We review the recent progress in the Big-Bang nucleosynthesis which includes the standard and non-standard theory of cosmology, effects of neutrino degeneracy, and inhomogeneous nucleosynthesis within the framework of a Friedmann model. As for a non-standard theory of gravitation, we adopt a Brans-Dicke theory which incorporate a cosmological constant. We constrain various parameters associated with each subject

Keywords: Cosmology; Light-elements; Big-Bang Nucleosynthesis

PACS Nos.:98.80.-k; 26.35.+c; 98.80.Ft

1. Introduction

Big-Bang nucleosynthesis (BBN) is one of the best astrophysical sites to understand the origin of the light elements,¹ because it produces the primordial abundances of ⁴He, D and ⁷Li.^{3,4} The simplest and most trustful theory is called the standard Big-Bang nucleosynthesis (SBBN), where we assume the cosmological principle that the universe is homogeneous and isotropic in a large scale.² Unfortunately, current situation of SBBN is incompatible with the observed abundance of ⁷Li, although it has been pointed out that observational determinations of the ⁷Li abundance contain uncertainties associated with an adopted atmospheric model of metal-poor stars⁵ or some unknown physical processes.⁶

On the other hand, heavy element nucleosynthesis beyond the mass number

A = 8 has been investigated in a framework of inhomogeneous BBN (IBBN) .^{8–13} The baryon inhomogeneity could be originated from baryogenesis¹² or some phase transitions^{13, 14} which occur as the universe cools down during the expansion. It should be noted that IBBN motivated by QCD phase transition encounters difficulty, because the transition has been proved to be crossed over by the Lattice QCD simulations,¹⁶ which means that the phase transition occurs smoothly between the quark-gluon plasma and hadron phase under the finite temperature and zero chemical potential. Although a large scale inhomogeneity of baryon distribution should be ruled out by cosmic microwave background (CMB) observations,^{17, 18} small scale inhomogeneities are still allowed within the present accuracy of observations. Therefore, it is possible for IBBN to occur in some degree during the early era.

Considering recent progress in observations for peculiar abundance distributions, it is worthwhile to re-investigate IBBN^{21,76,77} It has been found that²³ synthesis of heavy elements for both p- and r-processes is possible if $\eta > 10^{-4}$ and that the high η regions are compatible with the observations of the light elements, ⁴He and D. However, the analysis is only limited to a parameter of a specific baryon number concentration, and a wider possible parameter region should be considered. Therefore we adopt a two-zone model and derive constraints comparing the BBN result with available observations.

In the meanwhile, whole validity of general relativity has not been proved. For example, some kinds of scalar fields may exist in the present epoch. Therefore, we need to examine whether a possibility for a non-standard theory of gravitation survives from the viewpoint of BBN. Simple version of a scalar field theory is the Brans-Dicke theory which include a scalar field. This theory leads to a variation of the gravitational constant and induces an acceleration of the universe. Therefore, we show compatibility between the observations of light elements and the Brans-Dicke theory with a Λ term.

In section 2, we give the framework of SBBN and present a detailed comparison among observations and Big-Bang nucleosynthesis in section 3. As an approach to explain a wide range of observational He abundances, we give the effects of neutrino degeneracy on the production of He in section 4. Section 5 is devoted to nucleosynthesis with use of a simple approach for the inhomogeneous BBN. Finally, we give non-standard BBN based on the Brans-Dicke theory in section 6 which remains a room beyond the general relativity. Section 7 summaries possible variations of BBN.

2. Thermal evolution of the universe

In this section, we summarize the evolution of the standard cosmological model, i.e. Friedmann model based on the cosmological principle or the Friedmann-Robertson-

Walker metric^a,

$$ds^{2} = g_{\mu\nu}dx^{\mu}dx^{\nu} = -dt^{2} + a^{2}(t)\left(\frac{dr^{2}}{1 - kr^{2}} + r^{2}d\theta^{2} + r^{2}\sin^{2}\theta d\phi^{2}\right),$$

where a(t), t, and k are the cosmic scale factor, the cosmic time, and the spatial curvature, respectively. The Friedmann model has been constructed with use of the Einstein equation,

$$R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R = 8\pi G T_{\mu\nu}.$$

Here $R_{\mu\nu}$, R, G and $T_{\mu\nu}$ are the Ricci tensor, the scalar curvature, the gravitational constant, and the energy-momentum tensor of the perfect fluid written as $T_{\mu\nu} = pg_{\mu\nu} + (p+\rho)u_{\mu}u_{\nu}$, where p is the pressure, ρ is the energy density, and u_{μ} is the four velocity.

