Abstract

The LHC running periods of ATLAS and CMS have established hybrid pixel detectors as the instrument of choice for particle tracking and vertexing in high rate and radiation environments as they exist close to the LHC interaction points. With the HL-LHC upgrade coming in sight, for which the tracking detectors will be completely replaced, new generations of pixel detectors are being devised. They have to address enormous challenges in terms of data throughput and radiation levels, ionizing and non-ionizing, that harm the sensing and readout parts of pixel detectors alike. Advances in microelectronics and microprocessing technologies now enable large scale detector designs with unprecedented performance in measurement precision (space and time), radiation hard sensors and readout chips, hybridization techniques, light weight supports, and fully monolithic approaches to meet these challenges. This paper reviews the world-wide effort on these developments.

1. Pixel detectors at the heart of particle physics experiments: demands, challenges and concepts

This article reviews recent advances and future directions in pixel detectors to measure high energy charged particle trajectories in high rate and radiation experiments. A general treatment of pixel detectors can be found in [1]. The current state of the art is represented by the detectors in operation or under construction at the Large Hadron Collider at CERN, in the ATLAS, CMS, LHC-b, and NA62 experiments.

The ATLAS experiment installed a 3-layer hybrid pixel detector in 2007 [2] and an additional layer at lower radius, inserted within the original detector envelope and therefore called Insertable B-Layer (IBL), in 2014 [3]. The IBL pioneered the use of 3D silicon sensors (in a limited acceptance range) and introduced a new readout integrated circuit (ROIC or readout chip) called FE-I4 [4] with several of the features needed for future high rate detectors.

The CMS experiment installed a 3-layer hybrid pixel detector in 2008 [5], and has replaced it with a new, 4-layer detector in 2017 [6]. The new detector has lower inner radius, significantly lower mass, and higher data rate capability. The upgrade baseline ROIC was redesigned for the outer 3 layers, replacing analog signal readout with on-chip ADCs and digital readout at higher rate [7]. A different ROIC has been designed specifically for the inner layer to handle higher rate and radiation, while keeping to the original footprint. To reduce the mass of the services, radiation hard voltage regulators [8] have been introduced just outside the acceptance, but still inside the CMS inner barrel volume.

The LHC-b experiment is replacing their strip vertex detector with a 26 plane pixel detector (fixed target geometry) [9]. The detector will use triggerless readout at the full 40 MHz collision rate of the LHC. The high data volume will be handled by up to four 5 Gbps serial outputs per ROIC [10], transmitted over high bandwidth copper cables outside the physics acceptance.

The NA62 experiment has installed a fixed target geometry hybrid pixel detector called Gigatracker to measure timing with high resolution (200 ps) as well as position in each pixel [11]. This is a small area detector, but is pioneering the use of per-pixel timing in particle tracking.

The challenges that drive ongoing development can be broadly categorized into scale, intensity, and performance. Particle physics programs demand pixel detectors with larger outer radius to cope with higher rates, and greater length along the beam direction to increase acceptance. Significant development is therefore focused on how to produce pixel detectors with less effort and lower cost. The two main directions are lower cost production of hybrid pixels and diode sensors (chapter 3), and development of monolithic technology in CMOS foundries (chapter 6).

Increasing collider intensity places two main demands on pixel detectors: the ability to store and process greater hit rate per unit area (chapter 4), and higher radiation tolerance (chapters 3, 4, 6). All hits “raining” on a pixel detector unit area must be time-stamped and stored for a trigger latency interval. This means more memory per unit area in the ROIC, which directly translates to a need for a technology with higher logic density (i.e. smaller feature size, following Moore’s Law). Note that the need for higher logic density is not a function of pixel size, but of hit rate per unit area. Smaller pixels are needed to maintain efficiency (to avoid pileup of hits in a single pixel), for resolution (chapter 2),

and for radiation tolerance (to keep the leakage current per pixel small). Higher intensity also means that collision events all 'look alike', because every event has a large number of superimposed low energy scatters (pileup), and may or may not have a hard scatter of interest as well, typically with less energy than the sum of the underlying pileup. As distinguishing events of interest becomes more difficult, triggers must increase rate (for a given signal acceptance more background will pass the trigger) and/or use more information, including tracking. Pixel detectors must therefore output much more data (section 4.8).

Achieving larger scale and coping with higher intensity are necessary to increase the physics reach of particle physics experiments. The basic performance of a detector can also improve the physics reach, and therefore, the challenges of scaling and intensity are compounded by the desire to increase performance. Given signal size, sensor capacitance, and device specific transconductance in the ROIC, the pixel front end achievable performance is determined, and actual ROIC's come close to this limit. From a single pixel perspective, there is no further improvement possible within given ROIC and sensor technologies. New developments to increase performance are therefore looking beyond the basic model of a pixel detector as a collection of individual pixels with an output of 3D space points. Correlations between pixels and measurements with internal degrees of freedom (in addition to the usual spatial coordinates) can be used to improve pattern recognition, suppress background, and even provide input to a trigger system. The main degrees of freedom under study are timing, direction, and cluster shape and charge distribution (see chapter 2).

2. Space–time point resolution

2.1. Demands and current directions

The basic detection mechanism of silicon detectors is the generation and drift of mobile charges (e/h) in a depleted silicon junction. This charge cloud has a rich spatial and temporal structure with some dependence on incident particle type and trajectory as well as existing electric and magnetic fields in the silicon. In the past, silicon tracking detectors typically had granularities in space and time greater or equal to the charge cloud deposit, resulting in one 3-D space point per particle crossing a sensor with a fairly coarse arrival time stamp, sufficient to associate the point with a given accelerator collision event. Measurement of the magnitude of the collected charge was generally also available for pixel detectors (e.g. by measuring the time over threshold), and has been used to improve the 3-D space point precision through interpolation as well as for particle identification through specific ionization measurement.

In current detector development we are starting to see increased space and time granularity, in order to measure and make use of the structure of charge deposits. There are many interesting applications of this extra information beyond pure space points. We will give below a few present or anticipated examples: multi-track to cluster association using machine learning, angular information from cluster length, 3-D cluster shapes using charge arrival time, disentangling of multiple interactions from sub-nanosecond hit timing.

To be fully exploited, the trend towards fine granularity in space and time, to resolve the charge deposit structure and even the sequence of particle impacts within a detector, must be accompanied by an evolution of the pattern recognition and track fitting algorithms used. Interestingly, algorithm evolution seems to lag detector development. Currently used techniques are still largely based on space points, with extra information added for specific tasks after space point reconstruction. In this chapter we review the basics of space point reconstruction and extend towards new space-time measurement directions as far as they are known and published today. But we expect to soon see modifications of the conventional, well known formulas to include angle, direction, and time measurements.

In general, the tasks of pixel detectors in HEP experiments can be listed as follows:

1. Pattern recognition and identification of particle tracks at large background and pile-up levels
2. Measurement of primary and secondary vertices;
3. Multi-track separation and vertex-ID in the core of (boosted) jets;
4. Momentum measurement of particles (together with other detectors, like strip detectors);
5. Measurement of specific ionization.

Small pixel size keeps the pixel occupancy down at high particles rates (important for item (1)) and also leads to good hit resolution. Space point resolutions in the order of 10 μm or less has been routinely achieved at least in one dimension. Best possible resolution is of utmost importance to cope with the above challenges.

Recent developments (e.g. [12]) also address processing of multi-hit pixel clusters as complex objects to exploit directional information and improve the two track resolution, in particular inside the core of jets.

Time resolutions at the 10–100 ps level have not been realized so far with semiconductor tracking detectors. If achieved this will add another measurement dimension which can be exploited for example to distinguish calorimeter jets coming from a hard interaction from those with large pile-up contributions by using the arrival time distribution (being broad for pile-up jets). Precise timing might also allow coincidence measurements e.g. between tracks in the forward and backward regions of a detector.

2.2. Space point and direction measurements

Figure 2.2 sketches two typical situations for pixel hit clusters. Case (1) represents the case of a track impinging close to perpendicular to the pixel module leading to pixel clusters of typically one to two hits. Case (2) represents tracks impinging under steep angles, thus producing larger pixel clusters with some directional information when properly treated by reconstruction algorithms, in particular when such clusters appear in several detector layers along a track. Exploiting the hit information this way could become important for hit assignment and track recognition in high track density at LHC (see for example [12]).

Point measurements

The precision of a space-point measurement enters the momentum resolution in a track measurement with N detector layers as given by the Gluckstern formula [13]:

$$\frac{\sigma_{p_T}}{p_T} = \left(\frac{p_T}{0.3|z|} \frac{\sigma_{\text{point}}}{L^2 B} \sqrt{\frac{720}{N+4}} \right) \oplus \left(\frac{\sigma_{p_T}}{p_T} \right)_{\text{MS}} \quad (1)$$

where p_T is transverse momentum in GeV/c, L is radial length m, and B magnetic field in T; σ_{point} is the point resolution of the detectors in m, and N is assumed to be large in this approximation. Important for a precise momentum measurement is the point resolution, but also (quadratically) the total length L of the tracker and the bending field B . The multiple scattering (MS) contribution for a large number of layers N can be written as¹:

$$\left(\frac{\sigma_{p_T}}{p_T} \right)_{\text{MS}} = \frac{0.054}{\beta B L / \sin \theta} \sqrt{\frac{x / \sin \theta}{X_0}}, \quad [L] = \text{m}, [B] = \text{T} \quad (2)$$

where $L / \sin \theta$ is the projected tracker length, and $(x / \sin \theta) / X_0$ is the total material thickness traversed by a particle incident under θ in units of radiation length. Even though the hard high energetic collisions at LHC produce high energy jets, low momentum tracks around and below 1 GeV/c transverse momentum play an important role, especially in the forward direction. For example, efficient jet tagging - jets in general and b-jets in particular - and suppression of pile-up contributions by primary vertex identification suffer from unprecise detection of

¹For small N , e.g. $N = 3$ the MS resolution decreases only by about 4% compared to large N as assumed for eq.(2).

low momentum particles. For HL-LHC, low p_T tracks will become even more important as pile-up increases. This renders low mass (low x/X_0) extremely important.

Similarly, the precision of secondary vertex measurement with an N layer tracker can be expressed by the impact parameter resolution (here in linear extrapolation):

$$\sigma_{d_0} \approx \frac{\sigma_{\text{point}}}{\sqrt{N}} \sqrt{1 + \frac{12(N-1)}{(N+1)} \left(\frac{r}{L}\right)^2} \oplus \theta_0 r_{pv} \sqrt{\frac{N(2N-1)}{6(N-1)^2}} \quad (3)$$

where the first term results from the extrapolation from the tracker to the primary vertex with r/L being the ratio of the extrapolation distance to the tracker length. The point resolution enters linearly. For a pixel detector with four layers as in ATLAS, at radii between 3.3 cm and 12.3 cm and with a point resolution of about 10 μm , this yields $\sigma_{d_0} \approx 12.5 \mu\text{m}$ without multiple scattering.

The second term is due to multiple scattering approximated by assuming extrapolation from the first layer to the primary vertex, the slope of which is smeared by multiple scattering with θ_0 being the multiple scattering angle [14]

$$\theta_0 \approx \frac{0.0136 \text{ GeV}/c}{\beta p} \sqrt{x/X_0}, \quad (4)$$

and r_{pv} the distance of the first pixel layer to the primary interaction vertex. For a 4-layer geometry like in ATLAS and a material thickness of typically around 3% X_0 this yields

$$\sigma_{d_0} \approx \frac{90 \mu\text{m GeV}/c}{p}. \quad (5)$$

Spatial resolution also impacts pattern recognition performance in complex interplay with pixel occupancy, material thickness, and layout, too complex, however, to be within the scope of this review.

Space-point reconstruction methods

In designing a pixel detector one decides for the (initial) amount of charge sharing. The tuning parameter for a given sensor thickness is the ratio of the Lorentz angle, determining the deviation of the drift path of charges in a magnetic field from perpendicular drift [15], and the tilt angle of the module with respect to perpendicular particle passage. While charge sharing between pixels allows for better spatial resolution by charge interpolation, a signal decrease caused by irradiation during the detectors's life time demands minimal charge sharing. Whether collected charge causes a hit also depends on the pixel threshold. Noise deteriorates the precision of reconstruction and causes spurious hits.

For the present LHC pixel detectors with relatively large pixels, covering mainly central rapidity and not having too steep incidence angles, the number of hits in a cluster from a single track is rarely greater than 2. At large incidence angles in the forward regions of a barrel pixel detector or in the future with smaller pixel sizes, the cluster distribution can become much larger and this information can also be exploited (see below).

Resolutions achievable with classical space point reconstruction methods can be classified as follows:

Figure 1: Pixel hit clusters for tracks under different incident angles.

- For single hit clusters - independent of having binary (yes/no) or analog origin - resolution is given by the well-known $\text{pitch}/\sqrt{12}$ RMS resolution assuming a flat prior distribution of track position within the pixel (most conservative assumption). For an arbitrary given cluster size and track direction the resolution still is constant and is determined by the RMS of the prior track distribution that can produce a cluster of this size. For large clusters, high spatial resolution is possible even with binary readout, due to the averaging of many pixels.
- Analog hit information can be obtained at the expense of a larger total data volume (see e.g. [2][16] for ATLAS) or by processing the analog pulse off the module as done in CMS [5]. In this case the reconstructed hit position x_{rec} can be obtained e.g. by the centre of gravity method

$$x_{rec} = \frac{\sum (S_i + n_i) x_i}{\sum (S_i + n_i)} \quad (6)$$

where the S_i and n_i are the signal and noise fractional weights, respectively, and x_{rec} is the reconstructed position. The achievable resolution is:

$$\sigma_x^2 = \sigma_n^2 \left[\left(\sum_{i=1}^N x_i^2 \right) + N \langle x^2 \rangle \right] + \mathcal{O}(\sigma_n^3), \quad (7)$$

where σ_n denotes uncorrelated noise and N is the number of hit pixels [17] [18].

- If two hit clusters is the most abundant case for pixel detectors the η -reconstruction method [19, 20] is optimal for space reconstruction of gaussian charge clouds, since detector effects are automatically included. For two adjacent left and right electrodes the function

$$\eta = \frac{S_L}{S_L + S_R}, \quad (8)$$

constructed from measured signals $S_{L,R}$ is position dependent, $\eta = \eta(x)$, and the hit position is obtained from the inverse η^{-1} :

$$x_{rec} = \eta^{-1} \left(\frac{S_L}{S_L + S_R} \right) = \frac{a}{N} \int_0^\eta \frac{dN}{d\eta'} d\eta'. \quad (9)$$

Experiment	R/O method	pitch [μm]	inc. angle	σ_x [μm]
ATLAS [21]	binary/ToT	250	0°	66.5
ATLAS [21]	ToT	50	0°	10
ATLAS [2]	ToT	50	10°	7
CMS [22]	analog	150	0°	44
CMS [22]	analog	150	30°	21
CMS [22]	analog	100	0°	9.4

Table 1: Spatial resolutions obtained with the ATLAS and CMS pixel detectors under LHC conditions.

Including noise $n_{L,R}$ (fractional, i.e. in units of the signal) (9) becomes [17][18]:

$$\begin{aligned}
x_{rec} &= \eta^{-1} \left(\frac{S_L + n_L}{S_L + S_R + n_L + n_R} \right) = \eta^{-1} \left(\frac{\eta(x) + n_L}{1 + n_L + n_R} \right) \\
&\approx x + \frac{d\eta^{-1}(s)}{ds} \Big|_{\eta(x)} \cdot \left(n_L(1 - \eta(x)) - n_R\eta(x) \right) \quad (10)
\end{aligned}$$

with $s = \eta(x) + n_L(1 - \eta(x)) - n_R\eta(x)$. Obviously, a steep response function η yields the best resolution, given by:

$$\sigma_x^2 = \sigma_n^2 \left\langle \frac{1 - 2\eta + 2\eta^2}{\eta'^2} \right\rangle + 2\langle n_L n_R \rangle \cdot \left\langle \frac{\eta^2 - \eta}{\eta'^2} \right\rangle, \quad (11)$$

where the second term vanishes for uncorrelated noise, $\langle n_L n_R \rangle = 0$.

Using analog information either directly (CMS) or via a ToT measurement (ATLAS) resolutions as shown in table 2.2 have been obtained.

Limitations to the space point resolution of a pixel detector

When aiming for ultimate spatial resolutions with hybrid pixel detectors the following limitations are encountered:

- Since for hybrid pixels the chip's pixel area must match the sensor's pixel area the smallest pixel size is determined by the amount of CMOS electronics needed to amplify, discriminate, and process the hit information in the area occupied by the pixel cell. For 65 nm technology a limit is about $50 \times 50 \mu\text{m}^2$ or $25 \times 100 \mu\text{m}^2$, the limit coming from logic density as explained in section 4.
- The signal of a traversing mip spreads due to diffusion according to $\sigma_x = \sqrt{2Dx/v_D}$, where D is the diffusion constant, x the drift distance to the electrode and v_D the drift velocity. For a typical detector thickness of 150–200 μm , σ_x becomes 4–8 μm . Hence pixel pitches well below this (at the same sensor thickness) would lead to excessive charge sharing.
- Pixel hybridization technology (see section 3) can currently cope with bump pitches in the order of 25–50 μm . The technological limit for galvanic or evaporation methods for the coming decade seems to lie in the order of 5–10 μm [23] (see also section 3.3).

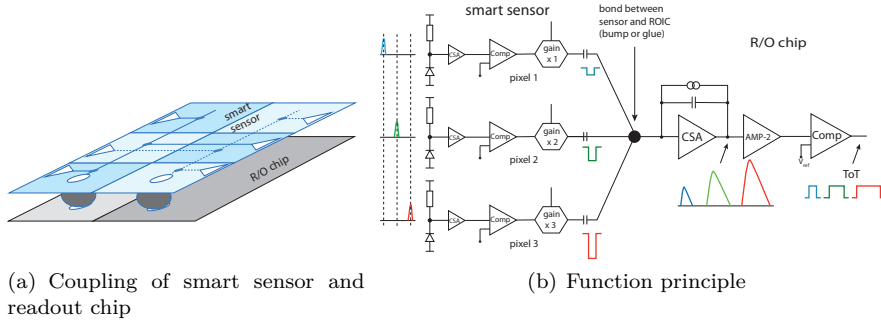

Figure 2: In-pixel en- and decoding using a 'smart sensor' bonded to a pixel readout chip (here showing 6 smaller sensor pixels bonded to two readout pixels). The sensor pixels contain amplifications with adjustable gains (here $\times 1$, $\times 2$, $\times 3$). The gains are set such that the origin of a hit can be decoded from the output pulse height encoded as ToT (time over threshold).

In-pixel decoding

It has been proposed [24] to effectively achieve smaller pixel size by encoding and decoding the pixel sensor cell by means of 'smart sensors' when using depletable substrates with a CMOS electronics layer (see also section 6).

Figure 2.2 shows the principle. Two pixels of the readout chip (e.g. FE-I4 with $50\text{ }\mu\text{m} \times 250\text{ }\mu\text{m}$ each) match six (sub-)pixels of the smart sensor with sizes $33\text{ }\mu\text{m} \times 125\text{ }\mu\text{m}$. Three sub-pixels at a time are connected to one of the two FE-I4 inputs via AC coupling, either by a capacitor included in the sensor pixel plus DC connection (bump bonding) to the corresponding FE-I4 chip pixel, or by gluing the sensor chip/wafer to the FE-I4 wafer, in which case the coupling is also capacitive. The digital (voltage) output pulse of the smart sensor is capacitively coupled into the CSA input of the readout chip. The three digital output stages of the sensor pixels can be programmed with three different gains (high, medium, low) such that digital pulses of different height are capacitively coupled to the input of FE-I4 depending on which of the sub-pixels has been hit. Further processing of the pulse by the FE-I4 amplification and discrimination stages turns different pulse heights at its input into different time-over-threshold (ToT) values at the output. Hence the sub-pixel hit by the mip is finally decoded from its ToT value. Test beam measurements demonstrated the functionality of the method principle [25, 26].

