Abstract

Experimental excitation functions for proton induced reactions on natural vanadium in the 37-65 MeV energy range were measured with the activation method using a stacked foil irradiation technique. By using high resolution gamma spectrometry cross-section data for the production of ^{51,48}Cr, ⁴⁸V, ^{48,47,46,44m,44g,43}Sc and ^{43,42}K were determined. Comparisons with the earlier published data are presented and results predicted by different theoretical codes (EMPIRE and TALYS) are included. Thick target yields were calculated from a fit to our experimental excitation curves and compared with the earlier experimental yield data. Depth distribution curves to be used for thin layer activation (TLA) are also presented.

Keywords: proton activation, vanadium target, theoretical model calculation, cross sections, Cr, V, Sc and K radioisotopes, thick target yield, TLA

1. Introduction

Many authors published experimental cross-section data for proton induced reactions on natural vanadium, especially at lower energies in the frame of basic nuclear physics research [1-4]. A few works reported experimental thick target yields [5-8]. As mentioned, most of the literature cross-sections data were obtained in the low energy region (below 30 MeV incident energy) and only a few (in some cases contradictory) data sets were measured at higher energy. We participated in an IAEA-CRP setting-up an activation data library for proton and deuteron induced reactions for the FENDL project. Vanadium was included into this library as an important construction and alloying material in accelerator technology. During compilation of the experimental data and comparison with the TENDL library it was recognized that the activation data at higher energies are contradictory and the theoretical model description for radionuclides far from the target mass number is very poor. The maximum proton energy presently available for us was 65 MeV at the Cyclone 110 cyclotron of Louvain la Neuve (LLN) Belgium through the HAS-FWO (Vlaanderen) collaboration. We decided therefore

to re-measure the cross-section data for all possible γ emitting activation products of natV in the 37-65 MeV proton energy range. Natural vanadium consists of two isotopes: for more than 99.75 % it is formed by stable 51 V while the very long-lived 50 V ($T_{1/2} = 1.4\ 1017$ a) occurs only in 0.25 %. Experimental data on ^{nat}V can hence be interpreted in broad energy range as coming from a monoisotopic ⁵¹V target and reaction crosssections can be derived. Among the reaction products ⁵¹Cr is an attractive radionuclide for use in diagnostic nuclear medicine due to its favorable nuclear characteristics such as a half-life of 27.7010 days and decay by electron capture, resulting in emission of gamma photons with energy of 320.0824 keV (9.91 %). Its main applications is labeling of red blood cells for measurement of mass or blood volume, labeling of platelets to determine their survival time as well as in sequestration studies for the diagnosis of gastrointestinal bleeding [9]. The favorite routes for no carrier added production are the (p,n) and (d,2n) reactions on vanadium [10, 11]. Among the scandium radionuclides ⁴⁴Sc, ⁴⁷Sc and ⁴⁶Sc have been used in biological and medical studies. The ⁴⁷Sc has attracted attention because of its favorable decay characteristics (half-life: 3.35 d; average electron energy: 162 keV; E_{γ} : 159 keV) for the rapeutic application and for SPECT imaging. The applicability of ^{44g}Sc as a matching pair for ⁴⁷Sc through PET imag-

ing, 44m Sc for radionuclide therapy. The longer-lived 46 Sc was used for regional blood flow studies and investigation of radiochemistry of scandium. Recently 46 Sc has been advocated as an additional monitor for proton and deuteron reactions and will be taken up in the recommended data base of the IAEA-CRP [12]. The main charged particle production routes to gain carrier free Sc radioproducts include proton and deuteron induced reactions on calcium, titanium and vanadium. 43 Sc was shown to be an excellent tool for studying blood perfusion in the heart and for diagnosing myocardial infarcts. The main production routes at charged particle accelerators are the 40 Ar(α ,p), nat Ca(p,x) or nat Ca(p,x) and high energy reactions on Ti and V, but in these last cases the cross sections are small.