In practice, we can follow the evolution of temperature T and energy density ρ by solving the Friedmann equation

$$H^2 \equiv \left(\frac{\dot{a}}{a}\right)^2 = \frac{8\pi G}{3}\rho - \frac{k}{a^2},\tag{1}$$

where H is called as the Hubble parameter. The total energy density ρ is written as

$$\label{eq:rho_star} \rho = \rho_\gamma + \rho_\nu + \rho_{e^\pm} + \rho_b + \rho_{\rm DM} + \rho_\Lambda,$$

where the subscripts γ , ν , e^{\pm} , b, DM and Λ indicate photons, neutrinos, electrons and positrons, baryons, dark matter, and the vacuum energy, respectively.

The energy conservation law, $T^{\mu\nu}_{;\mu} = 0$, reduces to

$$\frac{d}{dt}(\rho a^3) + p\frac{d}{dt}(a^3) = 0.$$
(2)

The equation of state is described as

 $p/\rho = \begin{cases} 1/3 & \text{for photons and neutrinos,} \\ 0 & \text{for baryons and dark matter,} \\ -1 & \text{for vacuum energy.} \end{cases}$

Therefore, we obtain the evolution of the energy density as ρ_b and $\rho_{\rm DM} \propto a^{-3}$, and $\rho_{\gamma,\nu} \propto a^{-4}$. The temperature varies as $T_{\gamma} \propto a^{-1}$ except for the era of the significant entropy transfer from e^{\pm} to photons at $T \simeq 5 \times 10^9$ K.

Usually, the present values of the energy densities are expressed as the density parameter $\Omega_i = \rho_{i,0}/\rho_{cr}$ for $i = \gamma, \nu, b$, DM, and Λ with the critical density $\rho_{cr} = 3H_0^2/8\pi G$. Here the subscript 0 means the value at the present time.

For the baryon density, we also use the baryon-to-photon ratio η ,

$$\eta \equiv \frac{n_b}{n_\gamma} = 2.74 \times 10^{-8} \Omega_b h^2, \tag{3}$$

^aWe adopt the system in units of c = 1.

where h is the dimensionless Hubble constant: $h = H_0/100 \text{ [km/s/Mpc]}$. The value of η is kept constant after the electron-positron pair annihilation, because the number densities of photons n_{γ} and baryon n_b vary as n_{γ} and $n_b \propto a^{-3}$. From the results of observation of CMB by the Planck satellite, $0.02180 < \Omega_b h^2 < 0.02272$ at 95% confidence levels (C.L.),⁵⁰ we obtain the range

$$5.96 < \eta_{10} < 6.22 \tag{4}$$

where $\eta_{10} = \eta / 10^{-10}$.

3. Standard Big-Bang nucleosynthesis

3.1. Physical process of the Big-Bang nucleosynthesis

In this section, we describe the standard model of BBN. At the stage $T > 10^{10}$ K, photons, neutrinos, and electron (plus positron) are dominant. The energy density is written as follows:

$$\rho = \frac{\pi^2 k_{\rm B}^4}{30\hbar^3} \left(2 + \frac{7}{2} + \frac{7}{4} N_\nu \right) T^4,$$

where $k_{\rm B}$, \hbar , and N_{ν} are the Boltzmann constant, the Planck constant reduced by 2π , and the effective number of neutrinos (we fixed the value $N_{\nu} = 3$). The first, second, and third terms are contributions of photons, electrons and positrons, and neutrinos, respectively. From Eq.(1), the expansion rate of the Universe is $H \sim G^{1/2}T^2$. At that time, neutrons and protons are coupled through the weak interaction as follows:

$$n + e^{+} \longleftrightarrow p + \bar{\nu}_{e},$$

$$n + \nu_{e} \longleftrightarrow p + e^{-},$$

$$n \longleftrightarrow p + e^{-} + \bar{\nu}_{e}$$
(5)

The rate of the weak interaction Γ_{wk} can be written as $\Gamma_{wk} \sim G_F T^5$. Here G_F is the Fermi coupling constant. The number ratio of the neutrons to protons is written as

$$\frac{n_n}{n_p} = \exp\left(-\Delta m/k_{\rm B}T\right),\tag{6}$$

where Δm is the mass difference between the neutron and proton: $\Delta m = m_n - m_p = 1.29$ MeV.