Directional information from hit clusters

Multivariate algorithms like artificial neural nets (ANN) have now also entered the area of hit/cluster to track association for improved track reconstruction in high multiplicity environments. Not only the single hit precision is the figure of merit to tune, but also the capability of cluster shape analysis (especially for inclined tracks) and the analysis of pattern information of clusters from dense tracks over several layers. For example in [12] it is shown how successive employment of ANNs can improve (a) the association of merged clusters to tracks, (b) track reconstruction inside the core of (boosted) jets, and (c) heavy flavour and τ -jet identification. The amount of charge per pixel, for instance provided by the ToT technique [2], and a precise knowledge of the pixel coordinates is already sufficient as input for the ANN to identify merged clusters efficiently. The emission of δ -rays and secondary interactions of tracks prevent

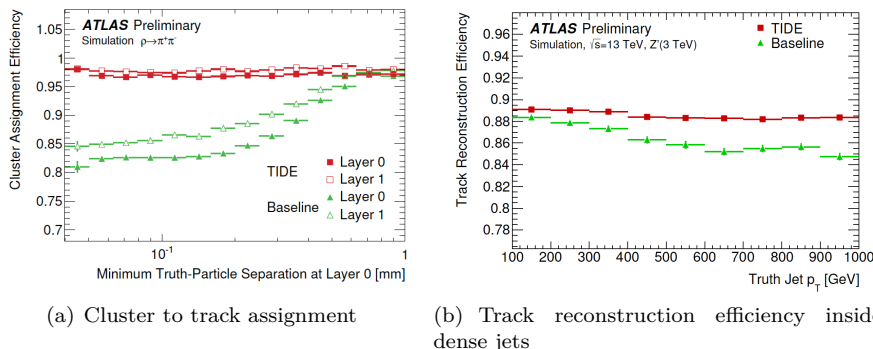

Figure 3: Improvement in hit cluster assignment and tracking efficiency using ANNs for merged cluster identification in dense track environments [12]. (a) Cluster assignment efficiency as a function of separation of two pion tracks from simulated $\rho^0 \rightarrow \pi^+\pi^-$ decays at the innermost pixel detector layers. (b) Track reconstruction efficiency inside dense jets for high p_T jets.

a perfect ANN performance. The approach benefits from knowing the incident angle of tracks, estimated from the coordinates of modules with respect to the beam spot, and from correlating information from consecutive layers of the pixel detector [12]. Figure 3(a) demonstrates the gain in cluster assignment efficiency using this technique on a sample of simulated $\rho^0 \rightarrow \pi^+\pi^-$ decays. Figure 3(b) shows the improvement in tracking efficiency inside dense jet-cores obtained using the ANN-based improved merger identification. Improvement in high- p_T heavy flavour identification of 7–13% (b-tagging and b-jet identification) and of 5% in 3-prong τ -jets above $p_T = 600$ GeV is the result [12].

2.3. Time measurement

The charge collection time, i.e. the time until the arrival of the last electron at the pixel electrode, typically is in the order of 3–10 ns, sensor thickness and E-field dependent. The induced current pulse at the electrode instantly starts with the particle passage and consists of the incoherent sum of induced pulses from each carrier’s path towards (e^-) and away (h^+) from the pixel electrodes. The individual contributions are weighted by the pixel weighting field (see e.g. [27, 1, 17]) leading to the fact that the carriers’ paths close to the pixel implant have the strongest contributions to the signal. In a typical pixel detector the current pulses are integrated by the input stage of the subsequent readout chip, a charge sensitive amplifier (CSA). While such a readout method has low noise performance² it does not allow timing measurements at or below 100 ps, values at which timing becomes interesting for high energy particle detection.

For a time coordinate measurement to reach equivalent spatial resolutions in the cm to mm regime, time resolutions of the order of a few tens of picoseconds are needed. To achieve this with pixel detectors, where charge collection times are in the ns range, is a real challenge. Recently, amplification structures in silicon have been brought forward to cope with these demands [28, 29, 30].

²Typical ENC’s are on the order of 150 e^- for the present LHC detectors and will be around 80 e^- for future detectors with smaller pixels.

Figure 4: Cross section through an LGAD structure using a high ohmic p-type bulk and featuring a metallurgical junction underneath the n^{++} electrode acting as the amplification layer (adapted from [35]). The shape of the electric field strength is indicated on the left.

Potential benefits are the suppression of pile-up jets by recognizing the time-wise association of tracks to a primary vertex.

LGAD structures

In order to reach into the picosecond timing regime with silicon detectors, in-silicon amplification can be employed. Avalanche generating silicon based devices have been developed in the context of photodetectors (see for example [31],[32],[33]). They can be distinguished by their operation mode, either as linear avalanche photodiodes (APD) operating in a linear amplification mode or as so-called Geiger APDs operating near the breakdown point thus sensing a light pulse by a large breakdown pulse with follow-up recovery time. Timing in Geiger-mode operation will be governed by the time jitter introduced by the breakdown process (multiplication jitter), similar to the case for gaseous detectors where fast timing is addressed for example with RPCs (resistive plate chambers) [34]. Another approach has been chosen by [28], namely by operating avalanche silicon diodes at a low gain operation point, so-called *Low Gain Avalanche Diodes*, LGADs.

In order to create precise time stamps, fast and large signals and low noise are needed. The *slew rate* can serve as a figure of merit, defined as

$$\frac{dV}{dt} \approx \frac{\text{signal height}}{t_{rise}}. \quad (12)$$

Figure 4 shows a principal cross section of an LGAD structure [35]. In a p^- bulk, faced on both surfaces by the usual very highly doped³ n^{++} and p^{++} electrodes rendering the structure of the detector, an additional, highly doped p^+ layer ($N_A \approx \mathcal{O}(10^{16}/\text{cm}^3)$) is implanted immediately underneath the n^{++} electrode, thus creating a very local high electric field of up to 300 kV/cm. This is the multiplication layer amplifying all arriving electrons by a factor of the order of 10-20, thereby creating secondary e/h-pairs.

The signal induced on the electrodes therefore has several components (see fig. 5):

- Electrons and holes drifting from the point of creation along the track towards their respective collection electrodes. The individual e/h parts of

³We here adopt the notation p^{++} for $N_A \gg 10^{16}/\text{cm}^3$, likewise for n^{++} .

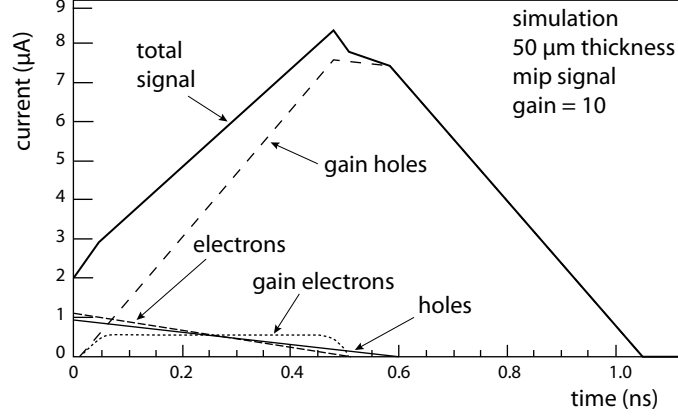

Figure 5: LGAD signal pulse detailing the contributions from electrons and holes before and after amplification following weighting field simulations [36]. The contributions from both electron and hole signals are shown before and after amplification as well as the total signal (adapted from [35]).

this contribution are small before amplification takes place and end when the last carriers have arrived at their respective electrodes.

- Amplification electrons created in the multiplication layer reach the top electrode (fig. 4) quasi instantaneously and their contribution to the induced signal current $i_S(t)$ is close to negligible, because - according to the Shockley-Ramo theorem [37, 38] -

$$i_S(t) = e\vec{v}_D(t) \cdot \vec{E}_w$$

with E_w = weighting field and v_D = drift velocity, there is almost no current contribution since the drift duration for electrons is quasi non-existent and ending before the next primary electrons reach the amplification layer.

- By contrast, the multiplied holes drifting from the amplification layer towards the backside contribute to $i_S(t)$ as long as they are drifting. Their contribution adds up, provided that the weighting field is formed such that it does not suppress contributions from distant holes too much. This implies that the pixel/pad implant widths must be large compared to the implant distances and should be in the same order of magnitude as the detector thickness.

As can be seen from fig. 5, a large slew rate and hence fast timing requires fast (primary) electron arrival at the amplification zone together with fast (amplified) hole (away)-movement. Short bunching and fast movement in high fields (~ 20 kV/cm) benefit from thin sensors.

The time resolution has several contributions [39]:

$$\sigma_t^2 = \underbrace{\left(\frac{V_{th}}{dV/dt} \bigg|_{rms} \right)^2}_{\sigma_{\text{time walk}}^2} + \underbrace{\left(\frac{\text{Noise}}{dV/dt} \right)^2}_{\sigma_{\text{noise}}^2} + \sigma_{\text{arrival}}^2 + \sigma_{\text{dist}}^2 + \sigma_{\text{TDC}}^2 \quad (13)$$

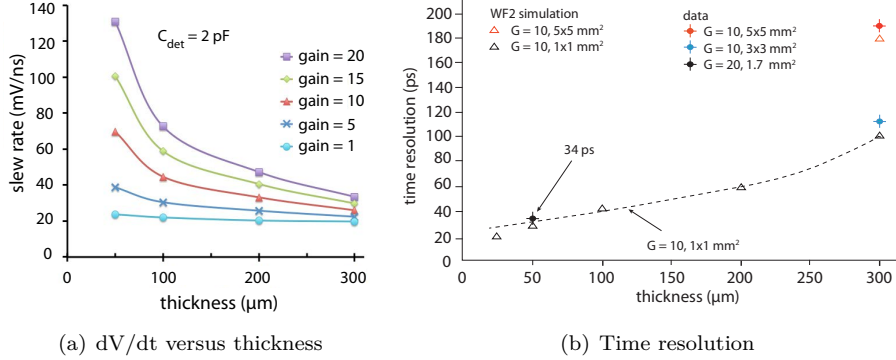

Figure 6: LGAD weighting field simulations and measurements: (a) slew rate as a function of detector thickness for different amplification gains (simulation); (b) comparison of time resolutions from weighting field simulations (WF2) and from testbeam measurements using constant fraction discrimination. Open triangles are simulation points, crossed circles are measured resolutions without errors given (bars do not indicate the measurement errors). Note the different pad sizes entering the figure. The WF2 simulations for $1 \times 1 \mu\text{m}^2$ are underlined by the dashed line only to guide the eye. The data are taken from [35],[40],[41],[30], and [39].

The first term represents time walk introduced by different signal pulse heights due to different energy deposits coming from Landau fluctuations in the energy loss process and its resulting pulse height fluctuations at the discriminator input. Minimization of this term is possible e.g. by employing a constant fraction discrimination or a ToT correction architecture in the readout. The second term is noise jitter, i.e. time fluctuations due to noisy signals. Both contributions are made small when large slew rates are achieved. An irreducible contribution comes from fluctuations resulting from non-uniform depositions of charge deposits along the particle track moving towards the amplification junction, hence causing an intrinsic jitter in the arrival time σ_{arrival} (third term). Fluctuations from secondary ionizations and from the amplification process enter here as well. The thinner the detector the less disturbing is this effect. An additional 4th contribution is signal distortion due to non-uniform weighting field regions and variations in (non-saturated) drift velocities. The final term are time fluctuations due to uncertainties in the time digitization. It is assumed that the latter can be made negligible (below 10 ps) with GHz TDCs.

The key ingredients for fast timing and small time jitter are thin detector substrates ($\mathcal{O}(50 \mu\text{m})$) providing three essential benefits:

- larger slew rate ($\times 1.6$ slew rate increase going from $d = 100 \mu\text{m}$ to $50 \mu\text{m}$ at a gain of 20),
- better bulk radiation hardness,
- smaller arrival time fluctuations due to a shorter charge deposition path.

In fig. 6(a) the slew rate is plotted against the diode thickness for different gains assuming an input capacitance of 2 pF [35]. It is evident that large slew rates can be obtained with thin detectors and sufficient gain ($\gtrsim 10$). Much higher gains compromise the S/N ratio, because bulk shot noise is also amplified by

the amplification structure (called excess noise) such that there is an optimal gain for maximum signal-to-noise (see for instance [33] or [39]).

Prototype LGAD structures have been fabricated [35, 40] with still relatively large pads (from $8 \times 8 \text{ mm}^2$ to $1 \times 1 \text{ mm}^2$), rather than pixels, mainly to validate the underlying models and simulations of the achievable time resolution. Figure 6(b) shows the predicted time resolution by simulations [36] as a function of the detector thickness. At the right hand side measured data from $300 \text{ }\mu\text{m}$ thick LGAD pad detectors are compared with simulations. Extrapolation to thin detectors yield time resolutions in the order of 30 ps. Very thin detectors have only recently become available. In a test beam measurement with 180 GeV pions using a $50 \text{ }\mu\text{m}$ LGAD sensor with $1.2 \times 1.2 \text{ mm}^2$ large pads has been characterized achieving 34 ps time resolution at a bias voltage of 200 V [41] in excellent agreement with predictions from weighting field simulations (fig. 6(b)).

A major concern for the use of LGADs at the HL-LHC is their performance in high radiation areas. Apart from the usual effects caused by radiation in silicon detectors like leakage current increase and deteriorated charge collection efficiency, effective doping changes play a sensitive role. Since the metallurgical junction providing the amplification gain requires p-doping concentrations in the order of 10^{16} cm^{-3} , radiation induced acceptor removal will have detrimental effects to the gain. Detailed radiation studies are currently ongoing [39], including to use very thin sensors ($\lesssim 50 \text{ }\mu\text{m}$) and also to substitute Boron as p-dopant in the amplification implant by Gallium which is less prone to interstitial capture due to its higher mass [42]. Another proposed method is using Carbon-enriched wafers with (abundant) Carbon being caught by Si interstitials rather than Boron.

Currently LGADs are not (yet) discussed for pixel tracking detectors but rather as a forward calorimeter layer (ATLAS HGTD) providing precise time information of jets aiming to distinguish primary vertex positions (in z) from each other (see e.g. [43]). CMS-TOTEM is planning to use LGADs in Roman Pot stations [44].

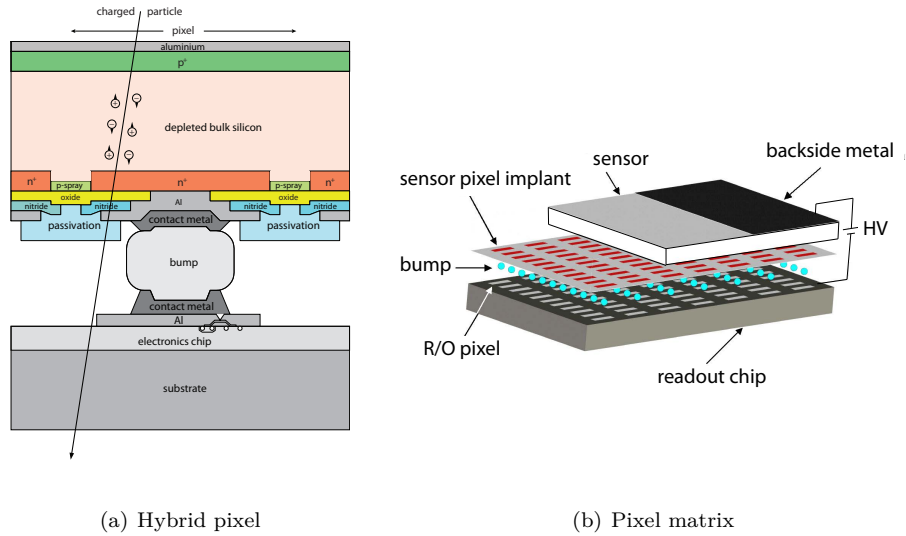

Figure 7: Hybrid pixel detector: (a) Layout of an individual pixel cell having a sensor and an electronics cell in 1–1 correspondence; (b) a hybrid pixel matrix; sensor and electronics chip have pixels of the same size, bonded to each other by means of bump contacts.

3. Pixel sensors and hybridization

'Hybrid pixels' including a sensor (electronically passive) and a readout chip as separate entities (fig. 7) currently are the state-of-the-art technology for large scale pixel detectors in most particle physics experiments [1]. For both parts, the radiation requirements at LHC-type experiments constitute a true challenge which is addressed by dedicated R&D and process engineering techniques. In this chapter we describe 'passive' sensor types used in hybrid pixel assemblies, to be contrasted to CMOS 'active' monolithic sensors that integrate electronics circuitry and sensor, described in chapter 6. The mechanical and electrical mating of sensor and readout chip, called 'hybridization', requires state-of-the-art processing technologies, also described in this chapter (section 3.3). The hybridization mating partner, the readout chip (ROIC) is described in detail in chapter 4.

After the success of so-called planar sensors in LHC run-1, having planar pixel implants at one side of the sensor (fig. 8(a) and section 3.1)) and being fabricated using 4'' sensor wafer technologies, the desire for large detector modules at affordable cost has fueled the move to 6'' and possibly even 8'' wafer sensor technologies. In line with this a better understanding of radiation damage effects and radiation hard sensor device engineering became a research branch on its own, coordinated within the CERN RD50 collaboration [42].

Radiation hard device engineering includes using silicon with increased oxygen content supplied in the growth process [45, 46, 47] and operation at low-temperature, both employed to reduce the damage's impact on the detector performance. Furthermore, so-called 3D-silicon sensors [48] (see section 3.2) have been developed having vertically structured electrodes driven into the silicon substrate (fig. 11). Their main feature is a better ratio of ionization thickness

to charge collection distance than for planar sensors. After an operation performance proof in the first pixel upgrade of ATLAS (Insertable B-Layer, IBL [3]), an innermost pixel barrel layer at a distance of 3.5 cm from the interaction point, equipped with 25% 3D-Si sensors (at high η) and 75% planar pixel sensors, both sensor types now compete for the HL-LHC upgrade as pixel sensors for the radiation hot areas near the interaction point.

A challenge for both sensor types imposed by the very high radiation fluences of $>10^{16} \text{ n}_{eq} \text{ cm}^{-2}$ is the small foreseen sensor thickness (100–150 μm) and the correspondingly increased handling and hybridization difficulty.

Another big advancement in cost reduction of sensor wafers is the use of high quality p-substrate material ($\gtrsim 2 \text{ k}\Omega\text{cm}$). With n-in-p type sensors cost-efficient single sided processing suffices for fabrication while maintaining electron collection (n-type pixels). During the initial LHC pixel development period (late 1990s) high ohmic p-type sensor wafers were not favoured, largely for reasons of historical development⁴, and n^+ -in- n planar pixel sensors have been used instead, requiring processing steps on both sides of the wafer.

With CMOS technology vendors becoming more open to smaller market customers, the use of high ohmic 8" wafers fabricated in (much lower cost) CMOS processing lines come in focus as (planar) sensor options (see section 3.1).

Currently, therefore, the trend in hybrid pixel module development goes to large readout chips and thin sensors, preferentially using p-type bulk material, all being beneficial for cost, radiation tolerance, and detector mass, while the handling and hybridization demands increase. The latter together with the increased interest for large area coverage using pixel detectors also revived collaboration with industry to develop lower cost hybridization techniques even with thinner wafers/chips.

3.1. Planar pixel sensors

The proven standard of planar pixel sensors at the LHC experiments has n^+ pixel implants on n -type substrate material as shown in fig. 8(a). The fabrication demands double-sided processing. The negative bias potential on the backside is brought down to zero potential at the sensor edge by a many guard ring structure implanted on the backside. The pn-diode originally is on the unstructured backside of the sensor, changing to the electrode side after radiation has turned the bulk's n^- doping into effectively p-type (type inversion). For typical substrate resistivities of 2–5 $\text{k}\Omega\text{cm}$, this happens after fluences of some $10^{12} \text{ n}_{eq}/\text{cm}^{-2}$. After type inversion the depletion zone grows from the electrode side into the bulk guaranteeing that signals induced by moving charges can be sensed on the pixels even if the substrate is no longer fully depleted, i.e. not depleted at the side opposite to the pixels. To prevent an electron accumulation layer short circuiting the n^+ -in- n pixels before type inversion, shallow p -doping in between the pixel electrodes, with a smoothly changing doping profile preventing high field corners, has turned out optimal for the designs. Details are given in [1].

⁴Single sided Si sensor development had begun using n-substrate material with hole collection on p-electrodes. For radiation tolerance reasons electron collection became favored leading to n^+ -in- n structures with double sided processing. For n-in-p sensors it then has taken time to develop n-side multi-guard-ring structures and reliable HV bias isolation from the electronics before high quality p-type sensors were fabricated.

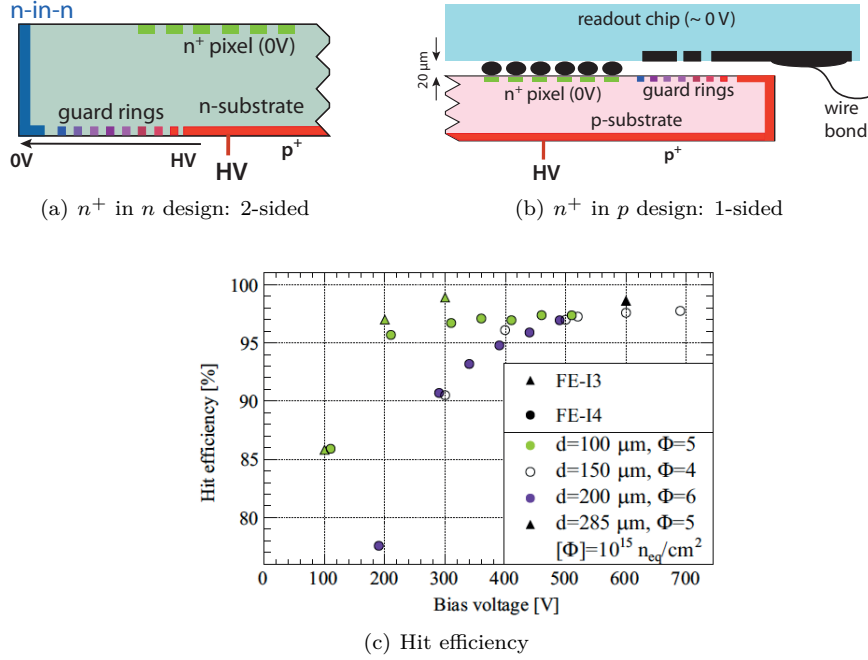

Figure 8: Planar sensors: (a) LHC conventional n^+ -in- n design requiring 2-sided wafer processing; (b) n^+ -in- p design with single-sided processing (bump) bonded to a readout chip. Note the small distance between readout chip and guard ring implants; (c) hit efficiency as a function of bias voltage for different fluences and various sensor thicknesses [49].