2. Experimental and data processing

The excitation functions for the $^{nat}V(p,x)$ reactions were measured via an activation method by using the stacked foil irradiation technique followed by high resolution γ -ray spectrometry without chemical separation. The irradiation was performed at the LLN Cyclone110 cyclotron with 65 MeV protons for 1 h at 35 nA beam intensity. The stack contained a 19 times repeated set of 10 μ m Al, 116 μ m In, 99.2 μ m Al, 8.41 μ m V, 99.2 μ m Al, 26.2 μ m Ho and 99.2 μ m Al foils. The Al-monitors were also used as recoil catchers as well as for exact determination of beam intensity and energy by re-measuring the excitation function for the 27 Al(p,x) 22,24 Na reactions over the entire energy domain [13]. The target stacks were irradiated in a Faradaycup like target holder, equipped with a long collimator (effective beam diameter on target is 5 mm). The gamma activity of the produced radionuclides was measured with standard high purity Ge detectors at the Cyclotron Laboratory of VUB-Brussels. Measurements of the induced activity started about 20 h after EOB (End of Bombardment), hence only activation products with a half-life longer than 3 h could be assessed. The samples were counted repeatedly at varying sample detector distance for weeks after EOB. The evaluation of gamma-spectra was made by automatic peak recognition programs and in a manually controlled interactive way. For most of the radionuclides assessed different independent γ -lines are available, allowing an internal check of the consistency of the calculated activities. The cross-sections were calculated by using the wellknown activation formula with input parameters: measured activity, particle flux and number of target nuclei. In this study only a couple radionuclides formed as a result of a cumulative process by decay of a parent nuclide. The exact physical situation will be discussed individually for each activation product. The decay and spectrometric characteristics, needed to transform count rates to activity of the different activation products at EOB, were taken from the NUDAT2 data base [14] and are summarized in Table 1. This table also includes the reaction Q-values of the contributing reactions [15]. The number of incident particles was initially derived from continuously measured beam current on target. The mean energy in each target foil was estimated by a stopping calculation from the incident beam energy and target thickness [16]. The beam energy and intensity parameters were further adapted by taking into account the comparison of the excitation function of the 27 Al(p,x) 22,24 Na reactions, re-measured over the whole energy domain studied, with the recommended values in the updated version of IAEA-TECDOC 1211 [17]. The uncertainties of the median energies were estimated from the uncertainties of the cumulative contributing processes (taking into account possible incident energy variation, thickness variation of the different targets and straggling effects) resulting in around ± 0.3 MeV for the first foil and about \pm 1.3 MeV for the last foil. The uncertainty on each cross-section point was estimated in the standard way [18] taking the square root of the sum in quadrature of all individual contributions, supposing equal sensitivities for the different parameters appearing in the formula. The following individual uncertainties are included in the propagated error calculation: absolute abundance of the used γ -rays (5 %), determination of the peak areas including statistical errors (4-10 %), the number of target nuclei including non-uniformity (5 %) and detector efficiency (10 %). The total uncertainty of the cross-section values was estimated to be 814 %. The strongly non-linear effect of the possible uncertainty of the half-lives, cooling time and measuring time for samples was not taken into account.

3. Model calculations

The cross-sections of the investigated reactions were compared with the data given in the last two online TENDL libraries to show the development of the predictions (from TENDL-2010 to TENDL-2014 and TENDL-2015) [19]. These libraries are based on both default and adjusted TALYS calculations (Koning 2012)[20]. For comparison also the results of the latest version of the EMPIRE code (EMPIRE 3.2 (Malta) are presented [21, 22]. Default input was used in the most cases, expect the TENDL libraries, where the TALYS

 ε is total EC + β^+ The Q-values refer to formation of the ground state. In case of formation of a higher laying isomeric state it should be corrected with the level energy of the isomeric state shown in Table 1. When complex particles are emitted instead of individual protons and neutrons the Q-values have to be decreased by the respective binding energies (pn \rightarrow d + 2.2 MeV, p2n \rightarrow t + 8.5 MeV, 2pn \rightarrow 3 He + 7.7 MeV, 2p2n \rightarrow α + 28.3 MeV).

results are adjusted in an unknown (for the public user) way.

4. Results

The cross-sections for all the reactions studied are shown in Figs. 111 and the numerical values are collected in Table 2. No practical contribution from the reaction on the low abundance ⁵⁰V can be distinguished, hence all results are practically equivalent to reaction cross sections on ⁵¹V.