When $\Gamma_{wk} \simeq H$ at $k_{\rm B}T \simeq 1$ MeV, the ratio (6) is frozen (except for neutron's β -decay) and the ratio of the neutrons and protons is fixed to be 1/7. The ratio in this epoch is very important. As shown later, the most abundant nuclide except for ¹H in the BBN epoch is ⁴He. The abundance of ⁴He is defined by the ratio as follows:

$$Y_{\rm p} = \frac{\rho_{^4\rm He}}{\rho_b} \sim \frac{2n_n}{n_p + n_n} \sim 0.25$$

Fig. 1. Nuclear reaction network in Big-bang nucleosynthesis.

where $Y_{\rm p}$ is the mass fraction of ⁴He.

When the temperature reaches to 0.1 MeV, the synthesis of light elements starts by the neutron capture reaction of protons: $n + p \longrightarrow D + \gamma$. Figure 1 illustrates the 12 important reactions of BBN.

Figure 2 shows the numerical result of BBN with $\eta_{10} = 6.19$ and the neutron life time $\tau_n = 880.1 \text{ sec.}^{51}$ In the BBN era, the heavy element such as CNO cannot be synthesized, because there are no stable element of the mass number A = 5 and A = 8. In Fig. 3 we show the produced final values of Y_p , D/H and ⁷Li/H as a function of η . The line widths for individual elements correspond to the errors attached to the nuclear reaction rates of NACRE II⁵³. Although a new decay rate of free neutrons $\tau_n = 880.1 \pm 1.1$ sec yields⁵¹ $Y_p \simeq 0.245$, we adopt the conservative rate considering the uncertainty of the half life.³⁰ When the baryon density is high, more D can be synthesized from neutrons and protons. However, reactions which yield helium also begin. As a result, ⁴He increases while D decreases as shown in Fig. 3. We note that the ⁷Li abundance decreases with increasing η for $\eta_{10} < 3.0$. For $\eta_{10} > 3.0$, the tendency becomes opposite. For high baryon density, ⁷Be can be synthesized through ⁴He capture reaction on ³He, and consequently, it is converted to ⁷Li through the electron capture reaction after recombination of ⁷Be.

Fig. 2. Evolution of mass fractions of ¹H (X_p) and ⁴He (Y_p) and number abundances of other nuclides in SBBN.

3.2. Nuclear reaction rates

To obtain primordial abundances of the light elements numerically shown in Fig.2, it is necessary to solve differential equation of two body reaction for a number fraction y_k as follows:

$$\frac{dy_k}{dt} = \sum_{i,j,l} y_i y_j [ijkl] - \sum_{i,j,l} y_k y_l [klij],$$

where [ijkl] means the rates of a thermonuclear reaction: $i + j \rightarrow k + l$. Usually the rate is a function of the baryon density and temperature. The other main channel responsible for BBN is the transformation between n and p. We note that three body reactions can be negligible in SBBN.

For BBN study in these 10 years, the reaction rates given by Descouvement et al.⁵² (DAA) and NACRE II.⁵³ have been used. The DAA rates are obtained by adopting the *R*-matrix theory so as to fit with the low energy data. The NACRE II rates are the updated version of the NACRE compilation⁵⁴ which include the thermonuclear reaction rates obtained experimentally for nuclei with $A \leq 16$. We compare the BBN results between DAA and NACRE II.

Figure 4 shows the results of BBN calculated by using the reaction rates of DAA and NACRE II. The abundances of ⁴He and D are almost the same. However, ⁷Li by NACRE II is 0.5 % higher than that by DAA. This is because, as shown in Fig.5,

Fig. 3. Abundance of light elements produced in SBBN as a function of η . The vertical region $\Omega_b h^2 = 0.02222 \pm 0.00023$ indicates the constraint from Planck.⁵⁰

the rate of the reaction ${}^{3}\text{He}(\alpha, \gamma){}^{7}\text{Be}$ of NACRE II is higher than that of DAA at the temperature range of BBN.