With increasing radiation fluence the bias voltage needed for sufficient depletion must be increased, eventually reaching values of more than 500 V at fluences around and beyond $10^{15} \text{ n}_{eq}/\text{cm}^2$. For the innermost layers close to the interaction point this corresponds to detector lifetimes of only a few years at current LHC luminosity.

The development of planar sensors for the LHC high luminosity upgrade has therefore concentrated on tailored designs guaranteeing high fields and sufficiently large depletion depths after fluences of up to and above $10^{16} \text{ n}_{eq}/\text{cm}^2$. This has been achieved using n^+ pixel implants in p -substrate material and thin (100-150 μm) sensors operated at bias voltages of 500-700 V [49]. While providing smaller signals per MIP, the benefits of thin sensors are higher electric fields as well as shorter and faster electron collection for a given bias voltage and hence better radiation tolerance. Thin 6" or even 8" sensor wafer production is enabled by techniques employing SOI or Si-Si handling wafers, or by thinning (e.g. by cavity etching) and forming a back side ohmic contact at low temperature after the front side processing is complete. Currently the limit in thickness is considered to be around 50 μm [50].

The guard ring designs, bringing down the potential from the bias implants (HV) to the pixel implants (0 V), play an important role in optimizing the breakdown behaviour of sensors after irradiation. Number of rings, implant distance and size, as well as metal overhangs for vertical field suppression are the parameters to optimize. Optimal performance regarding radiation tolerance has been obtained [50] with 10–11 rings with metal overhangs on both sides of

the implant over a total length of 350 μm . The distance from the edge to the active part of the sensor still is $\gtrsim 400 \mu\text{m}$. Other designs trying to minimize this distance at the price of breakdown performance at high fluences reach values down to about 50 μm [51].

Figure 8 shows a planar pixel design as used in present LHC hybrid pixel detectors (200 μm thick, n^+ -in- n design) compared to a thin n^+ -in- p design. Note that, if cost saving single sided processing is to be used, the guard ring structure needs to be placed on the electrode side and is thus in very close vicinity ($\lesssim 20 \mu\text{m}$) to the readout chip, a challenge for the design. Dedicated passivation with BCB (benzocyclobutene) or parylene, however, indicates to be able to solve this issue [52]. Figure 8(c) shows that high hit efficiencies can be achieved after irradiation with thin sensors for bias voltages in excess of 500 V.

Use of 8" wafers and CMOS fabs

It is also possible to fabricate planar sensors on 8" wafers using high ohmic substrates either in dedicated sensor fabs or by employing CMOS processing lines, as has been successfully demonstrated for strip and pixel sensors [53, 54]. This has the following advantages compared to the standard small volume sensor fabrication:

- Large volume production lines can be used with price advantages, suited in particular for large area detectors, e.g. in outer tracking layers at collider experiments.
- Wafer sizes of 8" or 12" are a commercial standard allowing large sensors when stitching over reticle boundaries is applied. Stitching is a method to cross the boundaries between reticles of a wafer with metal lines and implant areas, widely applied in the digital imaging industry [55]. Current reticle sizes are about $25 \times 25 \text{ mm}^2$. By putting individual building blocks of a design separately (rather than together) on the reticle/mask one can join them together over the reticle's boundary by special lithographic programming, thus allowing IC fabrication of sensor sizes much larger than the reticle area of the CMOS process.
- The wafers can be purchased with solder bumps already provided by the CMOS vendor (e.g. so-called C4 bumps [56], pitch $\gtrsim 150 \mu\text{m}$).
- One or two metal layers can be exploited for AC coupling of the sensor cell to the amplifier and for connection redistribution, e.g. to connect amplifier inputs to pixels in areas not 1:1 covered by readout chip cells (regions in between readout chips).

A sketch illustrating some features employing passive CMOS sensors is shown in fig. 9. Measurements on passive CMOS pixel sensors irradiated to fluences of $1.1 \text{ n}_{eq}/\text{cm}^2$ in the lab and in test beams have shown performance equal to those of planar sensors fabricated in dedicated sensor production lines [57]. Figure 10 shows the mean hit efficiency as a function of bias voltage measured with 3.2 GeV electrons for DC and AC coupled passive CMOS sensors bonded to the ATLAS readout chip FE-I4. In particular the AC-coupled devices show excellent performance without any efficiency losses. The DC devices are a bit less efficient due to the area taken by the punch-through dot for biasing of the pixel implants.

Figure 9: Hybrid pixel module using passive CMOS pixel sensors (schematic). Depleted sensor employing CMOS technology with 1-2 metal planes that can be used for (i) AC coupling and (ii) rerouting. The insert details these features. The yellow area in every pixel denotes the charge collection node.

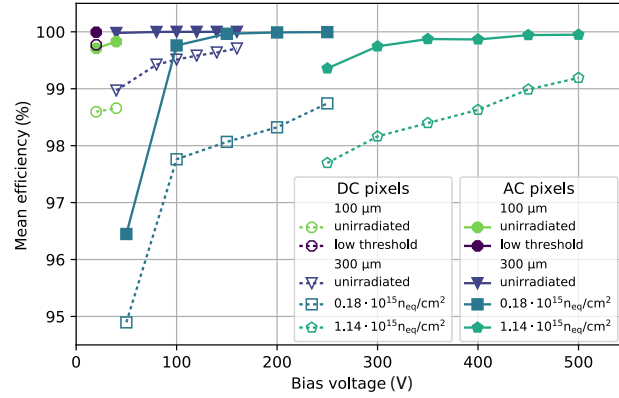

Figure 10: Hit efficiency measured in 3.2 GeV electron testbeams [57] of passive CMOS pixel sensors as a function of bias voltage, unirradiated and for two fluence levels.

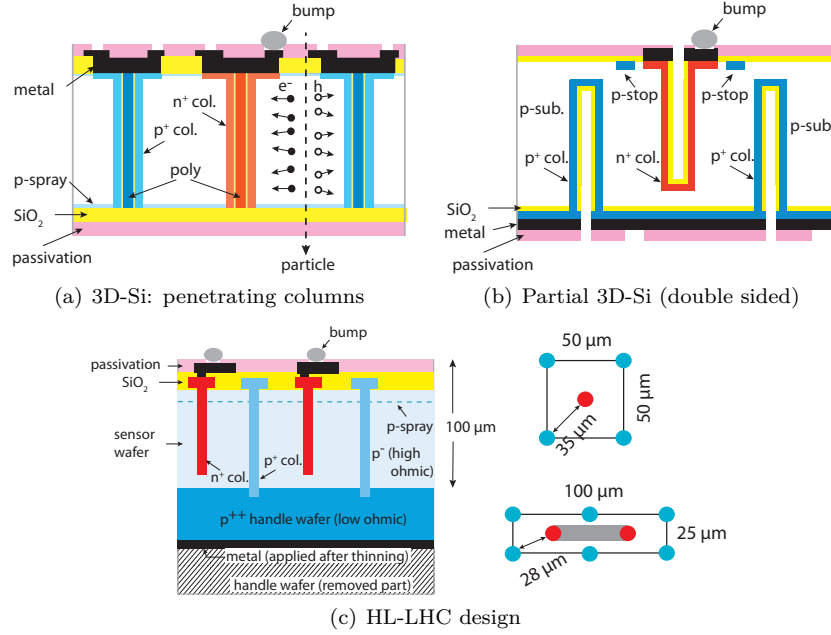

Figure 11: 3D-Si sensors: (a) Design (single sided) with columns going completely through the sensor bulk [59]; (b) double sided design with columns entering from both sides, but not reaching through (adapted from [63]); (c) thin design optimized for HL-LHC (adapted from [64]) with two top view sketches for $50 \times 50 \mu\text{m}^2$ and $25 \times 100 \mu\text{m}^2$ pixel sizes, respectively [65].

3.2. 3D-Si sensors

So-called 3D-silicon sensors have been developed since the late 1990s [48, 58] featuring columnar electrode implants driven into the Si substrate perpendicular to the sensor surface (fig. 11). The electrode distance is made smaller ($50 \mu\text{m}$) than the typical sensor thickness ($200\text{--}250 \mu\text{m}$), thus rendering a shorter average drift distance for particles impinging on the sensor face than in the case of planar sensors (see fig. 11(b)). In addition high drift fields are obtained with still moderate bias voltages. Both these facts result in an increased radiation tolerance due to a reduced trapping probability.

The 3D-Si technique has been developed over many years. The first structures were fabricated at Stanford (later also at Oslo) [59] using single sided processing with columns reaching completely through the bulk (called 'full-3D', see fig. 11(a)). Further development by CNM [60] and FBK [61] of sensors used in the ATLAS IBL detector, resulted in double-sided 3D designs with columns entering the bulk from both sides, either in full-3D or in partial-3D (see fig. 11(b)). The process fabricates about $10 \mu\text{m}$ diameter columns by etching, followed by a $1 \mu\text{m}$ polysilicon layer covering the inside of the etched holes, then passivated by a wet oxide [60]. In addition the sensor edges can be fabricated with active edge implants thus rendering sensors with an unrivaled active area fraction [62]. More details on etching holes into silicon can be found in section 3.5.

Within the ATLAS IBL detector 3D-Si pixel sensors have been proven to operate well in a running experiment [3]. After two years of operation the performance of 3D-Si pixel modules in terms of operation characteristics (signal,

Figure 12: 3D-Si sensors: hit efficiency as a function of bias voltage for different fluences and various design variants [65].

noise, threshold settings, in-time efficiency) are on par with planar pixel modules operated with significantly higher voltages [66].

Current developments towards HL-LHC demands [65, 60, 67, 64] target the following goals to optimize radiation hardness, granularity, material budget, and processing costs [64]: (a) thin sensors ($\sim 100 \mu\text{m}$) on 6'' wafers, (b) narrower electrodes ($\sim 5 \mu\text{m}$), (c) shorter electrode spacing ($\sim 30 \mu\text{m}$), and (d) very slim ($\sim 50 \mu\text{m}$) or active edges. Single sided processing is preferred providing cost benefits. An advanced design [64] is shown in fig. 11(c). A thin, highly resistive (p-type) sensor wafer is supported by a low ohmic (p^{++}) handle wafer that can be backside thinned after processing. While the p^{+} columns are deep etched through to the handle wafer where they receive their electric potential, the n^{+} columns stop about $15 \mu\text{m}$ short from the handle wafer. Besides for technical reasons (i.e. wafer-to-wafer bonding), studies have shown that also for single-sided 3D-Si sensors the trade-off between signal efficiency and breakdown performance favors non-passing-through n-columns [68]. At the top surface isolation of the n-columns is achieved by a p-spray layer preventing the electron accumulation layer underneath the oxide to create shorts. Sensors are designed to meet the currently considered pixel area sizes of $50 \times 50 \mu\text{m}^2$ or $25 \times 100 \mu\text{m}^2$, respectively, as shown on the right of fig. 11(c). The performance of such designs has been shown to yield high breakdown voltages before and after irradiation [69].

The hit efficiency obtained with 3D-Si structures designed by CNM [65] is demonstrated in fig. 12 for fluences of up to $0.9 \cdot 10^{16} n_{eq}/\text{cm}^2$ [65]. A $>97\%$ efficiency plateau is reached with comparatively low bias voltages of 150 V even at the highest fluences, with the missing 3% being largely due to tracks with straight incidence into the column structures, a case not possible for tracks from actual LHC collisions. Smaller implant pitches with lower voltages for the same field strength also reduce power dissipation due to leakage currents after irradiation. This creates some safety margin against thermal runaway, not completely negligible even at the moderate bias voltages of 3D-Si sensors [70].

3D-Si sensors therefore are a strong contender for hybrid pixel modules for the innermost pixel detector layers at the HL-LHC. It should be noted, however, that the involved fabrication technology does likely not allow to cover very large area ($> \text{m}^2$) with this technology choice.

3.3. Bonding Techniques

Wafer- and chip-bonding as well as 3D-integration technologies are a widespread demand in the semiconductor industry regarding IC module assembly and stacking. Many techniques exist that are suitable for a large variety of applications and given fabrication constraints. A large amount of literature is available, reviewed and summarized for example in [71, 72, 73].

For hybrid pixel detectors, as predominantly addressed in this review, the mating of readout chips to substrate (sensor) plates or substrate wafers is the main application of bumping/flip-chipping and 3D-integration techniques. The overriding demands in these applications are small capacitance additions to the preamplifier by the bond connection, good yield with $< 10^{-4}$ defect rate (open or short), good contacts ($< 100 \text{ m}\Omega$), and robustness against temperature cycling (-40°C to $+60^\circ\text{C}$). The need for small pitches between bond connections imposed a very high demand on industrial standards when pixel R&D for the LHC started. At the time the required pitch of $50 \mu\text{m}$ was about 15 years ahead of industrial demands. This pitch has become a standard today and requirements for current hybrid pixel R&D often targets pitches less than $50 \mu\text{m}$.

Bump or underbump metal (UBM, see below) application usually is a wafer-scale process. Flip-chipping, on the other hand, is conventionally employed to mate bumped readout chips to (bumped) sensor plates⁵. For the existing detectors at the LHC experiments and likely also for the detectors of the coming-up upgrades *eutectic soldering*⁶ [74] and *In-In* thermocompression bonding are the methods that have been preferred over other techniques (see e.g. [1]) like for example anodic bonding, fusion bonding, and adhesive bonding (see below). In current techniques ICs are usually bonded to sensor plates or wafers (chip-to-wafer bonding, C2W). Wafer-to-wafer bonding (W2W) is a cost attractive future possibility for pixel detectors that might become interesting for applications in connection with further advances in vertical electrical interconnection in so-called 3D integration techniques. In particular *through silicon vias* (TSV) open the possibility to provide elegant and space efficient electrical contacts for hybrid pixel module fabrication when employing W2W or C2W bonding techniques. TSVs also allow reaching through to the backside of a chip (or sensor). This can be exploited to use the chip's backside metal for redistribution of readout or service lines (redistribution layer, RDL).

Solder bumps and bonding

One can perhaps subdivide the bonding technologies relevant in this review into (a) technologies requiring intermediate media to perform the bonding like for example eutectic bonding by means of solder or adhesive bonding using glue layers and (b) direct bonding, either metal-to-metal or silicon oxide-to-oxide. When intermediate materials are used no requirements on special surface treatments exist except for flatness. After bump (resp. UBM) fabrication oxide removal is needed before flip-chipping can be done. The bonds are strong and

⁵Depending on the techniques one of the mating partners can have bumps as well, e.g. for *In-In* flip-chipping, or can just have an *Underbump Metallization* (UBM) for the mating process, e.g. for solder bump flip-chipping.

⁶Eutectic systems are solid mixtures that form a superlattice by striking a unique atomic percentage ratio and thus have the same melting point.

Figure 13: Eutectic solder bumps and flip-chipping process: (a) Solder bump attached to a readout chip is bonded to the UBM (*Underbump Metallization*) of the pixel sensor; (b) SEM micrograph of a SnAg bump (courtesy of Fraunhofer IZM Berlin) .

postprocessing - like thinning - is often possible. The lack of electrical connections (in the case of adhesive bonding) or price and pitch constraints (for solder bonding) are drawbacks.

The bonding technique currently used most often is the electrochemical application of solder micro bumps to either of the mating parts (chip or sensor). A description of the method and the process steps is given in [1]. Solder bumping has first been introduced already in 1969 by IBM in the so-called C4-process (Controlled Collapse Chip Connection) [56]. The process is still in use by CMOS vendors and is often offered with CMOS wafer production as an add-on. The pitch of the applied bumps is limited to 170 µm or larger, often too large for fine-pitch, high granularity pixel detectors in particle physics. However, price and reliability arguments render C4-bumping still very attractive for low cost, large area applications at LHC upgrades, as for example addressed in section 3.1 on page 19.

Eutectic solder bumping has meanwhile been developed with high connection density down to pitches of 25 µm [75] and bump dimensions of (15 µm)³. High yield is obtained with Sn/Pb as well as with lead free Sn/Ag or Au/Sn alloys [76]. The ultimate pitch limit is believed to be around 5–10 µm [23]. Readout ICs typically have Al or Cu pads for bump connection bounded by a passivation layer for chip protection. Typically a thin (100 nm) Ti:W layer is first sputtered onto the wafers to promote adhesion and provide a barrier to prevent Cu atoms from diffusing into the pad metal (Al). Then a Cu or Au plating base (> 150 nm) is applied for the electrochemical contact followed by a well wettable Cu layer (1–5 µm). This layer stack is called *Underbump Metallization* (UBM) and is applied to both mating parts. In a wafer-based process cylinders of an electrodeposit are now grown onto the UBM of one part and turned into a spherical shape by reflow. Bonding of both parts is so far mostly done after singularization of bumped readout ICs and sensor plates or wafers supplied with UBM in a flip-chipping process and subsequent remelting of the solder bumps. Note that this reflow process provides self-alignment of the mated parts.

Eutectic solder bumping is regarded as present day's workhorse bonding technique for hybrid pixel detectors. For the ATLAS pixel detector very high bond yields of more than 99% have been obtained (i.e. number of modules not rejected due to bonding issues).

Figure 14: In-In bonding: indium bumps produced before (a) and after (b) reflow to a sphere (from [1], courtesy of S. Ritter, PSI) .

In-In bonding

In-In bonding has also been used in LHC pixel detectors for a large quantity of pixel modules. The technique usually employs vapour deposition⁷ of indium through openings in the lift-off masks deposited on wafer (see e.g. [1]). The mask is pulled off from the wafer by a wet lift-off process, requiring the bumps to be fairly flat and thin ($\approx 10\text{ }\mu\text{m}$, fig. 14(a)). Also a UBM is necessary for this process, usually Ti-Pt-(Au) is used. The applied indium bumps are then bonded by thermocompression at about $100\text{ }^\circ\text{C}$. The advantages of the technique are its ease of application and the low temperature requirements. The bonds are, however, comparatively fragile, and the fabricated modules tend to have lower mechanical damage threshold than solder bumped assemblies. In the Run-1 ATLAS pixel detector about 50% of the modules were produced using In-In bonding, showing high reliability with acceptance yields around 90%. For the CMS pixel detector a reflow step has been introduced after bump deposition [77], turning the In bumps into spherical shapes (fig. 14(b)). The two spheres are merged in a second reflow at $180\text{ }^\circ\text{C}$. This provides a larger distance between chip and sensor, it introduces self-alignment and stronger bonds.

Adhesive bonding

Recently adhesive wafer-to-wafer bonding has been discussed in the context of active CMOS sensors, capacitively coupled to readout chips where the capacitive coupling is provided between the metal pads of sensor and chip, respectively, separated by the adhesive bonding layer. Adhesive bonding has been claimed to reduce production cost avoiding cost effective hybridization steps like underbump metallization (UBM), bump deposition, and reflow steps. This has, however, not yet been demonstrated and is not at all obvious. Planarity requirements are stricter and requirements for alignment for chip-to-chip/sensor placement are the same as for standard bump bonding, the latter being the cost driver, not to mention the need of (very cost intensive) electrical connections of the mated parts if provided by TSVs.

In the context of capacitive coupling of 'smart sensors' to readout ICs (CCPD) adhesive bonding has been investigated regarding thickness control and

⁷electroplating of indium is also possible

uniformity of the adhesive as well as radiation tolerance [78]. Good glue uniformity at the micrometer level has been achieved, however further evaluation of its competitiveness is needed, in particular whether electrical connections can be provided by cheap techniques like e.g. wire bonding, thus, however, abandoning the goal of compact module shapes.

Cu-Cu direct bonding

Metal-metal adhesion (Cu-Cu or Au-Au) of flat and polished surfaces is known for a long time. The bonding forces principally contain capillary, Van der Waals, and electrostatic forces, as well as solid bridges caused by impurities and hydrogen bonds between OH groups.

Two mirror-polished wafers are put into contact and held together by adhesive forces without any intermediate material [71]. The process completes by Cu atom diffusion between the two Cu layers. Thermocompression (diffusion) bonding is simplest, but the required temperatures are usually too high for typical sensors and CMOS chips used in pixel detector applications.

