2 \text{ cm}^{-1}$	$23886 \pm 1.2 \text{ cm}^{-1}$

Table 2: Table comparing the experimental and theoretical values of the anharmonicity constant as well as the harmonic constant for the  $2^1\Sigma$  state of  $\text{CaH}^+$  based on fitting Equation 5 to the first five states. The uncertainties are the errors from the fit. We observe good agreement between the experimental and theoretical values for all the constants.

on previous calculations, which are a reasonable match to the measured results for both the energy spacing between peaks and the expected widths. Our own theoretical modeling of the relative peak intensities agrees with the experimental results with the notable exception of the  $\nu = 0 \rightarrow \nu' = 0$  transition. We attribute this discrepancy to the limited experimental characterization of the dissociation process.

Experimental and theoretical studies on possible dissociation pathways from the  $2^1\Sigma$  state are necessary to resolve this conflict. One possibility is that the theoretical calculations are off by  $800\text{ cm}^{-1}$ , but this seems unlikely for such a simple molecule. Another solution is the dissociation process involves excitation to the  $2^1\Sigma$  state followed by photon emission back to an excited vibrational  $1^1\Sigma$  state before photodissociation. Alternatively, the dissociation could be due to predissociation [36] from the  $2^1\Sigma$  state to the  $1^1\Sigma$  state, but we expect this rate to be slower than fluorescence. In order to unravel these possible pathways, one can look for laser-induced fluorescence when driving these vibronic transitions and also design experiments to measure the electronic state of the dissociated  $\text{Ca}^+$ .

We plan to extend our measurement technique to the measurement of rovibronic lines in  $\text{CaH}^+$  by narrowing the spectrum of our laser source. The measurement of rotational lines is vital for testing the preparation of the molecular ions in their rotational ground state using optical pumping methods. This internal state control, combined with our previous realization of the ground state cooling of axial modes of molecular motion [6], will facilitate the implementation of quantum logic spectroscopy on  $\text{CaH}^+$ . In addition, our experimental method can be used to measure the rovibronic spectrum of other alkali-earth monohydride ions with the appropriate laser-cooling ion, as well as the deuterated forms of these molecules.

Regarding state preparation, some optical pumping schemes for rotational cooling will require a good knowledge of the rovibrational spectrum for the ground electronic state. By using a  $1+2'$  resonance enhanced multi-photon dissociation scheme, it is possible to measure the fundamental rovibrational transitions in the  $1^1\Sigma$  state by sweeping the frequency of the first photon from a  $6.9\text{ }\mu\text{m}$  laser. The second photon would excite to one of the  $2^1\Sigma$  vibrational states, and the third photon would dissociate the molecules [4, 37]. An IR laser source with a wide tuning frequency would enable the measurement of multiple overtones as well.