3.3. Constraints from observations of ${}^{4}He$, D, and ${}^{7}Li$

The observation of ⁴He is important to constrain physics of the early universe, because the theoretical value of ⁴He is sensitive to cosmological models, such as the gravitational model beyond general relativity and effective neutrino number.

Helium-4 is the most abundant element nuclide except for ¹H produced in BBN. It is also yielded through hydrogen burning inside stars. Since the abundance of ⁴He grows after BBN era, its observed value is an upper limit to the primordial abundance. Thence, it is not easily to determine primordial Y_p . However, it is deduced that primordial ⁴He remains in a low-metallicity region, because star formation does not occur there. Then ⁴He is determined from the recombination lines of proton and helium in extragalactic HII regions.

Recently, observational abundance of ${}^{4}\mathrm{He}$ has a conflict between two groups. Izotov et al. report

$$Y_{\rm p} = 0.254 \pm 0.003 \tag{7}$$

using linear relation Y-O/H for 111 highest-excitation HII regions.⁴⁴ And adding

Fig. 4. Produced abundances of light elements. The solid curves are calculated from the rates of NACRE II and the dashed ones are of DAA.

the HeI λ 10830 Å emission line, they derived⁴⁵

$$Y_{\rm p} = 0.2551 \pm 0.0022. \tag{8}$$

On the other hand, using A Markov Chain Monte Carlo analysis for 93 HII regions, Aver et al. 43 reported

$$Y_{\rm p} = 0.2465 \pm 0.0097. \tag{9}$$

Also they reported⁴⁶

$$Y_{\rm p} = 0.2449 \pm 0.0040. \tag{10}$$

by evaluating the effects of adding He I $\lambda 10830$ infrared emission line in helium abundance determination.

Helium-3 is made from deuteron by $D(p,\gamma)$ ³He in the star. Therefore, observations of D give a upper limit of primeval values. Since the abundance of D strongly depends on the baryon density, D is called as "baryometer". The abundance of D is measured in QSO absorption line system at high-redshift. Recently, the primordial D abundance is determined with a high-accuracy. Pettini & Cooke reported⁴⁸

$$D/H = (2.535 \pm 0.05) \times 10^{-5}.$$
 (11)

Fig. 5. Rates of ³He $(\alpha, \gamma)^7$ Be from NACRE II relative to DAA (adopted value). The horizontal axis means the temperature normalized by 10⁹ K. The shaded area indicates the uncertainty of the reaction rate by DAA. The red curves correspond to the high (upper curve) adopted (middle curve) and low (lower curve) values of reaction rates in NACRE II, respectively.

from the metal-poor damped Lyman α (DLA) system at z = 3.05. And Cooke et al. reported⁴⁷

$$D/H = (2.53 \pm 0.04) \times 10^{-5}.$$
 (12)

from the very metal-poor DLA toward SDSS J1358+6522.

The primeval abundance of ⁷Li can be estimated from observations of Population II stars in our galaxy. In the old galaxy, the relation between [Li/H] and [Fe/H] becomes constant at a low metallicity star (it is called "Spite-Plateau"). The observed abundance of ⁷Li in Population II stars is given by Sbordone et al. :⁴⁹

⁷Li/H =
$$(1.58 \pm 0.31) \times 10^{-10}$$
. (13)

To find reasonable values of η_{10} which satisfy the consistency between BBN and observed values, we calculate χ^2 as follows:

$$\chi_i^2(\eta) = \frac{\left(Y_i^{th}(\eta) - Y_i^{obs}\right)^2}{\sigma_{th,i}^2 + \sigma_{obs,i}^2},$$
(14)

where Y_i and σ_i are the abundances and their uncertainties for elements i ($i = Y_p, D, {}^7\text{Li}$), respectively. The value $\sigma_{th,i}$ is obtained from the Monte-Carlo calculations using 1σ errors associated with nuclear reaction rates. The observational values, Y_i^{obs} and their errors $\sigma_{obs,i}$, are taken from (8), (10), (12), and (13).