Especially interesting is surface-activated Cu-Cu bonding as it works at ambient temperature. Surface-activation in this context means increasing the bonding force by surface treatment, e.g. by augmenting the number of hydrogen bonds (hydrophilicity) or by generating new types of chemical bonds. The treatment methods comprise wet chemical processes and (oxygen) plasma etching. The bonds are electrically conductive, an advantage for any wafer-to-wafer but also chip-to-wafer bonding project.

Requirements for good bonding are native oxide and other remnant removal, excellent chemical-mechanical polishing (CMP), and highly planar parts (wafers) with sufficient total Cu fraction. Very fine pitch ($< 4 \mu\text{m}$) and low capacitance contacts are possible. The demands on surface cleanliness and flatness are the biggest drawbacks. Wafers must be processed soon after fabrication. Wafers must be very planar and sufficiently stiff which might compromise very thin solutions. At present the technique is also still fairly expensive.

Oxide-Oxide direct bonding

Under room temperature conditions silicon wafers are covered with an oxide layer that can be used for direct wafer bonding, a method commonly used for SOI wafer production. Most common is 'hydrophilic' wafer bonding in which the wafers are, after cleaning, rinsed or stored in deionized water. Water is bonded via Si-OH groups on the silica surface. The bonding can be done at room temperature but the bonding strength increases with temperature (and time). With the addition of an electric field one speaks of 'anodic bonding' which can tolerate rougher surfaces.

Required is high quality CMP polishing and extremely good surface cleaning to avoid large bonding voids. The bonds are non-electrical. Hence TSVs or other electrical connections are needed for pixel assemblies. For this process wafer-to-wafer bonding is much easier than chip-to-wafer or chip-to-chip.

Solid-Liquid Interdiffusion bonding (SLID)

SLID bonding uses an intermetallic alloy formation and represents an alternative fine-pitch bonding technique based on thin (often eutectic) Cu-Sn connects [79, 71]. Between two Cu layers of several micron thickness a thin ($3 \mu\text{m}$)

Figure 15: Process steps of Solid-Liquid Interdiffusion bonding (SLID): (a) structure with metal stacks before bonding, (b) alloy forming step under pressure at 240–320 °C, (c) resulting bond connection.

Sn layer is applied on one of the Cu layers (fig. 15). They are brought in contact and heated to a temperature of around 240–320 °C. At this temperature the tin diffuses into the copper forming the Cu-Sn alloy. As the melting point of this alloy is around 600 °C multiple layers can be stacked and connected without melting the previously formed SLID connections. Furthermore, the process is also a flux-free bonding alternative with pitches much below 20 μm , whereas the number of processing steps is about the same as for solder bonding (reflow step is not needed). Technically, for SLID, pressure and temperature are required during the bonding step. This renders sequential bonding of multi chip pixel modules necessary (chip after chip), whereas bonding by reflow does not require pressure (c.f. page 23) and can be done in parallel for a number of chips bonded to a sensor plate.

Despite their similarity SLID and soldering are fundamentally different processes with distinct and unique properties. A major difference is that soldering is reversible, whereas SLID is irreversible and only melts at temperatures much higher than the SLID process temperature. This implies also that no reworking is possible. Some process similarities also exist to metal-metal thermocompression bonding. A detailed comparison is given in [71]. SLID is particularly suited for wafer-to-wafer and chip-to-wafer bonding.

3.4. Wafer thinning

Thin wafers are a goal not only for low-mass pixel detectors in particle detection, but also for a number of integration processes, in particular for Through-Silicon Vias. While thick wafers are better for handling, other process steps like for example etching benefit from small wafers thickness. However, dedicated 'handling wafers' are needed to deal with flatness and bowing issues. Often handling wafers are of the SOI-type (Silicon-on-Insulator) because the Si-SiO₂ interface transition offers a sharp etch stop with the oxide also acting as a sacrificial layer after ion etching.

Wafers are thinned by (backside) grinding. The active (front) side is first protected by tape. Grinding in two steps (coarse/fine) is performed using grinding wheels with diamond grain sizes from 1–8 μm (fine) to 20–80 μm (coarse) diameter. After the thinning process, breaking strength, warpage, and bow are characterization parameters that depend on the grinding tool characteristics and the grinding speed. More details are given in [72].

3.5. 3D-Integration and Through-Silicon Vias

Extending electronics integration into the third dimension is - apart from feature size shrinking - regarded as the second route to ever increasing circuit density. 3D-stacking of several electronic device layers (tiers) is thus an eminent field of industrial research. Further advantages are reduced power consumption due to smaller connections and smaller involved capacitances as well as larger I/O bandwidth and more functionality at lower cost. Vertical vias running through layers of silicon (TSVs) are a key ingredient for 3D-stacking [72]. Tiers can be different CMOS layers but also electronics and sensor layers or layers interfacing to an optical signal transport. Figure 16(a) is a sketch illustrating the principle of 3D-interconnection via TSVs.

Besides TSV fabrication, wafer thinning and aligned wafer bonding are the key follow-up processes for 3D-integration. Direct bonding, especially Cu-Cu fusion or SLID (see above) are the preferred bonding techniques for 3D-stacking, providing strong fine-pitch bonds that are also conductive.

For future pixel detectors in particle physics 3D-integration and TSVs are of interest if (a) wafer scale production comes in focus and/or (b) if TSVs allow better connectivity of detector modules by avoiding space consuming wire bonds and providing better buttable modules. In addition TSVs can reach through to the backside of a chip, an advantage when redistribution of electrical connections on the chip's backside metal is addressed. The latter in turn saves material else added by flex circuits which is conventionally used for circuit line redistribution.

Figure 17: Different types of vias. (left) *via-first*: fabrication before or during FEOL, (middle) *via-middle*: fabrication after FEOL during BEOL, (right) *via last* fabrication after IC completion (post-BEOL) (adapted from [81]).

TSV fabrication

In IC fabrication all processes before the first wiring metal are called *front end of line* (FEOL), whereas the *back end of line* (BEOL) begins with this first metal processing and ends with the last IC processing step. Different types of TSVs are distinguished depending on at which point in the process flow they are fabricated [83], i.e.

- *via-first* or FEOL via (polysilicon) applied before or during FEOL fabrication.
- *via-middle* or BEOL via (metal) applied after FEOL during BEOL fabrication
- *via-last* or post-BEOL via(metal) applied after IC fabrication post-BEOL. Here one distinguishes also *frontside via-last* as in fig. 17 (right) and *backside via-last*, depending on whether the via is etched from the front through the BEOL stack (difficult) or from the back through (thinned) silicon substrate.

Note that the conducting material for FEOL TSVs must be doped polysilicon for reasons of thermal and material compatibility, having the disadvantage of higher resistivity compared to metals. For BEOL and post-BEOL vias tungsten and copper are most common. Figure 17 shows these distinguished TSV types schematically.

Important TSV specs are diameter, pitch, and aspect ratio (length-diameter ratio). Present typical ranges are given in table 3.5.

The main process for TSV production is *deep reactive ion etching* (DRIE, invented by Bosch [82]). The process employs a directional repetitive sequence of ion etching and wall passivation resulting in anisotropic etching of the silicon bulk. The principle is shown in fig. 18. The alternating cycles (typically lasting about 5 s) are: etching under a bias voltage with SF_6 or NF_3 in argon atmosphere to form gaseous SiF_x^+ products - passivation of the surfaces with C_3F_6 , C_4F_8 , or CHF_3 in argon forming a protecting fluorocarbon polymer surface layer on sidewalls and bottom. The bias voltage provides a directional orientation of the

Figure 18: Deep Reactive Ion Etching (DRIE) in the Bosch process [82]. From top to bottom a sequence of ion etching and passivation is executed (see text).

via type	smallest diameter	smallest pitch	typical aspect ratio
via-first	3 – 5 μm	6 – 10 μm	10 : 1
via-middle	3 – 5 μm	6 – 10 μm	5–10 : 1
frontside via-last	10 – 20 μm	20 – 40 μm	5 : 1
backside via-last	5 – 20 μm	10 – 40 μm	5–12 : 1

Table 2: Typical TSV parameters (2017) [72, 83, 84].

bombardment. The resulting via has a typical scalloped surface with undercuts that are, however, substantially reduced by advanced DRIE parameters.

First HEP experiences with TSVs

A characteristic of TSV application for HEP pixel detectors is the fact that readout chips or sensors are still comparatively thick (100-200 μm) for via fabrication. On the other hand the required via pitch and density often is relaxed, for example when only service lines need to be via-connected or when I/O pads can have large pitches.

Therefore, the first successful HEP pixel module operation employing TSVs [85] was obtained with small aspect ratio ($\sim 1:1$) tapered vias as shown in fig. 19, fabricated at Fraunhofer IZM, Berlin. Chip wafers (FE-I3) of the ATLAS pixel detector production were thinned to about 80 μm thickness. The I/O pads were accessed through TSVs and redistributed on the backside of the chip. The via geometry can be seen from fig. 19(a): 110/45 μm diameters (top/bottom), $\sim 70^\circ$ tapering angle, 150 μm via pitch. After wafer dicing a pixel module was assembled by bonding a readout chip containing vias to a pixel sensor using solder bonding. The pixel module was operated and characterized with radioactive sources performing without performance loss compared to modules connected via wire bonds instead of vias.

Larger via depths and aspect ratios are required to connect large area chips like the ATLAS FE-I4 chip [4] having about $2 \times 2 \text{ cm}^2$ area. Unsupported by handling supports such chips show large bows and the thickness must be optimized for handling, bonding, and TSV yields. A successful approach was achieved using straight copper vias (Fraunhofer IZM, Berlin) with an aspect ratio of 2.7:1 applied to 160 μm thick FE-I4 wafers [86],[87] (fig. 20(a)). Similar efforts are carried out at LETI/CEA [88]. A $2 \times 2 \text{ cm}^2$ pixel module was produced along similar lines containing about 25 500 pixels, and characterized using radioactive sources. To increase the via yield to close to 100% a new approach using chip wafers thinner than 100 μm with handling wafer support using straight Cu-coated vias is under way.

4. Readout integrated circuits, data transmission, and power distribution

The readout integrated circuit (ROIC) provides the functionality of a hybrid pixel assembly. From the start, the purpose of the hybrid approach has been to allow independent specialization of ROIC and sensor [89]. The ROIC technology has followed the enabling lead of Moore’s Law (the doubling of logic density every 2 years in commercial electronics) towards deep submicron commercial CMOS, in order to meet rate and radiation tolerance demands. The alternative of stacking circuit layers in the 3rd dimension without reducing feature size has also been explored, but has so far been less successful. Data transmission and power distribution are system challenges concerning the ROIC as well as other elements such as optical components, encoding/decoding protocols, cables, and cooling.

4.1. CMOS ROICs

It is useful to classify CMOS ROICs in terms of generations, which have a rough correlation with the feature size used. First generation pixel chips are typified by those in the original ATLAS and CMS detectors [90, 91], Medipix [92], using 0.25 μm feature size CMOS with custom layout techniques for radiation tolerance. Second generation chips have been developed and fabricated using 130 nm CMOS and are running in current experiments or devices [4, 93, 94]. Third generation chips are under development, focusing on 65 nm CMOS [95, 96, 97]. Table 3 shows the evolution of memory and readout bandwidth between generations.

	1 st gen.	2 nd gen.	3 rd gen.
Hit data storage density	< 1 Gb/s/cm ²	5 Gbps	40 Gb/s/cm ²
Chip output bandwidth	40-160 Mb/s	0.3-1.2 Gbps	2-20 Gb/s

Table 3: Hit storage memory and output bandwidth for each generation of pixel readout chip.

The basic elements and organization of a hybrid pixel readout chip are common to all generations and applications. The defining characteristic is the use of a dedicated amplification and discrimination channel per pixel (*front end*), with the ability for all these front ends to operate in parallel, followed by parallel processing of the output signals. Section 4.6 reviews the front end characteristics. The output of the front end is most commonly digitized in some way on the pixel, but can also be sampled on an analog memory for later readout as an analog level [91]. On-chip digitization allows for higher readout bandwidth with pure digital readout and is expected for all third generation chips. The preferred digitization method has so far been Time over Threshold or ToT (see section 4.6). We normally refer to a pixel *firing* when the amplified signal exceeds the discriminator threshold. Managing power transients and noise coupling when all pixels are simultaneously *live* (having the ability to fire at any time) is a main system challenge of pixel ROIC design. Many chips are designed for a given maximum occupancy (number of pixels firing at once) and therefore only guarantee system stability in applications that do not exceed this occupancy.

Figure 21: Schematic representation of a conventional CMOS inverter (left) and the triple well process implementation (right).

While the front end architecture remains similar from one generation to the next, processing of the information produced by the front end, and the relationship of the front end to the rest of the chip, have evolved significantly. First generation chips were mainly analog circuits, with some logic and memory to manage hit buffering and readout. The most salient new feature of second generation chips was the use of synthesized logic side-by-side with analog front ends in the entire pixel matrix, but with an organization in columns and small digital blocks stepped and repeated. The third generation will go further, implementing an almost entirely digital chip, with a large number of pixels within a synthesized logic basic unit. The front ends will be embedded as data sources within a digital fabric entirely surrounding each analog unit.

Logic density is critical to pixel ROIC design, unlike in most other physics detector applications, where analog performance tends to be of the highest importance. Achievable logic density is intimately tied to rate capability as will be seen later. The 1st generation chips had a mainly analog pixel matrix, with digital operations implemented using full custom circuits (produced with analog design methods). Any digital processing and data buffering were done in the periphery. This resulted in a relatively large periphery area and the need for high bandwidth data transfer from pixels to periphery (see section 4.7). The most prominent new development in 2nd generation chips was the use of synthesized logic within the pixel matrix, enabled by a leap in logic density (see section 4.3). Thus the matrix became a mix of analog columns designed with conventional analog methods and digital columns synthesized with digital design tools. Digital processing and storage in the columns meant the periphery area could shrink and the hit rate capability increased (section 4.7). The 3rd generation chips are now expected to be essentially digital, with embedded analog amplifiers kept to a minimum and logic complexity rivaling commercial microprocessors. This opens the door to unprecedented functionality within the front end chip.

A key element in the transition to essentially digital chips has been isolation of circuits within the same chip. Digital switching produces current spikes. Even if analog and digital circuits use different power supplies and grounds, return currents induced in the silicon substrate, can inject parasitic signals into sensitive analog circuits. This can be mitigated by isolating circuits from the bulk substrate, using options provided in many deep submicron processes. Figure 21 compares schematically a logic inverter in conventional CMOS with the triple well version. It can be seen that the NMOS device and the local ground are isolated from the substrate in the triple well process. Some processes offer more sophisticated implant structures that allow further isolation of the N wells,

involving separately biased additional wells and/or insulating trenches. Silicon on Insulator (SOI) processes have not been popular for high radiation tolerance because they contain a thick oxide layer under the circuitry that accumulates trapped charge with radiation dose, giving rise to undesirable back-gating effects in fully depleted devices (FDSOI). The format of isolation structures exploited varies with vendor and technology. Designs also vary between isolating only analog circuits, only digital circuits, or both from the true bulk substrate. While such isolation strongly attenuates noise coupling, it does not completely eliminate it. Therefore, in addition to isolation, controlling power consumption transients or changes during chip operation is increasingly important. Isolation implants have also been exploited for monolithic active pixel designs, covered in chapter 6.

Logic density is most important in a triggered system (see section 4.7). This is the case for the highest rate detectors in a collider geometry, where the raw hit volume is too high to allow for read-all operation with an acceptable mass of data cables. In a triggered system the ROIC function is to remember the position, arrival time, and charge of all hits until a trigger arrives. The rate of hits depends on the rate of particles impinging on the detector and, since each hit requires a certain number of bits for digital storage, it can be characterized as a specific bandwidth in bits per second per unit area, as was done in tab. 3. Note that this does not depend on pixel size to first order, but on particle flux (one incident particle makes one pixel cluster regardless of pixel size, and with the use of region architectures (section 4.7) the effect of cluster size is small). Given a particle flux, the total memory needed depends on the trigger latency, which is typically a few microseconds. The achievable memory per unit area is limited by the CMOS process logic density. Thus, for a triggered system, higher hit rate (and/or longer latency) requires higher logic density. This requirement, not pixel size or radiation, has driven pixel ROICs for high rate and radiation to ever deeper submicron CMOS processes (e.g. 65 nm instead of 130 nm). This is not immediately evident, because pixel size also scales down with increasing hit rate. However, simply making smaller pixels would not require a new process with smaller transistors (smaller feature size), since the analog functionality uses a small number of relatively large transistors. The requirement that does demand smaller transistors is increased logic density. The reason pixel size must also be reduced with increasing hit rate is to avoid in-pixel pileup. After registering a hit, a pixel needs a certain recovery time before being able to record another hit. To avoid losing efficiency to in-pixel pileup, the average time between hits in any given pixel (which scales inversely with pixel area) has to be much longer than the recovery time. An alternative solution is synchronous operation (where every pixel resets before each beam collision). This has been investigated, but so far it has not been popular because, as such a front end must be faster, it consumes more power.

4.2. Increasing circuit density through 3D integration

The use of Through Silicon Vias (TSVs) in hybrid assemblies has been discussed in section 3.5 in the context of assembly integration. Very small TSVs can also provide an alternate path to increase logic density (in a given footprint) by stacking and vertically interconnecting multiple tiers of circuitry. Stacking of circuit layers this way results in a linear increase in logic density with number of layers, whereas feature size reduction results to first order in a quadratic increase

Figure 22: Conceptual comparison of (left) typical linear transistor layout and (right) an Enclosed Layout Transistor (ELT).

with feature reduction factor. In the commercial sector, industry has so far preferred Moore's Law scaling over 3D integration. Only for future system-on-chip architectures, below the 10 nm feature size or equivalent, do industry leaders favor 3D integration [98]. One big advantage of 3D integration is reduction of power. This is because power scales with distance between switching elements, and in 3 dimensions more switching elements can be placed in close proximity than in 2 dimensions. In fact, the main actual and growing use of 3D integration in commodity complex devices is to put memory as close as possible to processors, by integrating a 3D memory stack directly on top of a CPU chip [99]. This increases transfer speed and reduces power. But since high volume introduction of TSV in 2006, the fastest growth of 3D integration has been in DRAM memory and image sensors, where either simple and regular structures (DRAM) or heterogeneous structures (image sensors) are being stacked. The solid state RAM use case is obvious: it is not an alternative to Moore's Law scaling, but an augmentation of it. The DRAM levels being stacked already have the highest available 2D logic density and 3D integration is the only way to fit even more into a given footprint. In High Energy Physics, the use of 3D integration for higher logic density ROIC fabrication was explored (with 130 nm feature size CMOS), in parallel to the exploration of plain (not 3D) 65 nm feature size. Working devices were produced and good results were obtained [100, 101], but so far, as in industry, going to a smaller feature size process has been the more effective path to high logic density.

4.3. Radiation tolerance of readout integrated circuits

First generation radiation hard ROICs were only possible in commercial 0.25 μm CMOS processes with custom enclosed layout transistors (ELT). They achieved radiation tolerance above 50 Mrad [102]. In an ELT the gate completely surrounds the source (drain) and in turn the drain (source) surrounds the gate (fig. 22). This avoids some channel edge effects (discussed later) since the channel is edgeless, but uses more real estate than a traditional linear transistor. ELT in 0.25 μm CMOS represented a 2.5-fold increase in logic density over 0.8 μm feature size military grade radiation hard technology used in the 1990's, and this enabled sufficient logic density to produce the triggered ROICs for ATLAS and CMS. Early development of pixel ROICs using 0.8 μm radiation hard processes did not succeed to incorporate all the needed functionality in a uniform pixel matrix; the logic density was simply not high enough. Because of the ELT area penalty, radiation hard 0.25 μm lagged behind the Moore's Law scaling of their commercial counterparts (fig. 23). Starting with the 130 nm node, the minimum size linear transistor standard cell logic used commercially exhibited high total

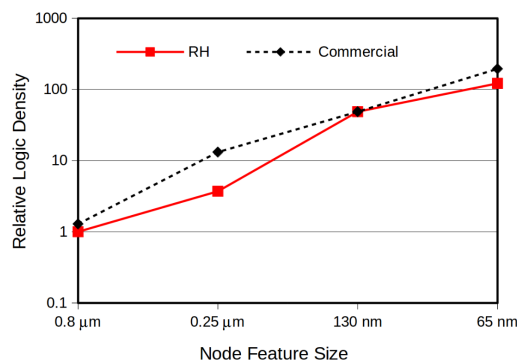

Figure 23: Relative density of radiation hard (RH) and commercial logic in different CMOS technology nodes. In each node, we compared a memory latch from a commercial 7-track standard cell library to the smallest memory latch in the radiation hard library used for LHC pixel chips. The points have no error bars since each corresponds to a single latch.

dose radiation tolerance. The ability to use linear transistors translated into a faster than Moore’s Law increase in radiation hard logic density, which went hand-in-hand with the transition to 2nd generation chips with synthesized logic in the pixel matrix. In addition to high logic density, the good performance of linear transistors enabled the out-of-the-box use of commercial logic libraries. These have been perfected and extensively validated by large scale commercial manufacturers of consumer electronics and come well integrated with powerful design and simulation tools. However, the use of linear transistors comes with some risks and side effects, which, once again, make radiation hard circuits in 65 nm lag their commercial counterparts in logic density.