4.1. Production of ⁵¹Cr

Many experimental data sets exist for production of 51 Cr ($T_{1/2}=27.701$ d) especially at low energies for basic research. Results were published by Tanaka, Albert, Shore, Taketani, Wing, Hansen, Albouy, Hontzeas, Humes, Johnson 1964, Dell, Harris, Chodil, Johnson 1958, Gadioli, Barandon, Mehta, Michel 1979, Michel 1980, Zyskind, Kailas, Bastos, Levkovskij(normalized), Jung, Musthafa and Carlson [1, 2, 23–46]. The data differ by a factor of two around the maximum. A recommended data set was also proposed earlier in the IAEA TLA library [47]. In the presently investigated energy range experimental data are available from five

groups (Albuoy, Michel 1983, Michel 1979, Hontzeas and Zhao)[29, 30, 37, 48, 49]. Our data are in good agreement with the earlier results of Michel and Zhao (Fig. 1). Both the TENDL and the EMPIRE predictions describe the experimental data acceptable well.

4.2. Production of ⁴⁸Cr

For production cross sections of 48 Cr ($T_{1/2} = 21.56$ h) the earlier experimental data of (Heininger, Hontzeas and Michel 1979)[30, 37, 50] show large discrepancies (Fig. 2). Our data support the results of the Hannover group (Michel et al.)[48]. The TENDL prediction shows only a moderate agreement (lower maximum, energy shift). A gradual change (increase) of the subsequent TENDL versions can be observed. The EMPIRE 3.2 results describe both the maximum and the magnitude of the excitation function well.

4.3. Production of ⁴⁸V

The measured activation cross sections for 48 V ($T_{1/2}$ = 15.9735 d) formation are cumulative. They include the direct production by (p,p3n) reaction with a threshold around 32 MeV and indirect production through the decay of the 48 Cr (21.56 h) parent isotope. The agreement with the earlier experimental data of Heininger,

Figure 1: Experimental excitation function for the $^{nat}V(p,x)^{51}Cr$ reaction and comparison with literature values and theoretical code calculations

Figure 2: Experimental excitation function for the $^{\it nat}$ V(p,x) 48 Cr reaction and comparison with literature values and theoretical code calculations

Figure 3: Experimental excitation function for the ^{nat}V(p,x)⁴⁸V reaction and comparison with literature values and theoretical code calculations

Hontzeas and Michel [30, 37, 48, 50] is good and the TENDL data are slightly shifted with an overestimation of the maximum (Fig. 3). EMPIRE 3.2 gives better estimation for the maximum, but underestimates the experimental values above 50 MeV.

4.4. Production of ⁴⁸Sc

The 48 Sc ($T_{1/2} = 43.67$ h) is produced directly, via (p,2pxn) reactions. The new experimental data are in good agreement with the earlier experimental data of the Hannover group (Michel)[37, 48]. The data of Hontzeas [30] however are significantly lower. The TENDL libraries overestimate the maximum (Fig. 4). EMPIRE gives strong overestimation.

4.5. Production of ⁴⁷Sc

The direct production cross sections of ${}^{47}Sc(T_{1/2} =$ 3.3492 d) are shown in Fig 5. The maximum around 38 MeV corresponds to the contribution of the ${}^{51}V(p,\alpha p)$ reaction with energy threshold of 10.3 MeV, while the rise above 50 MeV is due to the emission of individual nucleons. A good agreement was found in the overlapping energy region with the experimental data of the Hannover group (Levkovskij, Michel 1979 and Michel 1985)[37, 48]. The data of Levkovskij were normalized because of a known error in the original data-set [51]. The data of Heininger and Hontzeas [30, 50] differ significantly. Although the TENDL predicts well the shape of the excitation function but the values are underestimated below 50 MeV. EMPIRE 3.2 follows the shape of the experimental values but strongly overestimates them.

Figure 4: Experimental excitation function for the nat V(p,x) 48 Sc reaction and comparison with literature values and theoretical code calculations

Figure 5: Experimental excitation function for the ^{nat}V(p,x) ⁴⁷Screaction and comparison with literature values and theoretical code calculations

Figure 6: Experimental excitation function for the $^{nat}V(p,x)^{46}Sc$ reaction and comparison with literature values and theoretical code calculations

4.6. Production of ⁴⁶Sc

The cross-sections of 46 Sc($T_{1/2} = 83.79$ d) are cumulative as they include direct production and total decay of the 19.7 s half- life isomeric state. Up to 60 MeV the main contribution is from the 51 V(p, α pn) reaction. The comparison with the earlier experimental data shows good agreement with the data-sets of Michel and Zaitseva [37, 48, 52], and more or less with Heininger [50](Fig. 6). There are large disagreements with the data of Albert and Hontzeas [24, 30]. The TENDL predictions significantly underestimate the experimental data up to 80 MeV. The maximum position predicted by the EMPIRE 3.2 is better, but its overestimation is large.