Finally, we obtain the range of η_{10} with 1σ C.L. from individual observations:

$3.28 \le \eta_{10} \le 7.27$	from Aver et al. ⁴⁶ ,
$10.1 \le \eta_{10} \le 18.2$	from Izotov et al. 45 ,
$6.08 \le \eta_{10} \le 6.38$	from Cooke et al. ⁴⁷ ,
$3.28 < \eta_{10} < 4.40$	from Sbordone et al. ⁴⁹

As against the excellent agreement for D and ⁴He, the discrepancy for ⁷Li is unallowable. This is called "⁷Li problem". Since the baryon density is determined precisely from CMB observation by WMAP and/or Planck, this problem is conspicuous more than ever.

To solve this problem, many possibilities have been considered, such as unstable massive particles,^{74, 75} nuclear reaction rates coupled with other reaction paths,^{70, 71} and a scalar-tensor theory of gravity.^{72, 73} It is noted that the observations of ⁷Li involve uncertain atmospheric models concerning the low metallicity stars⁴¹.

4. Neutrino degeneracy

Within the framework of general relativity, BBN can be, for example, extended to include neutrino degeneracy (e.g. Ref.⁴²). Degeneracy of electron-neutrinos is described in terms of a parameter

$$\xi_{\rm e} = \mu_{\nu,e} / k_{\rm B} T_{\nu},\tag{15}$$

where $\mu_{\nu,e}$ is the chemical potential of electron neutrinos and T_{ν} is the temperature of neutrinos. To get abundance variations of both neutrons and protons caused by nonzero $\xi_{\rm e}$ values, we take a usual method to incorporate the degeneracy into the Fermi-Dirac distribution of neutrinos.⁴² In this study, we do not consider the degeneracy of τ - and μ -neutrinos.

In BBN calculations, we implemented the neutrino degeneracy as follows. Before the temperature drops to the difference $\Delta m/k_{\rm B}$ in the rest mass energies between a neutron and a proton, they are in thermal equilibrium through the weak interaction processes (5). Below $k_{\rm B}T = 4$ MeV, we solve the rate equations for n and p until $k_{\rm B}T$ drops to 1 MeV including the individual weak interaction rates. After that, we begin to operate the nuclear reaction network with the weak interaction rates between n and p included. We should note that in the present parameter range shown below, effects of neutrino degeneracy on the expansion and/or cooling of the universe can be almost neglected, because the absolute values of neutrino degeneracy are rather small, and affect the energy density by at most 10^{-3} %. (see Fig.7).

The produced amounts of D and ⁷Li are almost the same as those in the SBBN model, respectively, while ⁴He becomes less abundant if $\xi_{\rm e} > 0$, since β -equilibrium leads to lower neutron production. This is because the abundance ratio of neutrons to protons (n/p) is proportional to $\exp[-\xi_{\rm e}]$. This can be seen in Fig.6; while the abundance of ⁴He is very sensitive to $\xi_{\rm e}$, it is insensitive to η . On the other hand,

Fig. 6. Effects of neutrino degeneracy on the production of ⁴He and D/H. The degeneracy parameters is taken to be $\xi_e = -0.1, 0$, and 0.1 from the top to bottom curve. The vertical band comes from the baryon density determined by *Planck*. The horizontal bands correspond to the observational abundances of ⁴He and D/H with 2σ uncertainty.⁵⁵

although the abundance of D is almost uniquely determined from η , i.e., the nucleon density, it depends weakly on ξ_e .

To find reasonable values of ξ_e and η_{10} which satisfy the consistency between BBN and observed ⁴He and D, we calculate χ^2 as follows:

$$\chi^{2}(\eta,\xi_{e}) = \sum_{i} \frac{\left(Y_{i}^{th}(\eta,\xi_{e}) - Y_{i}^{obs}\right)^{2}}{\sigma_{th,i}^{2} + \sigma_{obs,i}^{2}},$$
(16)

where Y_i and σ_i are the abundances and their uncertainties for elements i ($i = Y_p$, D), respectively. The value $\sigma_{th,i}$ is obtained from the Monte-Carlo calculations using 1σ errors associated with nuclear reaction rates. The observational values, Y_i^{obs} and their errors $\sigma_{obs,i}$, are taken from (9) and (11).