The radiation hard design approach of 1st and 2nd generation ROICs was to make or find devices (transistors) that tolerate the required dose without significantly changing their response. The design process typically included increased margin on the specifications, but otherwise relied on the device models available from the manufacturer. After fabrication, the ROIC was tested to measure the actual radiation tolerance. This approach is still followed for analog circuits. Optimization of analog performance would suffer if one had to consider a wide range of properties for each transistor in the circuit, so working with fixed properties is desirable. Fortunately, since for analog circuits the transistor dimensions and geometry are fully under the designer’s control, it is possible to choose transistors that suffer little change with radiation, which means larger than minimum dimensions in the case of deep submicron CMOS (section 4.4).

On the other hand, for high density synthesized logic designers do not have the freedom to select devices that show little change with radiation. Instead, digital design must increasingly rely on accurate modeling of radiation damaged transistors. Conventional digital design already offers several different models for the same transistor: a *typical* model plus so called *corner* models, which simulate operation with different temperatures, voltages, and/or variation of fabrication process parameters within an allowed range. The same transistor will be faster or slower depending on temperature, and so on. The synthesis tools produce circuits to function in all the selected corners. The new design approach is to use additional corner models that represent the radiation damaged transistors. Such models can be custom made by parameterizing measurement

data. In this way, logic can be synthesized to work both before and after radiation damage, even though logic gate propagation delays, setup and hold times, etc. can change very significantly: a factor of 2 or more. This is to be compared to changes of just tens of percent between the operating temperature extremes. Such large changes will limit the achievable clock speed, but most pixel ROIC applications require clocks of order 100 MHz, rather than the typical GHz speeds of microprocessors in the same technology. Radiation damaged transistor models are also used to simulate analog and mixed signal circuits in order to confirm the design prior to fabrication and radiation testing, which still provides the ultimate validation.

4.4. Total dose radiation damage in CMOS transistors

Radiation damage in CMOS circuits is entirely due to charge carriers generated by ionization in the dielectric layers of the process, and not to bulk damage of the silicon lattice. Ionizing dose is delivered at hadron colliders by a combination of minimum ionizing particles (mainly pions) and background X-rays. The doping concentrations in CMOS transistors are high (10^{15} cm^{-3} and higher), compared to which the defect density introduced by bulk radiation damage is negligible [103] (below 10^{14} cm^{-3} for HL-LHC inner layers after 3000 fb^{-1}). However, there are many dielectric structures in a modern CMOS process and each one leads to its own radiation effect due to ionizing dose. It is not by accident that radiation tolerance requirements have kept pace with the logic density evolution in the ROIC generations. The reason is that both hit rate and radiation scale with particle flux. Required radiation tolerance went from 50 Mrad for the 1st generation, to 250 Mrad for the 2nd, to 1 Grad in the 3rd. 1 Grad corresponds to about 50 minimum ionizing particles crossing every Si lattice cell. Not all effects from charge generation in the dielectrics are equally important. As radiation dose increases, understanding and managing previously negligible effects becomes necessary. The importance of each effect also depends on transistor geometry and size. In this respect, the 130 nm CMOS technology node represented a 'sweet spot' for which commercial logic libraries could be used out-of-the-box up to doses well in excess of the 250 Mrad requirement (double or perhaps triple). In contrast, in the 65 nm node it is necessary to select or customize logic cell designs depending on the desired radiation tolerance, effectively trading off radiation tolerance for logic density. If the expected radiation dose is low, the out-of-the-box commercial logic can be used, while for higher expected doses, lower density logic cells must be substituted (The logic density point shown for 65 nm in fig. 23 was appropriate for an expected dose of 500 Mrad). These general statements should be seen as rough trends, and must be tempered by process specificity and environmental effects discussed later. Beyond 65 nm, which is at present well characterized, new research in high energy physics instrumentation is focused on understanding radiation damage in 40 nm and 28 nm feature processes [104], with detailed investigations expected over the coming years.

Oxide charge and its effects

Three oxide structures have been identified as producing radiation damage effects in the bulk CMOS processes used so far: the gate oxide, the shallow trench isolation oxide (STI), and the gate spacers, all shown in fig 24. Ionizing

Figure 24: Conceptual diagram of a MOS transistor of channel length L and width W , not to scale. A PMOS (NMOS) transistor would have N-type (P-type) substrate and P^+ (N^+) implants, where the $+$ sign indicates high doping. The gate conductor (not shown) would fill the region between the spacers. Spacers are used to control the doping at the ends of the channel. The spacers and the STI (Shallow Trench Isolation) oxides are responsible for radiation damage effects. The STI closing off the front of the figure is not shown.

radiation generates charge carriers within these oxides, which can lead to an accumulation of positive static charge, because hole mobility in SiO_2 is 6 orders of magnitude lower than electron mobility. While charge in the gate dielectric would be most problematic, because it would directly cause a threshold shift, gate oxide in $0.25\text{ }\mu\text{m}$ feature size and below cannot charge up. The gate oxides are thin enough (6 nm and below) that quantum mechanical tunneling is an important effect, resulting in an effective electrical conductivity. Tunneling also means that there is a gate leakage DC current (unrelated to radiation), which is what eventually caused industry to move away from silicon dioxide gates in nodes below 45 nm feature size. The gate leakage in the nodes used so far for pixel chips is not yet large enough to result in significant standing power consumption, but it is visible in bias networks, which are high impedance nodes feeding large gate areas.

STI and spacers are both thick oxide structures and therefore will accumulate positive static charge. However, not all the positive charge is truly static. Charge held in so-called deep traps is static at normal temperatures, but charge in shallow traps will gradually drift in an applied electric field (as present during chip operation) and will thus reach the oxide-silicon interface. This is a complex region which undergoes manipulation during the fabrication process [105]. This manipulation involves the passivation of so-called dangling bonds, which would otherwise manifest themselves as states within the energy band gap and spoil the semiconductor properties. Positive charge reaching the interface reverses some of the passivation, bringing back some of the traps that were painstakingly neutralized during fabrication. However, these will then trap negative charge, and that will actually compensate some of the oxide static charge. Remarkably, we would not be able to use commercial CMOS processes for ROICs, were it not for this fortunate cancellation of two detrimental phenomena: oxide charge and interface traps.

At relatively low dose (up to a few Mrad) the net results can be complex depending on the time constants for positive charge drift, the activation of interface traps, and their subsequent trapping of negative charge. These time constants can be vendor-specific, depending on oxide structure formation chemistry and steps, and are certainly affected by temperature. At high total dose

the movement of charge and activation of traps have equilibrated, leading to an approximate, but not perfect cancellation of interface charge. A positive net charge always remains, and this degrades transistor performance. Since the sign of this net charge at the oxide-silicon interface is always positive, it affects NMOS and PMOS transistors differently. The net positive interface charge results in parasitic lateral gating in the case of STI and in a modification of source and drain in the case of spacers. The former is known as Radiation Induced Narrow Channel Effect (RINCE) [106], while the latter is known as Radiation Induced Short Channel Effect (RISCE) [107].

RINCE

RINCE or lateral gating affects the sides of the channel (see fig. 24), causing them to be conductive in the case of an N-channel and non-conductive in the case of a P-channel. This does not have a significant impact on a wide transistor, because a small fraction of the total current flows near the sides. But in a very narrow transistor all the current is near the sides and the effect can be large, hence it is called Narrow Channel Effect. ELT's were used in 1st generation ROICs to avoid this effect, as the channel in an ELT has no sides (fig. 22). This was necessary in 0.25 μm technology, because the radiation-induced parasitic standing current in linear NMOS transistors was measured to be too high for a useful design. But note that, while an ELT has no sides, it also cannot have a very narrow channel. The width of the channel must be at least the perimeter of the source or drain, and so has to be many times the minimum feature size. Therefore, as long as standing parasitic current is tolerable, making wide conventional transistors is just as good as making ELT's, with the advantage that conventional transistors are standard and extremely well modeled. Thus, in 130 nm and below, ELT's have not been used. This led to some surprises at low total dose in the case of the ATLAS IBL detector [108]. The parasitic standing current in NMOS transistors, while completely tolerable at high radiation dose, can go through a transient period of being higher than tolerable depending on vendor and on temperature. Accurate modeling of this varying leakage current behavior has been now developed [109].

RINCE affects PMOS and NMOS transistors in opposite ways. NMOS transistors develop parasitic standing current, but this does not interfere with the transistor action, it simply adds to it. PMOS transistors are parasitically turned off near the sides, which hinders the transistor action. A critical question for PMOS is how far away from the sides is the channel affected by interface charge. The effect can be visualized as a radiation dependent width change, such that the effective width is $W_{\text{eff}} = W_{\text{layout}} - 2\Delta W_{\text{RINCE}}(\text{TID})$, where W_{layout} is the width as drawn, $\Delta W_{\text{RINCE}}(\text{TID})$ is how far away from the STI-channel interface is the channel affected, and TID is Total Ionizing Dose. From the observation that minimum width PMOS devices in 65 nm feature size are highly degraded at 500 Mrad, while those in 130 nm feature size are mildly degraded, we can say that $\Delta W_{\text{RINCE}}(500 \text{ Mrad}) \approx 30 \text{ nm}$.

RISCE

RISCE affects PMOS and NMOS in a similar way, by impeding charge flow between source or drain and channel. It can be roughly modeled as 'adding' a certain length to the channel (a longer transistor conducts less current than a shorter one). One may therefore think that making very short transistors

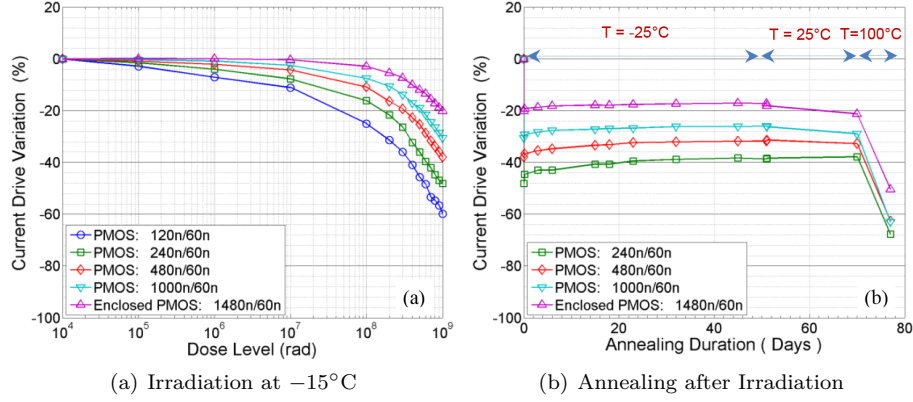

Figure 25: Current drive variation in 65 nm technology PMOS devices of minimum length but varying width, as function of (a) total ionizing dose at -15°C and (b) annealing duration and temperature under worst case bias [110].

would be a good strategy against RISCE, because this would be a way to compensate. But the opposite is true: longer transistors are less affected by RISCE, because the relative change in effective length is small if the original device is long to begin with. Once again we can write $L_{\text{eff}} = L_{\text{layout}} + 2\Delta L_{\text{RISCE}}(\text{TID})$, where we are now adding effective length rather than subtracting effective width. The magnitude of the effect is about twice as large in PMOS than in NMOS. A 60 nm long PMOS (NMOS) will experience a 70% (30%) reduction in full-on current after 500 Mrad. Since transconductance scales as $1/L$, a 70% (30%) reduction in current is equivalent to a 2.5 (1.4) increase in length. For the original channel length of 60 nm this implies $\Delta L_{\text{RISCE}}(500 \text{ Mrad}) \approx 45 \text{ nm}$ ($\approx 12 \text{ nm}$) for PMOS (NMOS).

Dependence on voltage and temperature

The above $\Delta W_{\text{RINCE}}(500 \text{ Mrad})$ and $\Delta L_{\text{RISCE}}(500 \text{ Mrad})$ should be seen as rough sketches of a more complex underlying behavior, and were given to provide intuition about the magnitude and sense in which the transistors are affected, and why the effects become more important with decreasing feature size: effective width and length should not be regarded as a real model.

The RINCE and RISCE effects are modulated by transistor bias and by temperature. In general, both effects occur only when transistors are powered, which means there are electric fields in the STI and spacer oxides. The larger the field (which depends on transistor bias conditions) the greater the effect, though there are quantitative differences between NMOS and PMOS. The effective width and length given above are for worst case bias. Unpowered devices suffer little or no damage regardless of temperature - an important point to keep in mind when estimating how long a detector will last.

For powered devices, high temperature increases damage during irradiation, and can decrease (anneal) or increase damage after irradiation. Figure 25 shows results of a study [110] in which different width PMOS devices were first irradiated at low temperature and then annealed at different temperatures, always under power. All transistors are minimum length. When powered, devices can suffer very large damage in a matter of hours at 100°C , but the same damage

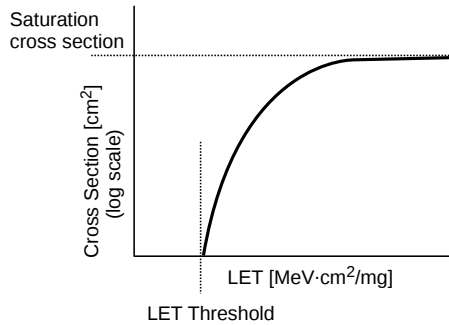

Figure 26: Conceptual plot of Single Event Upset (SEU) cross section vs. Linear Energy Transfer (LET) for a typical memory cell.

at 0°C would take over 10 years. This suggests that activation of deep traps is responsible. As an oxide can contain multiple traps with different activation energies, the effect can be complex and process-dependent, which is confirmed by observations. Since the combination of power and high temperature is explicitly excluded by interlocks in all pixel detectors, the main impact of high temperature annealing damage is to complicate qualification. The high integrated dose on a detector is delivered gradually over years. Past qualification protocols emulated this with high dose rate irradiation followed by high temperature annealing. However, application of such protocols is no longer straightforward in 65 nm. Activation energies must be precisely determined before thermal acceleration tests can be confidently applied.

4.5. Single Event Upsets and Mitigation

In addition to long term degradation due to accumulated dose, energy loss by ionizing particles leads to instantaneous soft errors called Single Event Upsets (SEU). The most common SEU is the flipping of a stored bit in a memory. SEU also can produce voltage transients on signal or control lines that can result in accidental operations - for example a single level asynchronous line to reset logic or memory would be vulnerable to SEU. Protection against SEU involves hardening of memory cells, avoiding designs with vulnerable control signals or hardening control signals where their use cannot be avoided, and circuit triplication. These techniques have been in use since 1st generation ROICs and have not seen significant changes in the 2nd generation. However, as collider rate continues to increase and higher logic density translates into lower deposited charge needed for upset, these techniques will no longer be sufficient. An approach being introduced in 3rd generation ROICs is to design for reliable operation while a significant level of upsets is taking place. Fundamentally this is abandoning the idea of circuit hardening as a solution to the SEU problem, and instead designing all functions such that SEU is not a problem to begin with. In practice, a combination of hardening and SEU-friendly functionality will be used.

Extensive literature and experience exist on SEU of memory cells in the context of electronics used in space. This is not directly applicable to particle physics pixel detectors, but nevertheless a good starting point. SEU of a given

Cell type	Cross section in cm^2
Standard latch	2.8×10^{-14}
DICE latch with interleaved layout	3.1×10^{-15}
TR standard Latch	1.2×10^{-16}
TRL with error correction and control triplication	2.3×10^{-17}
TRL with error correction, control triplication and separation of sensitive nodes	6.8×10^{-18}

Table 4: SEU cross sections of different memory structures in 65 nm technology with 24 GeV protons [115]. TR stands for triple redundant and L for latch.

circuit, like an SRAM cell, latch, or flip-flop, depends on the amount of energy deposited by an impinging ion, which is characterized by a Linear Energy Transfer (LET). It is important that this is meant to describe non-relativistic ions, which lose energy approximately uniformly along their path through electromagnetic interactions. The upset rate is characterized by the cross section to causing a bit flip (SEU cross section). Cross section vs. LET is typically fit with a Weibull function, resulting in a threshold and saturation cross section as shown in fig. 26. In submicron technologies, the typical LET threshold pretty much regardless of memory cell type is of order $1 \text{ MeV} \cdot \text{cm}^2/\text{mg}$. Saturation cross section varies with cell design, but is of order 10^{-7} to 10^{-8} cm^2 for common SRAM, latches and flip-flops. However, an energetic proton (or pion) has a LET of order $0.01 \text{ MeV} \cdot \text{cm}^2/\text{mg}$, which immediately signals that it cannot upset memory cells by the same energy loss mechanism as ions (it is far below the LET threshold). Upsets in this case are due to nuclear interactions. This can be seen from the fact that SEU cross sections are about the same for energetic neutrons and protons [111]. There is thus a kinematic threshold depending on the nuclei in the material, rather than a LET threshold. Typical SEU cross sections for protons are of order 10^{-13} cm^2 [111]. At relatively low energies, an adequate model has the proton imparting momentum to a nucleus which then becomes a traditional high LET heavy ion. But at the GeV energies of the LHC, inelastic collisions can produce showers of high LET particles affecting a large area of silicon. This is important for hardening techniques.

SEU hardening of memory cells exploits redundant connections or storage separated by some distance. This is more effective for heavy ions, which deposit energy very locally, but still useful for relativistic protons (or pions) which can produce extended deposits [112]. A type of memory called Dual Interlocked Cell (DICE) [113] is extensively used as its state can only be changed by switching two physically separate voltages in coincidence, which gives it a lower SEU cross section than common latches. Special layout techniques, such as *interleaving* can be used to carefully separate sensitive elements and prevent charge sharing [114]. Table 4 compares the SEU cross sections of common structures [115] in an high energy proton beam, for 65 nm technology.

One is not always free to choose the memory type with the lowest SEU cross section. The almost 4 order of magnitude gain from a standard latch to maximal use of triple redundancy in table 4 comes with an associated footprint increase of a factor of 10. Such cells can therefore not be used in the high density logic of the pixel matrix. Suppose every pixel has 8 bits of configuration and the acceptable fraction of corrupted pixels during an 8 h data run is 1%,

Figure 27: Schematic diagram of a typical pixel analog front end. Signal polarities and Time over Threshold (ToT) are indicated along the bottom.

with 1 GHz/cm^2 particle flux. The run-integrated fluence is $2.5 \times 10^{13} \text{ cm}^{-2}$ and therefore the pixel SEU cross section must be $1\% / (2.5 \times 10^{13} \text{ cm}^{-2})$ or less. As there are 8 bits per pixel, the single bit cross section must be $5 \times 10^{-17} \text{ cm}^2$ or less. Even without considering added design margin, tab. 4 shows that this requires triple redundancy, which may not fit due to its large footprint. A new solution to this problem in 3rd generation ROICs is to implement a control protocol that allows continuous writing of configuration data during data taking, instead of configuring in a distinct operation mode. If configuration values are constantly being refreshed from outside, one does not need to rely on 'long term memory' within the chip. For example if the time between consecutive writes is 1 s instead of the duration of the data run, this relaxes the SEU cross section requirement by 4 orders of magnitude. It should be noted that hit data have never required SEU protection, because the time that data bits spend in chip memory (before readout) is very short, given by the trigger latency. Thus the relevant time scale for hit data is of order $10 \mu\text{s}$ for triggered, 3rd generation ROICs. Even with a significant error amplification from data encoding⁸, the fraction of data lost due to SEU will be negligible with storage in standard latches⁹.

4.6. Analog front end and ADC

The analog front end elements are shown schematically in fig. 27. The front end design has universally consisted of a Charge Sensitive Amplifier (CSA), followed by a 2nd stage to provide additional voltage gain, and a comparator (C) to carry out the pulse height discrimination. The CSA has a 1st stage amplifier with capacitive feedback (C_f), a continuous reset (I_{rst}) and a low bandwidth feedback to compensate for sensor DC leakage current (I_{leak}). This is needed because hybrid pixels have so far always been DC coupled to the readout and sensor leakage current can be significant after irradiation (for development of AC-coupled pixels see section 3.1).