4.7. Production of ^{44m}Sc and ^{44g}Sc

The radionuclide ⁴⁴Sc has two long-lived isomeric states. The metastable ^{44m}Sc($T_{1/2} = 58.61$ h) is produced directly and decays with 98.8 % IT to the ground state and the rest 1.2 % is EC + β^+ . The ground state ^{44g}Sc ($T_{1/2} = 3.97$ h) is produced directly, through decay of its metastable state (58.61 h) and through the decay of its long half-life ($T_{1/2} = 44.3$ a) ⁴⁴Ti parent. Direct production cross-sections for the ground state were deduced after correction of the contribution of ^{44m}Sc decay. The possible contribution of the ⁴⁴Ti was neglected because of the irradiation conditions and its very long half-life that would not generate any significant signal in our experimental conditions. For both states reactions with emissions of clusters are playing the dominant role

Figure 7: Experimental excitation function for the ^{nat}V(p,x)^{44m}Sc reaction and comparison with literature values and theoretical code calculations

in the energy domain studied. The measured and calculated cross sections are shown in Fig. 7 and Fig. 8. In case of ^{44m}Sc our new data agree well with the earlier experimental data of Michel [48]. The data of Hontzeas and Heininger [30, 50] differ significantly. The TENDL predictions show a significant underestimation (see Fig. 7). EMPIRE 3.2 gives much better approximation both for the values and for the shape. For production of ^{44g}Sc only one earlier experimental cross-section data set was found [30], which is in good agreement with our results. The predictions of TENDL are representing well the experimental values (Fig. 8). EMPIRE 3.2 strongly overestimates the experimental values.

4.8. Production of ⁴³Sc

The cumulative cross-sections of 43 Sc ($T_{1/2} = 3.891$ h), by direct production and by the possible decay of the short-lived 43 Ti ($T_{1/2} = 509$ ms, formed through the 51 V($p,\alpha 5n$) reaction with a threshold of 59.53 MeV), are shown in Fig. 9 with earlier data of Hontzeas [30] and with the TENDL calculations. Our data are significantly higher than those of Hontzeas. The TENDL data are even lower and the effective threshold is also shifted (Fig. 9). EMPIRE 3.2 gives similar underestimation, but closer to the experimental values.

4.9. Production of ⁴³K

The direct production cross-sections of 43 K ($T_{1/2}$ = 2.3 h), essentially formed through clustered emissions in our experimental conditions, are shown in Fig. 10. The agreement with the data of Michel [48] is good.

Figure 8: Experimental excitation function for the ^{nat}V(p,x)^{44g}Sc reaction and comparison with literature values and theoretical code calculations

Figure 9: Experimental excitation function for the $^{\it nat}$ V(p,x) $^{\it 43}$ Sc reaction and comparison with literature values and theoretical code calculations

Figure 10: Experimental excitation function for the $^{nat}V(p,x)^{43}K$ reaction and comparison with literature values and theoretical code calculations

Figure 11: Experimental excitation function for the ^{nat}V(p,x)⁴²K reaction and comparison with literature values and theoretical code calculations

The data of Heininger and Hontzeas [30, 50] are higher. The underestimation by the TENDL prediction is significant. (Fig. 10). EMPIRE 3.2 gives better result with overestimation up to 50 MeV, above this energy the overestimation is much larger.

4.10. Production of ^{42}K

The 42 K ($T_{1/2} = 12.36$ h) is produced directly through clustered emission. The comparison shows good agreement with the results of Michel 1985 [48]. The data of Heininger and Hontzeas [30, 50] are significantly lower in the measured energy range. The situation is the same for the TENDL predictions (Fig. 11) as in the previous case. For EMPIRE 3.2 the same behavior can be observed as in the previous case, acceptable agreement with slight overestimation up to 60 MeV, and strong overestimation above.

5. Thick target yields

From excitation functions obtained by a spline fit to our experimental data, integral thick target yields [53] were calculated and are shown in Figs. 12 and 13 as a function of the incident proton energy. The deduced integral yields are compared with the experimental thick target yields from the literature measured by Dmitriev, Acerbi, Nickles, Abe, Bastos, L. Kanza-Kanza, etc.[5–8, 41, 54, 55], where overlapping energy regions made it possible. Our calculated ⁵¹Cr yield is in good agreement with the yields of Dmitriev and Bastos [41, 55], much higher than the yield of Abe [7], slightly higher

than the yield of Nickles [8] and slightly lower than the yield curve of Acerbi [6]. Our ⁴⁸V yield is in excellent agreement with the yield curve of Acerbi [6], but Dmitriev and Molin [55] reported much higher yield at 22 MeV than our value. For the other isotopes in Fig. 12 (⁴⁸Cr and ⁴⁸Sc) there were no literature yield data found. In Fig. 13 our calculated yields for ^{46,44m,44g,43}Sc and ^{43,42}K are presented. Previous data in the literature were only found for ⁴⁶Sc (Acerbi). Their data are in excellent agreement with our new results.