Figure 7 shows the contours enclosing 1σ , 2σ , and 3σ C.L. in the $\eta_{10} - \xi_e$ plane obtained from (16). In consequence, we get the following constraints for both η_{10}

Fig. 7. Contours having 1σ , 2σ , and 3σ confidence levels from Y_p and D/H observations in the $\eta_{10} - \xi_e$ plane. The horizontal line corresponds to SBBN ($\xi_e = 0$). The vertical band shows the baryon density from *Planck*.⁵⁵

and ξ_e :⁵⁵

$$6.17 < \eta_{10} < 6.38 \qquad -3.4 \times 10^{-2} < \xi_{\rm e} < -1.8 \times 10^{-2} \qquad (1\sigma \text{ C.L.}), \tag{17}$$

$$6.02 < \eta_{10} < 6.54 - 4.6 \times 10^{-2} < \xi_{\rm e} < -0.4 \times 10^{-2} \quad (2\sigma \text{ C.L.}).$$
 (18)

It is noted that, except for neutron decay, two-body reactions are dominant during BBN. Only two reaction of the β -decay of ³H with $\tau_{1/2} = 12.32$ y and e-capture of ⁷Be with $\tau_{1/2} = 53.24$ d⁷⁸ are important weak reactions of light nuclides. These half lives are modified by a small factor through neutrino degeneracy. However, the final abundance is not affected at all.

5. Inhomogeneous Big-Bang nucleosynthesis

5.1. Recent study of inhomogeneous BBN

The study of SBBN has been done under the assumption of the homogeneous universe. On the other hand, BBN with the inhomogeneous baryon distribution also has been investigated. The model is called an inhomogeneous BBN (IBBN). IBBN

Fig. 8. Abundance distribution at $T = 3 \times 10^9$ K with $\eta = 10^{-4}$. From Matsuura et al.²⁴

results from the inhomogeneity of baryon concentrations that could be induced by $baryogenesis^{12}$ or phase transitions such as QCD or electro-weak phase transition^{7-11, 14, 15} during the expansion of the universe.

A new astrophysical site of BBN is presented²⁴ that contains very high η . Figures 8 and 9 show nuclear abundance distributions in a high density region with $\eta = 10^{-4}$ on the nuclear chart covering heavy elements. As shown in Fig. 8, stable nuclei are first synthesized. When the temperature goes down, proton- and neutron-capture reactions are active for the nuclei with A < 100 and with A > 120, respectively (Fig. 9). Namely, it suggests that both the *r*-process and the *p*-process can occur at the BBN era. On the other hand, for $\eta = 10^{-3}$, a proton capture is only active.²⁴ The problem to be solved is the origin and evolution of the high density region. The size of the high density island is estimated²⁴ to be $10^5 - 10^{17}$ cm at the BBN epoch. The upper bound is obtained from the maximum angular resolution of CMB and the lower bound is from the analysis⁹ of comoving diffusion length of neutrons and protons.

Some models of baryogenesis suggest that very high baryon density regions in the early universe. Recent observations, however, suggest that heavy elements could already exist in high red-shift epochs and therefore the origin of these elements becomes a serious problem. Motivated by these facts, we investigate BBN in very high baryon density regions. The BBN proceeds in proton rich environment, in which a rapid *p*-process is operative.

However, by taking heavy nuclei into account, we find that BBN proceeds through both p- and r-processes simultaneously. Furthermore, p-nuclei such as 92 Mo, 94 Mo, 96 Ru and 98 Ru, whose origin is not well known, are also synthesized. The above issues should be refined and checked by investigating the possible model consistent with available observations.

Fig. 9. Abundance distribution at $T = 10^9$ K with $\eta = 10^{-4}$.²⁴

5.2. Two-zone model of IBBN

Quite interesting features²⁴ have been presented for the possibility of IBBN, but relevant parameters concerning the high and low density regions have not yet been specified. Therefore, we explore the reasonable parameters using a simple two-zone model.¹⁰ The early universe is assumed to contain high and low baryon density regions. For simplicity we ignore the diffusion effects.