On-chip signal amplitude digitization has used Time over Threshold (ToT)

⁸For example, a single bit flip corrupts an entire 64 bit packet

⁹Since no detector is 100% efficient, data losses well below the 1% level are insignificant.

of the comparator output. ToT is a simple digitization method that counts clock cycles while the comparator is high (meaning above threshold). The most important function of the pixel front end has been to discriminate true hits from noise with the correct timing to within one bunch crossing of the accelerator, which for the LHC means 25 ns. This requires a fast leading edge response (high slew rate), which can be achieved with high input gain. The input charge to output voltage gain is given by the inverse of the feedback capacitor C_f in fig. 27 and the characteristics of the first stage amplifier. On the other hand, the charge transfer efficiency from the sensor to the integrator is given by $(C_{\text{det}} + G \times C_f)/C_{\text{det}}$, where C_{det} is the detector load capacitance and G is the 1st stage open loop gain. Clearly, a high open loop gain is needed in order to have both high gain (small C_f) and good charge transfer efficiency. However, the specific transconductance (g_m/I_D , where I_D is the drain current) of CMOS transistors is only of order 10 S/A, which means that a simple (i.e. single transistor) inverting amplifier can only achieve $G \sim 10$ for 1 μ A current and 1 V supply, since $G \approx V_D g_m/I_D$, where V_D is the supply voltage. Two simple amplifiers in series would achieve an open loop gain proportional to g_m^2 (so $G \sim 100$), but with low bandwidth. The solution in pixel ROICs has always been to use a cascode topology for the 1st stage, which achieves an open loop gain proportional to $g_m(M1) \times g_m(M3)$ without sacrificing bandwidth. The labels M1 and M3 refer to fig. 28, where two cascode variants are shown. In the straight cascode configuration (a), the current source M4 is larger than the current source M2, and their combined current passes through the input transistor M1. A small change in the input will cause a change in the M1 drain voltage according to the transistor's gain. This in turn shifts the source of M3, leading to a significant V_{gs} change for M3, which amplifies the change in the output voltage. The M3 gate voltage is held at a fixed bias, V_{casc} . In contrast, in the regulated cascode (b), the current source M4 is smaller than the current source M5, and the additional transistor M2 shifts the M3 gate voltage in response to a change of M1 drain voltage, leading to additional output gain (bigger V_{gs} change for M3).

While the front end configuration and 1st stage cascode architectures have remained, there have been important quantitative changes between 1st and 3rd generation ROICs. The specific transconductance of CMOS transistors has nearly doubled going from 16 S/A in the 0.25 μ m process to 22 S/A in 130 nm to 28 S/A in 65 nm. The higher hit rate requirements have led to smaller pixels (with lower capacitance per pixel) and faster shaping to avoid in-pixel pileup. While some 1st generation ROICs used PMOS input transistors for better substrate isolation and better 1/f noise performance, with the faster pulse shaping and common substrate isolation techniques, NMOS has become the input device of choice for amplifiers in 130 nm CMOS and below [116]. The decrease in pixel capacitance (by about a factor of 4) and increase in transconductance have translated into higher gain and speed. The effect of time-walk is therefore significantly reduced in 3rd generation ROICs, even before making use of digital processing to correct the time of hits near threshold¹⁰. While so far all detectors have used ROICs with continuous reset as shown in fig. 27, there

¹⁰Time-walk is the variation in relative delay between front input pulse and comparator firing, as a function of pulse amplitude above threshold.

Figure 28: Cascode circuit variants with NMOS input transistor, as typically used for 1st stage pixel amplifiers. The bias V_{cas} and the gates of M2 and M4 in (a) and of M4 and M5 in (b) are held at DC voltages, typically generated by bias current mirrors (not shown).

has also been R&D on front end designs that reset before every bunch crossing (these are referred to as synchronous front ends) [117]. In this case there is by construction no time-walk, but the power consumption is higher due to the fast shaping and reset settling needed. So far this approach has not been adopted for pixel detectors.

The need for very high speed front ends with sub-ns time stamp resolution capability has been spearheaded by NA62 and its Gigatracker detector. The Gigatracker ROIC [118], implemented in 130 nm CMOS, uses a straight cascode front end with RC feedback. The RC time constant is 5 ns, which gives the device its 5 ns peaking time. Two differential gain stages are then used in front of a constant fraction discriminator to achieve a 200 ps time stamp resolution. Future fast timing detectors discussed in section 2.3 will continue to push this type of design to finer time resolution.

A pixel ROIC with free-running front ends is an inherently metastable circuit. Every pixel can fire at any time, and the act of firing switches logic that would not otherwise switch. Any coupling from digital switching to analog front end can be a positive feedback mechanism. For low enough threshold and/or enough pixels firing at the same time, this positive feedback can set off a chain reaction causing all pixels to fire. For a given instantaneous hit occupancy (fraction of pixels firing at the same time due to an external stimulus), there will be a minimum stable threshold. Each ROIC is different in this respect, but in general minimum stable threshold was around 2500 electrons (e^-) in 1st generation ROICs, whereas it will be around 500 e^- for the 3rd generation. This reduction has been deliberate: required by decreasing input signal values. Large pixels ($2 \times 10^4 \mu\text{m}^2$), thick sensors ($> 200 \mu\text{m}$), and moderate sensor radiation damage for 1st generation detectors translated into expected signals of order 10 ke^- , while small pixels ($0.25 \times 10^4 \mu\text{m}^2$), thinner sensors ($100 \mu\text{m}$), and heavier sensor

radiation damage will lead to signals as low as 2 ke^- at the HL-LHC. The minimum stable threshold is reduced by exactly the same factor, since the important figure of merit for pixel detectors is not signal to noise ratio, but rather signal to threshold ratio. The front end noise does set a lower bound to the threshold, but does not determine how far above this lower bound is the minimum stable threshold. Assuming a noise occupancy of 10^{-4} is acceptable, this corresponds to the Gaussian 1-sided tail fraction for 3.7σ . Inverting the question, for a 500 e^- minimum threshold, the noise must be less than $500/3.7=135\text{ e}^-$ equivalent input charge. But this is just an upper bound. How far below this bound the noise needs to be depends on how the threshold varies with time and how from pixel to pixel.

One can express the front end noise requirement as

$$\text{ENC} < \sqrt{(T/3.7)^2 - T_{\text{RMS}}^2(\vec{x}) - T_{\text{RMS}}^2(t)} \quad (14)$$

where ENC is the equivalent input charge noise, T is the threshold, and T_{RMS} is the threshold variation as a function of position (\vec{x}) or time (t). $T(\vec{x})$, or the pixel to pixel threshold variation, is known as dispersion. The main cause of dispersion is fabrication process mismatch between transistors and passives of identical design. While the mismatch amount is process dependent, and the translation from mismatch to dispersion is design dependent, a typical dispersion value is in the range of $300\text{-}500\text{ e}^-$. As this is clearly unacceptable, all ROICs so far have compensated for mismatch by programming a different threshold voltage in each pixel, such that in units of input charge all pixels have an equalized (or *tuned*) threshold value. With such tuning, a value of 40 e^- dispersion is typically achieved. The cost of this technique is circuit area in the pixel in order to implement the needed DAC and memory. However, tuning only controls $T_{\text{RMS}}(\vec{x})$, and not $T_{\text{RMS}}(t)$. The main source of $T_{\text{RMS}}(t)$ has been coupling of transients from other circuits to the front end, which has in turn been the main limitation on minimum stable threshold. This has been mitigated with circuit isolation, and control of power transients, as already explained. Still other sources of $T_{\text{RMS}}(t)$ may gain importance in the future. In particular, short term radiation damage can spoil tuning and cause threshold shifts [119]. If the radiation dose in between tuning cycles is high enough, $T_{\text{RMS}}(t)$ could become dominant for reasons unrelated to circuit isolation. This has not been a problem until now, but will need attention as accelerator intensity increases and windows of opportunity for tuning decrease. Techniques for near real-time equalization, which would compensate both $T_{\text{RMS}}(\vec{x})$ and $T_{\text{RMS}}(t)$ simultaneously, include periodic capture of the baseline level in each pixel, or auto-zeroing [120], and self-adjustment in the pixel to equalize to the same noise occupancy [121].

4.7. Readout architecture

Section 4.8 gives an overview of the hit rate impinging onto the ROIC as well as the bit rate coming out of the data links. Readout architecture refers to the transfer of data from the pixels, where it is generated, to the ROIC output(s), including storage and buffering along the way. There has been much evolution in this area from 1st to 3rd generation. The most significant requirement for the readout architecture is whether the system is full readout or triggered readout. In a full readout ROIC every hit from every pixel must eventually make its way to the data output. In the language of queuing theory this is a single server

Figure 29: Diagram of (a) classic Column Drain readout with triggered readout, (b) shift register implementation of column drain with full readout, and (c) Local Buffer triggered readout. W stands for wait and T stands for transfer.

queue with random customer arrival time (each pixel is a *customer*, while the ROIC data output stage is the single *server*), which is characterized by eq. (15), discussed below. A full readout system may not require high logic density, because, provided the data output stage has high enough bandwidth, there is no need to store hit data on chip for any length of time. The problem with a full readout system is that it may not be possible to implement sufficiently high output bandwidth to handle the pixel hit rate. In a triggered system, on the other hand, all pixel hits must wait a pre-defined *latency* until a trigger decision determines which ones to read out. In this case the data output bandwidth only has to match the trigger rate, and is decoupled from the primary pixel hit rate. But the full incoming hit rate must be stored during the trigger latency, and storage is limited by the process logic density.

Figure 29 compares schematically three readout architectures, where the buffered storage of hit data is represented by W for wait, and the motion of hit data by T for transfer. In the classic *column drain* architecture of 1st generation chips (fig. 29 (a)), all pixels in a column share a data bus that only one pixel at a time can use. As soon as a pixel is hit, it tries to grab the bus and transmit its data. The bus is of course arbitrated so each hit pixel must wait its turn. This column bus is itself a single server queue, just like the case of full chip readout. The bandwidth of the bus must exceed the incoming hit rate for this to be viable. Equation (15) shows the probability for waiting a time greater than t in such a simple single server queue ¹¹,

$$P(W > t) = \frac{\lambda}{\mu} e^{-(\mu - \lambda)t} \quad (15)$$

where λ is the input hit rate and μ is the output bandwidth. For a pixel hit rate r , $\lambda = Nr$, where N is the number of pixels served by the bus. Hits must be transferred within a short time, t_s , as there is no place to store them

¹¹In Kendall notation [122] this is an M/M/1 queue

within the pixel array. Therefore, to avoid hit loss, $P(W > t_s) \approx 0.001$, which means that $(\mu - \lambda)t_s \approx 6$. Since t_s is small, one must have $\mu \gg \lambda$: the well known condition that column drain needs a high bandwidth. Implementation of a trigger buffer in 1st generation chips was at the chip bottom, requiring all hits to be transferred out of the pixel matrix. Only after storage in the periphery was the trigger selection applied.

The LHC-b Velopix readout chip implements a read-all architecture using a shift register (SR) for transferring hit data instead of a bus. This is represented by fig. 29 (b). The SR not only transfers data, but is also temporary storage. The output bandwidth μ of the SR is simply the clocking speed (assuming one pixel hit is read out per clock cycle). But unlike an arbitrated bus, each pixel sees a different output bandwidth. The very first pixel feeding the SR sees the full bandwidth, but the next pixel sees less bandwidth because occasionally it will be blocked by data from the previous pixel already in the SR. Thus, pixel i sees an output bandwidth $\mu_i = \mu - \sum_j r_j$, where r_j is the hit rate of the j^{th} pixel. Because the SR stores hits, the short transfer time requirement of column drain is removed, and one just needs $\mu_i > r_i$ (as opposed to $\gg r_i$). If all pixels have the same hit rate r , one needs $\mu > \lambda$, where $\lambda = Nr$, as before. Since the last pixel sees the smallest output bandwidth, its waiting time is the longest, so one can choose μ such that the last pixel waiting time is less than the time between hits. This architecture is particularly well suited to the highest rate chips in the Velopix detector, because the hit rate is *not* the same in all pixels. The pixel nearest the beam line has the highest rate, and also happens to be the pixel farthest from the readout— that is, the first pixel in the SR. The last pixel in the SR has the lowest hit rate. Thus, the pixel dependent hit rate r_i nicely follows the pixel dependent output bandwidth μ_i .

Starting with the 2nd generation triggered ROICs, high logic density permitted the implementation of local hit storage within the pixel matrix (29 (c)). The input rate to the column bus is reduced as $\lambda' = \lambda \times h \times t_{BX}$, where h is the trigger rate and t_{BX} is the bunch crossing period. If the readout time can be long, then one can have $\mu \gtrsim \lambda'$, which makes for a very relaxed column bus transfer bandwidth requirement. In addition to higher hit rates, this relaxed requirement has been exploited to make larger ROICs (more pixels per column bus). Instead of being limited by the transfer rate, the hit rate that can be handled is limited by the amount of memory that can fit in the pixel matrix. All hits must be stored for the entire trigger latency, so the memory needed scales like $\lambda \times t_L$. The longer the trigger latency the smaller the hit rate that can be handled.

The local storage of hit data does not make efficient use of memory when done at the individual pixel level. This is because the mean time between single pixel hits is longer (but not much longer than the trigger latency). For example for 50 kHz single pixel hit rate and 5 μ s trigger latency, the average number of hits per latency period is 0.25. Using Poisson statistics, one would need to store up to 3 hits per pixel in order to keep 99.9% of hits. We refer to this number (3 in this example) as the *buffer depth*. Instead, grouping pixels into regions with shared storage significantly reduces memory needs. Consider grouping 4 pixels together. If the 4-pixel region average hit rate were 1 hit per latency period, then, using Poisson statistics, one would need a buffer depth of 5 region-hits per latency period in order to keep 99.9% of hits. That is only $5/4 = 1.25$ buffer locations per pixel instead of 3 as before. But the advantage

Figure 30: Block diagram of 4-pixel region logic on FE-I4 ROIC. N stands for neighbor, D for front end discriminator output, T for readout token.

is even greater, because in a pixel detector the hits among neighbor pixels are correlated (charged particles produce clusters). The correlation between pixels means that the region hit rate is less than the single pixel hit rate times the number of pixels per region. The amount of correlation depends on sensor and detector geometry. Charge information, on the other hand, must be stored for every hit pixel regardless of how the pixels are grouped, and this reduces the advantage of having many pixels per region. The simplest approach is to store a fixed number of charge bits per pixel times the buffer depth. Suppose in the above example one stores 10 bits of region hit arrival time and some flags, plus 4 bits per pixel charge information. If storage is independent per pixel, each pixel must store 14 bits per hit times buffer depth of 3, or 42 bits per pixel. Conversely, in a 4 pixel region, one must store $10 + 4 \times 4 = 26$ bits per region hit times buffer depth of 5, or 32.5 bits per pixel. The FE-I4 ROIC architecture is based on a 4-pixel region along these lines [16], shown schematically in fig. 30.

To take full advantage of larger regions (or to efficiently store higher precision charge information) one needs a more sophisticated storage mechanism that allocates memory only to hit pixels, and does not store zeros for pixels below threshold in the same region. Effectively, hit information must be transferred as soon as it is produced from the pixels to a central storage. This should evoke the column drain architecture of fig. 29 a. A large region with arbitrated storage can be labeled as 'region drain' and can be analyzed the same way as column drain. The main problem of column drain was the high bandwidth requirement for the column bus, $\mu \gg \lambda$. But given a bus bandwidth μ , one can always make λ small enough by reducing the number of pixels on the bus, N , since $\lambda = Nr$ (r being the single pixel hit rate). In other words, column drain can accommodate high hit rate for a small enough ROIC. Therefore, a large, high hit rate ROIC could be built as a matrix of 'little chips' each with column drain architecture. It is interesting that the architecture evolution moved away from column drain because it could not scale to larger size (or to higher hit rate for fixed size), in favor of region architecture, for which size and hit rate are decoupled. But,

Figure 31: Layout detail from RD53 Collaboration illustrating the concept of islands of analog circuitry (blue) embedded in a 'digital sea' of synthesized logic (green).

evolving to large regions eventually leads to the same point as replicating a column drain architecture many times, as a way to achieve both large total size and high rate.

Third generation ROICs will continue to expand region architectures. While the basic 4 pixel region described above probably represents a sweet spot for efficient memory usage, the use of larger regions is being explored [123]. Already in the 2nd generation an important change took place, in which a ROIC core went from being a collection of pixels circuits, stepped and repeated, to a collection of regions, stepped and repeated. A 3rd generation ROIC will be a collection of digital cores, stepped and repeated. A core is not the same as a region and can in fact contain many regions. A core is simply the smallest stepped and repeated instance of digital circuitry. A relatively large core allows to take full advantage of digital synthesis tools to implement complex functionality in the pixel matrix, sharing resources among many pixels as needed. Large cores can have 2 dimensional digital connectivity, removing the constraint on all previous ROICs that communication could only take place up and down pixel columns, but not along rows. Figure 31 shows a layout detail from the RD53 Collaboration in which identical 4-pixel analog front end islands can be seen completely surrounded by synthesized logic. The core logic has been dubbed 'digital sea' to stress that it results in a different and variable environment surrounding each analog island (depending on where synthesis tools place gates and connections). This is a radical departure from the single pixel step and repeat, perfectly symmetric environment of the 1st generation, raising potential concerns about systematic variations within the pixel matrix. The FE65-P2 prototype [119], which implemented 4 by 64 pixel cores, has shown that with modern isolation techniques (see section 4.6) excellent uniformity can be achieved within a large synthesized core.

4.8. Input hit rates and output data transmission (electrical)

Large increases in ROIC hit rates and output bandwidth are taking place between 2nd and 3rd generation ROICs. Until now and also for the planned detectors, output data are transmitted electrically for at least the first meter away from the ROIC (optical links are covered in section 4.9). The LHC-b

Figure 32: Geometry of LHC-b VELO detector. Beams circulate bottom left to top right and vice-versa, colliding near the center. The detector planes (dark grey and red) are oriented perpendicular to the beam, and shown in the open configuration: during collisions they will close onto the beam leaving a small square opening for the beam to pass through. Only interactions boosted forward (towards top right) will be in the detector acceptance. Taken from [9].

experiment is implementing a full triggerless readout system in the upgraded VELO detector using the Velopix IC [10]. They are able to do this because the hit rate, while very high, is not extreme, and the experiment has a fixed target geometry, allowing data cables to be placed outside of the physics acceptance. The ATLAS and CMS experiments, on the other hand, must contend with an order of magnitude higher hit rate per ROIC and have near 4π physics acceptance, so most data cables must pass through the active volume. They will therefore use triggered readout. However, the trigger rates will be an order of magnitude higher than today, which combined with busier events will make for a 20- to 40-fold readout bandwidth increase for 3rd generation ROICs. The LHC-b hit rate is projected to be 1.6 GHz/cm^2 for the most occupied pixel, but as the rate decreases almost quadratically with radius and the modules are perpendicular to the beam, the average hit rate in the most occupied ROIC is 0.3 GHz/cm^2 . In contrast, for ATLAS and CMS upgrades all pixels (and therefore all ROICs) in the innermost barrel layer have a similar hit rate, projected to be near 3 GHz/cm^2 for a 3.2 cm layer radius.

Figure 32 shows the geometry of the LHC-b VELO upgrade. The fixed target geometry allows for high bandwidth data transmission with almost no cable mass in the active volume. The Velopix IC supports 4 parallel differential outputs at 5.12 Gbps each, fed by the shift readout architecture described in section 4.7. The data use a fixed frame custom format, where each frame contains a time stamp and a bit map for a group of 8 pixels (no charge information is recorded, just hit/no hit). Reading individual pixels instead would use 30% more bandwidth, because it would not take advantage of the clustered nature of pixel detector hits.

A theoretical discussion of lossless data compression in pixel detector readout

Figure 33: Conceptual sketch of attenuation vs. frequency in an electrical transmission line (solid line). The attenuation is given by the signal amplitude at the output divided by the input signal amplitude (solid line, no specific functional form assumed). The horizontal axis represents the frequency of a pure sine wave signal. The shaded areas represent the frequency content of a DC-balanced transmission if done at low (left) or high (right) bit rate. The dashed lines represent the total attenuation of cable plus equalization, which must be flat across the frequency band of interest to avoid signal distortion.

can be found in [124], which explains that the information content (entropy) is roughly proportional to the number of clusters and the achievable compression depends on cluster size. The 30% compression afforded by multi-pixel frames in Velopix is not the maximum possible compression, but is adequate for LHC-b needs. The projected data packet rate for the most occupied chip is 520 MHz, while the Velopix output consisting of 4 links at 5.12 Gbps each will saturates at a 640 MHz packet rate.