6. Applications

6.1. Thin layer activation (TLA)

Among the investigated reaction products, the production and decay parameters of 51 Cr ($T_{1/2} = 27.7010$ d, E_{γ} = 320.0824 keV (9.91 %)) are the most suitable for satisfying the usual requirements (medium half-lives, intensive gamma-lines, high production rate) [56, 57] for application with TLA. Recommended cross sections and specific activity as a function of depth up to 20 MeV can also be found in the IAEA TLA [47] database for the $^{nat}V(p,x)^{51}Cr$ reaction. The recommended data are shown in Fig. 1 together with the experimental data [47]. The fitted curve follows reasonably well the more reliable selected data. The corresponding wear curve (specific activity versus depth) is already presented in our previous work on deuteron induced reactions on vanadium [58]. Fig. 14 demonstrates the capability of the method in this higher energy region, where other radioisotopes become suitable for wear measurement. As

Figure 12: Integral yields of the 51,48 Cr, 48 V and 48,47 Sc calculated from the fitted experimental excitation functions and compared with the literature data

Figure 13: Integral yields of the 46,44m,44g,43 Sc and 43,42 K calculated from the fitted experimental excitation functions and compared with the literature data

Figure 14: TLA curves for the 48 V radioisotope in natural vanadium matrix: irradiation time: 1 h, beam current: 1 μ A, bombarding proton energy: 50 MeV, cooling time: 10 days

an example, wear curves for ⁴⁸V (shorter, but proper half-life, intense γ -energies, cross section in this energy range is lower than that of the ⁵¹Cr around 11 MeV, but it is still applicable) are presented in Fig. 14. The used matrix is pure vanadium, because its interpretation for an alloy is straightforward. Both wear curves were constructed assuming 1 hour 1 μ A irradiation with 50 MeV proton beam (recommended to achieve linear activity distribution near to the surface), under irradiation angles of 15° and 90° (perpendicular) respectively. In the first case 140 μ m linear (within 1 %) distribution and about 800 μ m total penetration depth can be reached, while in the case of perpendicular irradiation these values are 540 μ m and more than 2 mm respectively. Depending on the required task one can choose the best irradiation angle in order to cover the selected wear-depth in question with constant [58] or linear activity distribution. If the tracing isotope does not have a local maximum in the selected energy range or lower penetration depth (lower irradiation energy) is required, the depth distribution should be set as linear, which requires the knowledge of the depth distribution function. For long term studies and higher wear rates, besides the ⁴⁸V, the ⁴⁶Sc is also a proper choice because of its 83.79 d halflife and intense gamma-energies. Unfortunately, its production also requires a high energy accelerator, which is not everywhere available.

7. Summary and conclusion

Eleven excitation functions for proton induced nuclear reactions on natural vanadium were measured up to 65 MeV. Our new experimental data were critically compared with the values measured earlier by different authors. The experimental data sets show excellent agreement with the experimental data of the Michel group [37, 38, 48] and with the Levkovskij and Zaitseva [42, 52] data in the overlapping energy region. The comparison with the theoretical model code calculations as available in the on-line library TENDL (2014, 2015, except 2010) shows agreement for radio-products of chromium formed through (p,xn) reactions. In case of vanadium radionuclides, especially for scandium and potassium activation products, the underestimation is significant, but an improvement can be observed against the earlier (2010) version. EMPIRE 3.2 (Malta) provides in some cases much better approximation but fails in cases, where the produced isotope is far from the target isotope (multiple path or complex particle emission play role). The provided physical yield curves help the user to select the suitable isotope and reaction for the required medical isotope production or industrial task. The applicability of some isotopes, especially the ⁴⁸V for wear measurements by using thin layer activation is demonstrated.

8. Acknowledgements

This work was done in the frame of MTA-FWO (Vlaanderen) research projects. The authors acknowledge the support of research projects and of their respective institutions in providing the materials and the facilities for this work.