We assume that all the produced elements are mixed homogeneously at some epoch between the end of BBN and the recombination era. To construct a two-zone model, we need to define n_{ave}, n_{high} and n_{low} as the average-, high-, and lownumber densities of baryons, f_v as the volume fraction of the high baryon density region, and X_i^{ave}, X_i^{high} and X_i^{low} as the mass fractions of element *i* in the average-, high- and low-density regions, respectively. Then the basic relations between these variables are written as

$$n_{ave} = f_v n_{high} + (1 - f_v) n_{low}, (19)$$

$$n_{ave}X_i^{ave} = f_v n_{high}X_i^{high} + (1 - f_v) n_{low}X_i^{low}.$$
(20)

If the baryon fluctuation is assumed to be isothermal,^{8, 13, 14} the following equations are derived by dividing Eqs. (19) and (20) by the the number density of photons n_{γ} :

$$\eta_{ave} = f_v \eta_{high} + (1 - f_v) \eta_{low}, \tag{21}$$

$$\eta_{ave} X_i^{ave} = f_v X_i^{high} \eta_{high} + (1 - f_v) X_i^{low} \eta_{low}.$$
 (22)

Here three kinds of η 's are

$$\eta_{ave} = \frac{n_{ave}}{n_{\gamma}}, \qquad \eta_{high} = \frac{n_{high}}{n_{\gamma}}, \qquad \eta_{low} = \frac{n_{low}}{n_{\gamma}},$$

Fig. 10. Evolution of light elements in IBBN with $f_v = 10^{-6}$ and $R = 10^6$. The left panel corresponds to the high density region $\eta_{high} = 3.05 \times 10^{-4}$. The right panel corresponds to the low density region $\eta_{low} = 3.05 \times 10^{-10}$.

where η_{ave} is set to be the observed value by CMB^{17, 18, 50} : $\eta = 6.1 \times 10^{-10}$. Both η_{high} and η_{low} are determined from f_v and the density ratio $R = n_{high}/n_{low} = \eta_{high}/\eta_{low}$.

We note that ρ_b is the average baryon density obtained from Eq. (19), and temperature T is set to be homogeneous. This assumption is critically important to build our model; otherwise we must treat the zones to evolve separately, which involves fundamental problem as opposed to the cosmological principle.

5.3. Constraints from light element abundances

We show in Fig. 10 an example of light element synthesis in the high and low density regions with $f_v = 10^{-6}$ and $R = 10^6$ that correspond to $\eta_{high} = 3.05 \times 10^{-4}$ and $\eta_{low} = 3.05 \times 10^{-10}$. In the right panel for η_{low} the evolution of the elements is almost the same as that of SBBN. In the left panel for η_{high} , D and ⁴He are synthesized at higher temperatures. This is because the reaction $p + n \longrightarrow D + \gamma$ starts at earlier epoch. In addition, the amount of ⁴He is larger than that in the low density region, because neutrons still remain when the nucleosynthesis starts. On the other hand, ⁷Li (or ⁷Be) is much less produced. It implies that heavier nuclei, such as ¹²C and ¹⁶O, are synthesized in the high density region. Using these calculated abundances in both regions, we obtain the average values of the light elements from Eq. (22). Then we can put constraints on f_v and R by comparing the values of Y_p and D/H with the observed abundances.

In Fig. 11, the constraints are shown in the $f_v - R$ plane. Contours of calculated

Fig. 11. Constraints on the $f_v - R$ plane from the observations of ⁴He and D/H. The region below the red line is acceptable region obtained from ⁴He observation by Izotov & Thuan⁴⁰ and Aver et al.⁵⁸ Constraints from the D/H observations^{48,56} are shown by the region below the blue lines. The gray region corresponds to the allowable parameters obtained from the two observations of ⁴He and D/H. In the narrow region bounded by two upper blue lines, only the D/H abundance is consistent with observations. This is the contribution of the low density region with $\eta_{low} \sim 10^{-12}$; The D abundance tends to decrease with increasing baryon density for $\eta > 10^{-12}$. The dotted lines show the contours of the baryon-to-photon ratio in the high-density region. Filled squares indicate the adopted parameters in §5.4.⁵⁷

abundances (solid lines) and the η_{high} (dashed lines) are drawn. In our analysis, we obtain only the upper limit to the parameter R. Note that the allowed region includes density values as high as $\eta_{high} = 10^{-3}$.