The ATLAS and CMS upgrades plan an output bandwidth of 5.12 Gbps per ROIC, which is actually less than 25% of the LHC-b maximum because the planned ROIC size is slightly larger. A critical difference is that ATLAS and CMS must have longer cable runs and at the same time minimize data cable mass, which means tolerating a high transmission line loss (meaning signal attenuation, not data loss). Figure 33 shows conceptually the attenuation of a signal passing through a lossy transmission line. Two vertical gray bands represent low and high bit rate transmission. These bands have a lower cutoff, rather than extending to zero frequency, because DC-balance has been assumed. DC balance avoids low frequencies by guaranteeing at least one transition every n bits (e.g. for the 8b/10b encoding $n = 5$). If the attenuation curve within a gray band is flat, that means the signal shape will not be distorted: a good condition for error-free transmission. This makes it obvious why DC balance improves transmission: the narrower the band, the smaller the variation of the attenuation within the band. However, for the band at high bit rate, even with DC balance there is a large variation of the attenuation within the band. This situation can be improved with equalization, indicated by the horizontal dashed lines. Equalization attenuates lower frequencies more than higher frequencies (the opposite of what cables do) to achieve a flat response within the band. All this is well known textbook material [125], but is only now playing a critical role in pixel detector design. The telecommunications industry and consumer electronics have long ago optimized performance in lossy transmission situations. As a consequence, particle physics designs are moving towards more sophisticated commercial protocols and solutions. State of the art equalization included in commercial FPGA's can achieve reliable transmission with line losses as high

as 28 dB. While prior ROICs (for example FE-I4) have used 8b/10b encoding, the RD53A ROIC will use an open source commercial protocol implementation of 64b/66b encoding, including a multilane version for balancing data over four 1.28 Gbps outputs. Equalization will be an integral part of future systems: RD53A drivers will have pre-emphasis capabilities, which boost high frequencies at the transmitter (sending a purposely distorted signal to counteract the cable distortion) and receivers with different types of equalization are also being developed [126, 127]. Receiver equalization has the advantage that it can be more easily made adaptive, so that it does not have to be manually tuned for every link and possibly vs. time, and it is not constrained by a strict power budget like driver pre-emphasis. Even with these techniques, because of various constraints including radiation damage, the ATLAS experiment aims to keep line losses at 20 dB or less.

It is clear from fig. 33 that there is a limit beyond which the signal is completely lost and no amount of equalization can recover it (recall the 28 dB mentioned above). The only remaining option to further increase the data rate on such a cable is to use multiple logic levels at a given frequency. For example with 4 logic levels instead of two, one can send two bits per clock cycle instead of one. The problem is that the available output voltage must then be divided among the logic levels. The voltage difference between two levels is $V_{\text{out}}/(n-1)$, where n is the number of levels. Noise can cause confusion between levels, so one can use multiple levels as long as $V_{\text{noise}} \ll V_{\text{out}}/(n-1)$. This also applies to standard equalized signals with two logic levels ($n=2$), which means that one cannot go too far to the right in fig. 33. But one can go further to the right for $n=2$ than for $n=4$, so whether multi-level transmission is advantageous or not depends on how fast the cable transmission cuts off. What should be clear from this discussion is that using higher voltage at the driver (for a given noise level) will increase the achievable data bandwidth. Commercial IC interface logic operates at a higher voltage than the core transistors, thanks to thicker gate oxide. But such thick oxide devices are much less radiation tolerant and therefore not adequate for pixel detector applications. For 65 nm the maximum operating voltage of core transistors is 1.2 V. Future development could include multi-level transmission using stacked core transistors, where the voltage difference between all levels remains around 1 V instead of $1.2 \text{ V}/(n-1)$. A final problem facing high speed drivers in pixel ROICs is that high speed logic is more vulnerable to radiation damage than low speed logic, because switching speed depends on transistor gain. This could be a pixel-specific reason favoring the use of multiple logic levels at lower clock speed over standard two levels at higher clock speed.

While not strictly an ROIC issue, the quality of available cables is a critical point for data transmission. Commercial data cables are not developed with low mass requirements and contain dielectric materials that are not radiation hard. Therefore, development of custom cables for low mass, radiation hard, high speed transmission is an ongoing activity. This includes flexible printed circuits [128], short run unshielded twisted pairs, long run shielded twisted pairs, and twin-axial [129].

4.9. Optical and wireless transmission

The technical design report for the original ATLAS pixel detector [130] specified optical links located on the module, less than 1 cm away from the closest

ROIC, with optical fibers forming part of the module interconnect. Such an arrangement was never realized and designs have instead moved further away from this model. There are three reasons why optical conversion is located some distance away from pixel modules: radiation, geometry, and reliability. Fibers and active optical elements both suffer radiation damage [131, 132] and are not currently suitable for environments exceeding 100 Mrad. For the laser drivers, but not the fibers, there have been promising developments in silicon photonic systems using Mach-Zehnder interferometers rather than switching lasers, following the trend in commercial high speed optical links [133]. But customization of such devices for particle physics has so far not been widely successful. Geometrically, pixel detectors are compact, with highly constrained cable routing to achieve hermetic coverage. Routing of fibers to all modules in a pixel detector would require complex manipulation ofunjacketed fibers, which are fragile and have a minimum bend radius that must not be exceeded. Electrical cables are much more forgiving and can tolerate any bend radius.

4.10. Power distribution

The 1st generation ATLAS and CMS pixel detectors achieved a power distribution efficiency of approximately 25%. This means the 75% of the power delivered by rack power supplies was dissipated in cable IR loss and voltage regulators. Since the only current return path is thorough the detector, the power delivery efficiency is given by V_L/V_{sup} , where V_L (load voltage) is the voltage across the detector elements connected to each single power supply channel, and V_{sup} is output voltage at the power supply. Inefficient power delivery was recognized as a problem, but nevertheless the 1st generation detectors could be built using simple, direct power delivery to each module within a material budget considered acceptable. The planned high luminosity upgrades, on the other hand, face a much greater power delivery challenge. Not only will the detectors be larger, but the deep submicron electronics used will operate at half the voltage yet with slightly more power per unit area. This leads to a total detector current requirement an order of magnitude higher than present detectors.

However, the current that can be delivered from rack power supplies to the ATLAS or CMS inner detectors is limited by external factors. The resistance of the cable plant supplying the inner detector has a lower practical limit, R_{min} , imposed by mass and space considerations. At the same time, the IR-loss heat load on the subdetectors traversed by these cables is limited to P_{lim} so as not to degrade their performance. Therefore, the rack power supplies are only allowed to deliver at most $I_{\text{sup}} = \sqrt{P_{\text{lim}}/R_{\text{min}}}$. Approximate values for ATLAS are $P_{\text{lim}} \approx 10 \text{ kW}$ and $R_{\text{min}} \approx 0.5 \text{ m}\Omega$ (round trip), yielding $I_{\text{sup}} \approx 5 \text{ kA}$. The only free parameter left to control the power supplied to the detector is the load voltage V_L . For an expected 3rd generation ROIC power of order 0.6 W/cm^2 , a 10 m^2 pixel detector would need a load voltage of 12 V to deliver the 60 kW total power using 5 kA of rack supply current. Since the ROIC operating voltage $V_{\text{ROIC}}=1.2 \text{ V}$, directly powering the ROICs is out of the question: power conversion at the load is required.

Form the above discussion, the voltage conversion ratio required for a HL-LHC pixel detectors is of order 10. Two conversion methods have been extensively investigated: DC to DC converters and serial power. The DC-DC conversion technologies investigated include magnetic switching using air core

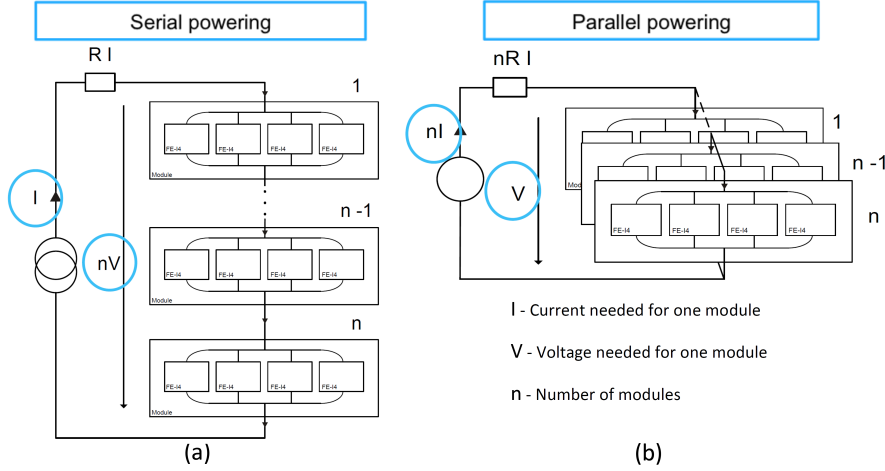

Figure 34: Schematic comparison of serial (a) vs. parallel (b) powering of a set of 4-chip modules. Each module has 4 ROICs that are always in parallel within the module, while the modules themselves can be placed in series (a) or in parallel (b). The load voltage for the parallel configuration is equal to the ROIC operating voltage V , whereas in the configuration with n modules in series the load voltage seen by the remote power supplies is $n \cdot V$. The voltage drop in the cables is shown above discrete resistors of value R (same R in both cases)

inductors [134, 135]¹², piezo-electric converters [136], and capacitor charge pumps [137]. While discrete DC-DC converters have now been developed compatible with LHC experiments [135], their use on pixel detector modules would result in too much added mass due to the high current per unit area required. Fully on-chip DC-DC conversion has been investigated [138] as this would not add any mass, but has not yet matured enough for consideration in the construction of HL-LHC detectors.

Serial power achieves power conversion without added mass by connecting devices in series and operating with constant current instead of constant voltage power supplies. Figure 34 compares 4-chip modules in serial vs. parallel power configurations. The serial configuration only needs two conductors and one power supply channel to serve n modules. Because $V_L = n \cdot V_{\text{ROIC}}$, the power delivery efficiency (V_L/V_{sup}) can be increased as needed by increasing n . Furthermore, constant current supplies are better suited to delivering power over resistive cables than the more common constant voltage supplies. Constant current powering is used commercially with very long, resistive cables, for example in undersea communications lines [139]. However, the requirements of pixel detector operation are very different and a custom serial power technology solution had to be developed. Serial power has been found to be reliable to implement and compatible with pixel [140, 141, 142] (and strip [143]) detector operation, and is the baseline for both ATLAS and CMS HL-LHC pixel detector designs. Implementation requires specialized constant current regulators, which have been developed [144] and included in the FE-I4 ROIC and the RD53A ROIC design. Prior efforts used simpler shunt voltage regulators [90].

¹²Ferromagnetic cores cannot be used in the strong tracker solenoid fields.

4.11. Future development

Even as monolithic solutions mature, hybrid technology with special purpose ROICs will continue to be necessary for the highest rate capability and the implementation of new functionality, such as fast timing. Looking to industry we find that the monolithic CMOS sensors in modern smartphones are actually 3D integrated devices. To the extent that such technology becomes open to low volume third party customization, monolithic devices for particle physics could also consist of multiple layers with processing and readout in small feature size CMOS exactly as conventional hybrid ROICs. In the coming years ROIC R&D will explore smaller feature sizes, with 28 nm being the likely candidate to follow 65 nm for 4th generation ROICs within a ten year horizon [145].

The 4th generation ROICs will add even more sophisticated digital functionality with minimal, but high speed analog front ends to enable fast timing. The operation of the individual pixels will likely be continually monitored and adjusted in real time with no need for storage of configuration data or lengthy calibrations. Improvements in communication and data compression will continue. Single lane output switching frequency will likely not increase beyond 5 Gbps due to issues with radiation tolerance of high speed logic, but data rate could be increased by making use of multi-level logic, essentially following industrial trends to maximize data rates in existing infrastructure originally designed for lower bandwidth. The point in particle physics is not to fit into existing infrastructure but to use the lowest possible mass cables. It is also possible that improvements in data cables themselves will be realized (higher bandwidth for lower mass), for example by replacing copper conductors and/or aluminum shields with carbon nanotube 'rope' or graphene foil, respectively. Some use of wireless technology is possible, if nothing else to facilitate testing by being able to communicate during detector construction/integration without physical connections. Finally, on-chip power management will surely increase, dynamically managing core voltage levels and possibly adding on-chip DC-DC conversion with high ratio (4 or more) providing an alternative to serial power.

5. Advanced materials: new possibilities for supports and cooling

The original ATLAS and CMS pixel detectors achieved an amount of material around 3.5% of a radiation length per layer at normal incidence [146, 147]. Of this, 0.5% was due to silicon (sum of ROIC and sensor). Since then, significant advances in mechanical support (section 5.2) and cooling (section 5.1) have taken place, and future ATLAS and CMS detectors are projected to be more than 50% lighter, between 1% and 1.5% per layer, out of which 0.3% will be silicon. Still lower mass is achieved with monolithic instead of hybrid technology, of order 0.3% per layer [148, 149]. The reason is not only less silicon, which can at most save 0.3%, but less stringent cooling requirements for monolithic sensors with small pixels and small depleted volume (and therefore small leakage current and no thermal runaway issues). However, monolithic active sensors compatible with high rate and radiation are still under development (see chapter 6).

Some critical developments have been CO₂ evaporative cooling, new composite materials, structure design and fabrication methods, and serial power distribution. Serial power distribution, which is an electronic system development, has been covered in section 4.10.

5.1. Cooling

The high power density and large extent of pixel detectors at the LHC demands a coolant that can transport a large amount of heat with low mass flow. Since evaporation can remove more heat for the same mass flow as single phase liquid cooling, it is preferred. Gas phase (air) cooling has been used for the STAR Heavy Flavor Tracker [150], but that detector is compact (20 cm active length and 0.2 m² active area) and based on CMOS sensors that do not need to be kept cold. Nevertheless, 0.2 W/cm² was removed with 10 m/s simple air flow (no fins or heat transfer enhancement features). An important advantage of evaporation is the absence of a temperature gradient along cooled structures. With an evaporative cooling system, the coolant temperature is fixed, regardless of heat load (for load less than maximum capacity). The heat is absorbed by the liquid to gas phase transition, so the difference between inlet and outlet of a cooled structure is the liquid fraction (high at the inlet and lower at the outlet). The maximum load capacity is reached when all the liquid has evaporated - a condition called dry-out, which should never be reached in a properly working system.

CO₂ is an ideal evaporative coolant for tracking detectors because it offers heat transfer coefficients an order of magnitude higher than traditional refrigerants, and its high evaporation pressure (around 50 bar) means small produced vapor volume, resulting in small diameter tubing. However, pressure safety is one of the challenges of using CO₂, requiring a rating of 200 bar throughout. The use of evaporative CO₂ for tracker cooling was pioneered by the AMS experiment [151], and in colliders by the LHC-b experiment. It was later adopted for the ATLAS IBL upgrade (fig. 35) and the CMS pixel upgrade. For a review see [152]. The original ATLAS and CMS detectors used other coolants that were better established at the time and did not need very high pressure plumbing. ATLAS used evaporative C₃F₈ [153], while the original CMS pixel detector used monophasic cooling with C₆F₁₄.

Figure 35: ATLAS IBL stave support with 1.7 mm diameter Ti pipe for CO₂ evaporative cooling. Full stave view (a) and cross section (b), showing thermally conductive foam interior and 100 μ m wall thickness pipe.

Figure 36: Photograph of a prototype mechanical support built with braided carbon pipes, embedded in carbon foam.

While aluminum has been used for cooling pipes in more conventional (fluorocarbon) evaporative systems [153], it is very difficult to prevent corrosion in aluminum pipes during detector construction [154], and weakening of pipe walls due to corrosion can be fatal for a high pressure system. Therefore, for many present CO₂ cooling systems the pipe material of choice is titanium, which is corrosion resistant and high strength (so can withstand high pressure with thin walls), yet relatively low mass. The main reduction in mass from CO₂ cooling comes not from the pipe material, but from the very small diameter pipes that can be used. Other materials have also been explored, most notably carbon fiber, for which braided fiber tubes are a common industrial product and so it is possible to produce braided pipes, but so far this has not been adopted. Figure 36 shows a prototype support with 2 mm diameter braided pipes embedded in carbon foam. For a review of pixel detector cooling and thermal management materials see [155].

A more recent development has been the use of silicon micro-channels with CO₂ cooling, in order to achieve very high cooling capacity with even lower mass than possible with separate mechanical supports cooled with metal pipes. This is suitable for fixed target geometries where mass can be placed immediately outside active elements, and has been pursued in the NA62 Gigatracker [156] (fig. 37) and LHC-b [157] upgrades.

For hybrid pixels, detector lifetime and cooling performance are closely coupled. The irradiated sensor leakage current scales with temperature (rule of thumb is that current doubles every 7°C), while the temperature depends on the power dissipated in the sensor, which in turn depends on leakage current. This leads to the well known condition of thermal runaway above a certain

Figure 37: Photograph of a micro channel cooled substrate (right), with diagram of cross section (top left), and photo of sectioned substrate showing micro channels [156] (bottom left).

Figure 38: Simple model of thermal behavior of hybrid pixel devices. The specific thermal resistance is known as Thermal Figure of Merit (TFM).

temperature [158]. The behavior can be captured by a simple model with the cooling performance of mechanical supports represented by a specific thermal resistance ($\text{cm}^2 \times ^\circ\text{C}/\text{W}$), also referred to as Thermal Figure of Merit (TFM) [159], as shown in fig. 38. With an evaporative cooling system, the coolant temperature is fixed, so the sensor temperature rises linearly with power dissipation, and the proportionality constant is the TFM. Thus the TFM defines positive feedback that leads to thermal runaway. High TFM means large positive feedback and therefore early thermal runaway (short lifetime), while zero TFM would be ideal. The mechanical supports of 1st generation ATLAS and CMS pixel detectors as built achieved a TFM of $30^\circ\text{C cm}^2/\text{W}$, while support structures prototyped for the HL-LHC upgrade detectors have achieved a TFM as low as $10^\circ\text{C cm}^2/\text{W}$ (can expect $15^\circ\text{C cm}^2/\text{W}$ for as built detectors). This impressive advance has been obtained by utilization of new, more performant carbon composite materials, such as thermally conductive carbon foam [160]. High thermal conductivity, low mass foam allows to take advantage of the CO_2 cooling by providing a way to efficiently collect heat from a large area module and couple it to a small diameter tube. Commonly used values of foam density and thermal conductivity are 0.2 g/cm^3 and 40 W/m/K , respectively¹³.

5.2. Supports

Support structures must combine the excellent cooling capacity discussed in section 5.1 with low mass and mechanical stability high enough to maintain module positions to within $10 \mu\text{m}$. Carbon composite designs and methods have enabled substantial mass reduction. A successful design approach for inner

¹³Foam thermal conductivity scales approximately with density, which can be adjusted in production

(a) I-beam

(b) Alpine

Figure 39: Photographs of carbon composite pixel support prototypes: (a) 'I-beam' geometry coupled layer and (b) 'Alpine' design with thermally conductive foam pedestals to hold modules out of plane.

pixel layers has been the use of coupled layer structures. Single layer supports spanning long distances (10s of cm) would suffer too large deformations from gravity sag and vibration without auxiliary stiffening elements, such as shells or frames, and the mass of these elements also contributes to the detector radiation length. By coupling layers in pairs, structures with a large moment of inertia can be made, which can be stiff enough over long spans without auxiliary support structures. The ALICE and STAR experiments used box beam structures for this purpose [161, 149]. In the case of STAR the approximately 30 cm long structures were held cantilevered from one end only. A further development in this direction, providing similar mass and stiffness with additional usable space, higher nesting freedom, and monolithic construction uses an I-beam rather than a box beam shape [162] (fig. 39 (a)).

New materials such as foam have also enabled development of more complex geometry supports that position modules with some tilt angle relative to the colliding beam direction [163]. An example of a support using foam pedestals, called Alpine, is shown in fig. 39 (b). Endcap pixel detectors have seen similar evolution, with CO₂ cooling and carbon composite developments allowing for lower mass and greater design freedom [6]. Planned high luminosity upgrades of ATLAS and CMS will have greater acceptance coverage and therefore larger endcap systems [163, 164].

6. CMOS active sensors: towards monolithic pixels

The hybrid pixel detector technology has many advantages due to its split functionality of sensor and chip in which both parts can be tailored to the LHC demands, i.e. the sensor especially to optimally stand irradiation and the readout chip to cope with high input rates ($\sim\text{MHz}/\text{mm}^2$). Complex signal processing already in the pixel cell is possible (see chapter 4). However, the hybrid choice also has some severe disadvantages. Hybrid pixels constitute a relatively large material budget, typically more than 1.5% X_0 per detector layer (ATLAS IBL) added up by the module parts as well as by cooling and support structures. The module production including bump-bonding and flip-chipping is complex and laborious, leading to a large number of production steps. Consequently, hybrid pixel detectors are comparatively expensive.

Modern CMOS imaging sensors instead make use of 3D integration to combine high resistivity and fully depleted charge collection layers with high density CMOS circuitry, in order to achieve high speed and high collection efficiency (for low light operation). Such a combination of fully depleted high resistivity silicon with CMOS readout sounds like a requirement from particle physics, not from consumer electronics, but smartphone image sensors have independently evolved in this direction for different reasons and with different optimization. For example, the pixels are very small ($< 20\text{ }\mu\text{m}^2$) and the depleted layer is very thin (few μm). Nevertheless, their out-of-the-box use for radiation and particle detection is being explored [165]. Such high end fabrication processes are currently not available to be customized for particle physics.

The following sections address current developments towards fully depletable, radiation tolerant, and high rate capable monolithic pixel devices, inheriting in part from successful adaptation of CMOS camera type sensors with thick epitaxial layers. The development of fully depletable devices becomes feasible by exploiting advances of CMOS industry, in particular the availability of multi-well technologies also for highly resistive substrate wafers.

6.1. From MAPS to DMAPS

Employing commercial CMOS technologies to produce a monolithic (rather than hybrid) pixel detector in which pixel sensor and electronics circuitry form one entity, has first been proposed [166] and realized [167] in the early 1990s. Some years later, so called MAPS detectors (*Monolithic Active Pixel Sensor*) were introduced [168, 169], exploiting as the sensing volume an epitaxial layer often grown on top of the lower quality substrate wafer and hosting the CMOS circuitry. The thickness of this epi-layer typically is in the range of 1–20 μm , where thicker layers are often used in processes addressing CMOS camera applications (fig. 40(a)).

For particle detection the charge deposited in the epi-layer can be as large as 4000 e^- for a typical thickness of 15 μm . Since the epi-material usually has low resistivity and the allowed biasing voltages are low in CMOS technologies, the epi-layer usually is not depleted (only very locally around the charge collection node). The deposited charge of a traversing particle therefore is mostly collected by diffusion rather than by drift. This renders the signal generation to be slow and incomplete (not all charges arrive at the collection node) and is, besides the lacking radiation hardness, the main reason why this original MAPS technology

Figure 40: (a) Conventional monolithic active pixel sensor (MAPS) with charge collection in an epi-layer mainly by diffusion. An *nwell* acts as the charge collection node. Other *nwells* in the circuitry must be shielded (here by a *pwell*). (b) DMAPS (Depleted MAPS) structure. Multiple wells on high resistive substrate allow complete embedding of the CMOS electronics layer in a charge collecting *deep nwell*.

is not suited for high rate applications as needed in LHC pp-experiments. Furthermore, other *nwells*, e.g. those hosting PMOS transistors, act as competing nodes for charge collection. The latter can and must be cured by additional deep *pwell* protections as is also shown in fig. 40(a).

MAPS pixel detectors have been successfully used in lower than LHC rate and low radiation experiments, such as the STAR experiment at RHIC [170, 171]. Also the ALICE ITS Upgrade [148] has chosen MAPS pixels based on the 180 nm CMOS node offered by TowerJazz with 6 metal layers [172]. Note, however, that the expected radiation level for HL-LHC ion collisions is 700 krad and $10^{13} n_{eq}/\text{cm}^2$, respectively, i.e. 1500 times lower than for LHC pp-experiments.

Depleted (D)MAPS

In order to further develop CMOS pixel detectors for LHC type rate and radiation applications, improved development lines have been pursued leading to *depleted monolithic active pixel sensors* (DMAPS) [24][173]. The goal of this new development is to employ commercial CMOS technology with some modifications to obtain sufficient signal and fast timing in monolithic CMOS designs, that merge sensor and readout chip into one entity, while maintaining charge collection via charges drifting in an electric field inside the chip's substrate. The technology and the sensing properties must survive the radiation environment at the HL-LHC, at least in the outer layers, far enough from the interaction point, such that the radiation levels are similar to those presently encountered at the inner layers, i.e. 100 Mrad ionisation dose and $2 \times 10^{15} n_{eq}/\text{cm}^2$ particle fluence, respectively.

Development of such detectors much relies on recent advancements and freedom in CMOS technologies, offered in particular by vendors interested in market corners away from mass IC production and offering process add-ons or modifications. The goal is to achieve some (50–100 μm) depletion depth

$$d \sim \sqrt{\rho V} \quad (16)$$

where ρ is the substrate resistivity and V is the bias voltage, yielding a reasonably large signal ($\sim 4000 e^-$) with fast and in-time efficient charge collection, while avoiding too long collection paths on which charges can be trapped after irradiation. At the same time full CMOS functionality shall be maintained, i.e.

Figure 41: (a) Capacitance contributions of a typical CMOS pixel cell to the amplification node. Apart from capacitances to the backside and between pixels a non-negligible contribution comes from the close-by wells, deep nwell and pwell. (b) Through the capacitance between p- and nwell digital signals can couple into the sensor bulk if no particular care is taken to prevent this.

equal and unconstrained usage of PMOS and NMOS transistors and no/little interference of electronics signals and detector signal pulses.

DMAPS detectors in particular exploit the following CMOS technology features:

- High voltage technology add-ons (from automotive and power management applications) that increase the voltage handling capability and create a depletion layer in a well's pn-junction of the order of 10–15 μm .
- Medium to high ($>100\ \Omega\text{cm}$) resistivity 8" silicon substrate wafers, accepted and qualified by the foundry. A depletion layer develops due the high resistivity with only moderate bias voltages applied from the electronics side or a (specially processed) backside contact.
- Multiple nested wells (see also chapter 4) that can be used to isolate transistors and shield deep well potentials in order to optimize charge collection. The foundry must accept some process or design rule changes in order to optimise the design for HEP applications.
- Backside processing add-ons allowing for example a backside biasing contact acting as additional field shaping potential of the device.

The interest in CMOS pixels for HL-LHC has particularly been aroused by its low cost potential and the feasibility of large area monolithic devices in outer tracker layers when stitching is employed, but also out of intellectual curiosity if such a one-piece pixel detector can be developed for HL-LHC environments demands.

DMAPS capacitances

Figure 41 shows the main capacitances in a DMAPS design that contribute to the total amplifier input capacitance of a pixel cell. In addition to the pixel-to-pixel (C_{pp}) and pixel-to-backside (C_b) capacitances, also present in any other sensor design, interwell capacitances to the well sides (C_{sw}) and between deep nwell and pwell (C_{ww}) play a significant role. In particular, if the deep nwell is large (large fill-factor, see below) C_{ww} can achieve significant values (as large as 100 fF for 10 000 μm^2 pixel area) increasing the total capacitance. This is to be compared to typical hybrid pixel capacitances of $C_D \approx 120$ fF (planar)

Figure 42: Two principal variants of CMOS cell geometries: (a) Large fill-factor: the charge collecting deep nwell encloses the complete CMOS electronics. (b) Small fill-factor: the charge collection node is placed outside the CMOS electronics area.

and $C_D \approx 180$ fF (3D-Si) [174]. A large amplifier input capacitance C_D directly enters the thermal noise (and also $1/f$ noise) figures of a pixel detector with CSA readout and shaping as well as the detector response time τ_{CSA} :

$$ENC_{thermal}^2 \propto \frac{4}{3} \frac{kT}{g_m} \frac{C_D^2}{\tau_{sh}} \quad \text{and} \quad \tau_{CSA} \propto \frac{1}{g_m} \frac{C_D}{C_f} \quad (17)$$

where C_f is the feedback capacitance, g_m the transconductance, τ_{sh} the shaping time, and kT Boltzmann constant and temperature.

While it may be possible to cope with additional input capacitance as a noise factor, e.g. by increasing g_m (which increases power), the interwell capacitance also couples the CMOS electronics with the sensor volume as illustrated in fig. 41(b). This requires careful circuit design and special measures preventing digital activity to couple into the sensor part thus faking particle signals. An alternative is to place the digital logic away from the active sensor part (nwell), at a price of a smaller fill-factor (see below).

Fill-factor choices

Figure 42 shows two principle variants of a pixel cell arrangement. While in fig. 42(a) the entire CMOS electronics is enclosed in the deep, charge collecting nwell, in fig. 42(b) the deposited charge is collected at a small nwell located outside the electronics area. A large fill-factor provides good charge collection properties over the entire pixel area with on average shorter travel distances and hence smaller trapping probabilities after irradiation, but it suffers from a comparatively large interwell capacitance contribution (~ 100 fF) as discussed above leading to larger noise figures and slower timing. Increased power (compared to hybrid pixels) for same pixel area is needed to cope with the larger capacitance. Most developments so far have chosen this variant to minimize radiation hardness issues, the main challenge at the HL-LHC. Note that with the advancement of CO₂ cooling a change in the power bill does not linearly translate into material. Thermal conductivity of the components is the key parameter (see also section 5.1). For example, for a cooling tube embedded in a carbon foam, increasing or reducing the power by a factor of 2 leads to a material in/decrease by a few percent [175].

The small fill-factor variant on the other hand promises node capacitances of only 5–20 fF and hence excellent noise and timing performance. However, the radiation tolerance is an issue, given that on average the drift distances of signal

Figure 43: Effective space charge concentration measured after neutron irradiation for different starting materials varying from 10 kΩcm to 2 kΩcm as a function of the neutron fluence [176]. The insert shows the same curves at low fluences.

charges are longer for same cell size. Small pixel sizes are therefore beneficial for a small fill-factor design at the expense of power density.

Substrate resistivity

According to eq. (16) high resistivity is a mean to obtain adequate signal sizes by sufficient depletion depth at moderate bias. Figure 43 [176], however, shows that independent of the starting substrate resistivity, over a large range of resistivities (10 Ωcm–2 kΩcm) one observes that after a fluence of about $10^{15} \text{ n}_{eq} \text{ cm}^{-2}$ the effective space charge concentrations approximate each other at a level of about $N_{eff} \approx 10^{14} \text{ cm}^{-3}$ corresponding to about 100 Ωcm. This effect is commonly attributed to irradiation induced acceptor removal, setting in earlier at higher p-doping concentrations and eventually leading to similar N_{eff} concentrations. Therefore, for high radiation applications, the starting resistivity is not very critical, and in fact an intermediate (100 Ωcm - 1 kΩcm), not too high initial resistivity may be advantageous as this will lead to a fairly constant charge collection throughout the lifetime.

6.2. Designs and technology variants

The high energy physics community has targeted different prototyping designs with various foundries providing standard CMOS technology add-ons necessary to cope with the given demands. The emphasis at the start was either on dedicated high voltage technologies [24] or on technologies accepting high resistivity substrate wafers for processing [177]. It turned out that both, mid to high resistivity ($\lesssim 1 \text{ k}\Omega\text{cm}$) as well as sufficient bias ($\gtrsim 150 \text{ V}$), are needed for good performance under irradiation. The general approach of different groups has been in three prototyping steps.

1. Simple prototypes to characterize technology features and charge collection performance.
2. Large pixel arrays with stand-alone readout as well as readout via a dedicated pixel readout chip (usually FE-I4 [4]) bonded to it.

Figure 44: (a) Pixel layout in 180 nm HV technology (AMS). The triple well technology contains both transistor flavours in a deep nwell acting as the charge collecting node at the same time. (b) DMAPS realisation employing SOI technology. A buried oxide layer (BOX) separates the depleted sensor substrate from the electronics layer. Vertical vias connect electronics to the bulk. Trench isolations shield individual transistors. Partially depleted (thick film) nwell and pwell regions prevent the 'backgate' effect.

3. Large, fully monolithic CMOS pixel matrices including on-chip digital readout architecture for rates and occupancies expected at the HL-LHC.

The development is currently progressing fast. One can say that steps 1 and 2 have been successfully carried out, and different designs for step 3 have been fabricated and are expected to be characterized by summer 2017.

Hybrid active CMOS pixels

A variant under step 2 exploits usage of a 'smart CMOS sensor' coupled to a readout chip like FE-I4 [4]. In this case the CMOS sensor provides first analog pulse processing (usually CSA preamplifier plus discriminator) providing a digital voltage output which is DC or AC coupled onto the FE-I4 analog input. This approach is commonly called 'capacitively coupled pixel detector', CCPD [178]). While it allows for some extra freedom to explore new functionality such as the implementation of subpixel decoding described in chapter 2 on page 10, it does not constitute any principal novelty compared to hybrid pixels and must be compared to those in terms of material budget and power performance.

DMAPS in HV/HR technologies with large fill-factor

CMOS pixels with some depletion depth have first been implemented in [179] using a dedicated HV technology (called HVCMOS) with 350 nm and later with 180 nm feature sizes (AMS H35 and H18) allowing for up to three nested wells. Both PMOS and NMOS transistors sit in a large deep nwell which at the same time acts as the charge collection node (large fill-factor, see fig. 44(a)). Because the PMOS transistors' nwell is identical to the collection node, care must be taken in its usage in the electronics design limiting somewhat the CMOS functionality. The achievable depletion depth is around 15–30 μm for low resistivity substrates around 10 Ωcm . Higher resistivities up to about 1 k Ωcm are under study. HVCMOS prototypes have been tested to TIDs well above 100 Mrad and fluences up to $5 \times 10^{15} \text{ n}_{eq}/\text{cm}^2$ [180]. The most critical performance metric is the so-called in-time efficiency of hits after irradiation which includes both radiation damage characterizations as well as rate demands at the LHC. The term *in-time* means that a hit must be time-stamped within one

Figure 45: Depletion depth measured using edge TCT for high resistivity (2–3 kΩcm) CMOS pixel devices [176]. Plotted is the extracted depletion depth as a function of bias voltage studied after seven increasing irradiation steps (up to $8 \times 10^{15} \text{ n}_{eq} \text{ cm}^{-2}$). Open symbols denote devices with and full symbols without backplane contact.

LHC bunch-crossing window of 25 ns. Testbeam characterization of prototype matrices coupled to the FE-I4 pixel chip via adhesive bonding yielded efficiencies of above 97% (99.7% up to $1 \times 10^{15} \text{ n}_{eq} \text{ cm}^{-2}$) and in-time efficiencies comparable to those of FE-I4 hybrid pixel modules used in the same testbeam ($>95\%$ within three BX of 25 ns) [180].

Prototype matrices were tested up to fluences of $1 \times 10^{15} \text{ n}_{eq} \text{ cm}^{-2}$ and TIDs of 50 Mrad [25] using an approach that differs from the above mainly in two aspects, (i) use of a quadruple well 150 nm process (LFoundry LF15A) as in fig. 40(b), and (ii) use of high resistivity substrate wafers (2–3 kΩcm). This technology allows for bias voltages in the 150–200 V range. The devices performed well in test beams, showing high time integrated efficiencies, but not yet with fast enough timing (1 BX in-time efficiency $< 91\%$) owing to the large capacitance inherent in the large fill-factor approach. The depletion depth of these devices has been measured for increasing radiation fluence [176] (up to $8 \times 10^{15} \text{ n}_{eq} \text{ cm}^{-2}$, fig. 45) using the edge TCT technique (*transient current technique*, see for example [181]) measuring the transient current generated by a laser pulse shooting into the CMOS sensor from the edge parallel to the pixel electrodes. As a function of bias voltage the square root shape of eq. (16) is observed nicely showing that depletion depth values of 30–50 μm are maintained even for fluences beyond $10^{15} \text{ n}_{eq} \text{ cm}^{-2}$.

Fully monolithic versions in these technologies (AMS and LFoundry) have been fabricated and are currently being characterized [182, 183].

CMOS on SOI

The Silicon-on-Insulator (SOI) technology provides a buried oxide layer (BOX) separating the CMOS electronics from the substrate layer. Both parts are connected by vertical via structures reaching through the BOX and leading to an n-implant which acts as the charge collecting node. Monolithic SOI-based pixel structures have been developed for some time using the so-called fully depleted (FD) SOI technology [184], invented for high speed CMOS electronics

Figure 46: Small fill-factor design of a pixel cell in a 180 nm quadruple well technology (TJ 180nm) [188]. Note that the electronics circuitry is fully enclosed in a large deep p-well while charge is collected by a small nwell collection node.

with reduced (parasitic) capacitances. The CMOS electronics layer is embedded in depleted silicon. The developments in this FD-SOI technology, however suffer from effects inherent to the BOX oxide layer, most notably the so-called back-gate effect and from radiation effects [184] that can be compensated to some degree [185] for moderate radiation doses, but not for the radiation conditions expected at the HL-LHC.

Thick film SOI, however, featuring trench isolation and doped, only partially depleted regions underneath CMOS transistors, thus shielding the transistors (cf. fig. 44(b)), are free of these difficulties and can also sustain much larger radiation doses. SOI CMOS pixel detectors have been realised by [186] and characterised [187] in the lab and in test beams. The devices show impressive TID tolerances tested up to 1 Grad. Also here the substrate resistivity is first increasing with hadron fluence due to acceptor removal. The measured in-time efficiency also needs (modest) improvement in order to cope with LHC demands.

Even though the CMOS on SOI approach towards monolithic pixel detectors remains very interesting, not the least because of the attractive approach of separating sensing and electronics volume by a buried oxide layer, it is currently not the main focus of the HL-LHC developments.

DMAPS with small fill-factor

Recently a development has started trying to achieve sufficient radiation hardness by a small fill-factor design promising low noise and fast timing due to the small resulting input capacitance. The development inherits from the design of the ALICE ITS pixel chip (ALPIDE) development [189, 172] introducing some technology improvements for better charge collection after irradiation [190]. Figure 46 shows a principal cell layout. The charge collection is obtained in a high ohmic ($> 1 \text{ k}\Omega\text{cm}$) epitaxial layer. The quadruple well features are very similar to those in fig. 40(b). The main difference is the layout of the charge collection node placed far outside the electronics area with minimal geometric size. The capacitance is very low, between 3–10 fF [191], depending on geometry details and pitch of the collection node. The pixel area must be small ($\lesssim 40 \mu\text{m}$) in order to limit the maximum path length for charge collection.

In a first prototype chip (TJ Investigator) the main features of such a design have been investigated [188] confirming the low capacitance and the good timing precision ($\tau_{\text{rise}} \sim 16 \text{ ns}$). To obtain a fully depleted volume the TJ process was modified replacing the epitaxial p-layer by a planar deep n⁺-p junction [188]. A fully monolithic chip including readout architecture has been recently submitted for fabrication with expected noise figures of 16–20 e[−] and similar timing precision. Results are expected in summer 2017.

6.3. Outlook on DMAPS pixels

The development of depleted CMOS active pixels currently has a large momentum in the high energy physics community. Many groups are active in developing DMAPS sensors and also DMAPS based modules. The specific developments discussed above are not an exhaustive survey and we are aware of other manufacturers and competing efforts that have not yet published results. Whether the development can be brought to a level of maturity sufficient for (parts of) an HL-LHC pixel detector in time for the soon coming technology decisions, remains to be seen. In any case, the possibility to devise radiation hard and high rate capable pixel detectors as single entities containing sensor and readout architecture in a monolithic fashion, avoiding laborious and cost intensive hybridization, seems very attractive also beyond the time line of the HL-LHC. With the advancement of stitching over reticle boundaries (see section 3.1) even large area monolithic pixel modules are in reach.

7. Summary and Conclusions

With the planned high luminosity upgrades of the LHC machine and experiments, pixel detectors operating in high rate and radiation environments are facing yet another extreme challenge, surpassing that of the current LHC by roughly an order of magnitude. While integrated (monolithic) pixel detectors have been developed already for some time (and are in fact used in detectors under less hostile experimental conditions), as of today hybrid pixel detectors still constitute the state of the art in tracking detector technology close to the interaction point of such high rate and radiation experiments.

In this paper we have reviewed the fundamentals of track space-time point and direction measurements and described development routes and choices to make for the next generation HL-LHC experiments. These address all components of the hybrid pixel technology, most prominently the sensor and the readout chip, but also interconnection and 3D-stacking techniques as well as light weight support and cooling structures. Beyond the traditional space point measurement, ways to extract and use additional information from pixel detectors are being explored, such as space vector information or precision timing information with the promise of so-called 4D tracking.

Silicon sensors capable to cope with fluences of and beyond $10^{16} \text{ n}_{eq} \text{ cm}^{-2}$ have been developed to sufficient performance (sections 3.1 and 3.2). Both, the conventional planar pixel approach with thin sensors and dedicated guard ring structures as well as 3D-Si sensors, having been further optimized after their successful performance in the IBL pixel upgrade of ATLAS [192], have been shown to be able to cope with the demands.

A major challenge is the development of a next generation of pixel readout chips which must cope with very harsh radiation conditions (total doses up to 1 Grad), with particle rates $> 3 \text{ GHz/cm}^2$, and with MHz trigger rates leading to data output bandwidths of $\mathcal{O}(10 \text{ Gb/s})$. The development of a close to 10^9 transistor readout chip is jointly addressed by ATLAS and CMS through the RD53 collaboration [95] using deep submicron 65 nm technology. Narrow and short transistor channel effects lead to complex radiation damage behavior that demands sophisticated modelling to be properly addressed (section 4.4). An approach dubbed 'analog islands in a digital sea' is employed to digest the very large rates and process data on chip. The RD53 chip will serve as the workhorse for the HL-LHC hybrid pixel detectors of the experiments.

Advances in evaporative cooling and in using light weight yet stiff composite materials render possible a material budget reduction per pixel layer from previously above 3% to below 1%, even for power and cooling intensive high rate and radiation applications (chapter 5). Coolant choices have narrowed down to CO_2 as today's state of the art. Very small diameter pipes (micro channels) are an attractive development path for high cooling capacity.

Finally, the monolithic pixel module ansatz is being revived by employing multiple well technologies on high resistive substrates that have become more commercially accessible to the HEP community and now offer good performance even under HL-LHC requirements (chapter 6). This has also launched R&D using CMOS technology lines for (passive) sensors in hybrid pixel detectors (section 3.1), offering advantages as low cost, capacitive coupling of electrodes as well as efficient routing between sensor and ROIC pixels by exploiting CMOS metal layers.