Since η_{high} takes a larger value, nuclei heavier than ⁷Li are synthesized more and more. Then we estimate the abundance of CNO elements in the allowed region. Figure 12 shows the contours of the summation of X_i^{ave} over heavier nuclei (A > 7). As far as our small BBN code is concerned,¹⁹ the total mass fraction of CNO nuclei amounts to $X(A > 7) \simeq 10^{-5}$.

5.4. Synthesis of heavy elements in high density region

We investigate synthesis of heavy elements in the high-density region considering the constraints shown in Fig. 11. The abundance change is calculated with a large nuclear reaction network, which contains 4463 nuclei from neutron, proton to Americium (Z = 95 and A = 292). The nuclear data such as reaction rates, nuclear masses and partition functions are the same as used in Ref. 35 except for the weak interaction rates³⁶ which is adequate for the high temperature stage $T > 10^{10}$ K. Note that the mass fractions of ⁴He and D obtained with the large network are consistent with those calculated with a small network in §5.3 within an accuracy of

Big-Bang nucleosynthyesis 17

Fig. 12. Contours of the total mass fractions of heavier nuclei (A > 7). The shaded allowed region is the same as in Fig. 9.⁵⁷

a few percents.

As seen in Fig. 12, heavy elements are produced at the level $X(A > 7) \ge 10^{-9}$ in the upper region of R in the allowed region. To examine the efficiency of the heavy element production, we select five models with parameters $\eta_{high} = 10^{-3}, 5.1 \times 10^{-4}, 10^{-4}, 5.0 \times 10^{-5}$, and 10^{-5} which correspond to $(f_v, R) = (3.24 \times 10^{-8}, 1.74 \times 10^6)$, $(1.03 \times 10^{-8}, 9.00 \times 10^5)$, $(5.41 \times 10^{-7}, 1.84 \times 10^5)$, $(1.50 \times 10^{-6}, 9.20 \times 10^4)$, and $(5.87 \times 10^{-6}, 1.82 \times 10^4)$, respectively. Adopted parameters are indicated by the filled squares in Fig. 11.

Tables 5.4 and 5.4 give the abundance of light elements in the high and low density regions. The mass fractions in the low density region are the same as those obtained in § 5.3, because the abundance flows beyond A = 7 are negligible. We should note that the averages of abundances $Y_{\rm p}$ and D/H in the two regions coincide with the observed abundances, respectively.

Figure 13(a) shows the result of nucleosynthesis in the high density region of $\eta_{high} = 1.04 \times 10^{-4}$. The nucleosynthesis paths proceed along the stability line during a few seconds, and afterwards they are classified with the mass number. For nuclei with $A \leq 100$, proton captures become very active compared to neutron capture at $T > 2 \times 10^9$ K and the path shifts to the proton rich side, which begins from breaking out the hot CNO cycle. For nuclei of 100 < A < 120, the path goes across the stable nuclei from proton- to neutron-rich side, since temperature decreases and the number of seed nuclei of neutron capture increases significantly. Neutron capture is not similar to the canonical r-process, since the nuclear reactions

Fig. 13. Time evolution of the mass fractions in high-density regions of (a) $\eta_{high} = 1.02 \times 10^{-4}$ and (b) $\eta_{high} = 1.06 \times 10^{-3}$, respectively.

proceed under the condition of the high-abundance of protons. For example, ¹⁵⁹Tb, ¹⁵⁹Gd and ¹⁵⁹Eu are synthesized through neutron captures. After $t = 10^3$ sec, we can see β -decays ¹⁵⁹Eu \rightarrow ¹⁵⁹Gd \rightarrow ¹⁵⁹Tb, where the half life of ¹⁵⁹Eu and ¹⁵⁹Gd are 18.1 min and 18.479 h,⁷⁸ respectively.

The results of $\eta_{high} = 1.06 \times 10^{-3}$ is shown in Fig.13 (b). The reactions also first proceed along the stability line in the high density region. Subsequently, the

Fig. 14. Comparison of the averaged mass fractions in the two-zone model with the solar system $abundances^{38}$ (indicated by large dots).⁶²

reactions directly proceed to the proton-rich side through rapid proton captures. We can see β -decays $^{108}\text{Sn} \rightarrow ^{108}\text{In} \rightarrow ^{108}\text{Cd}$, where the half life of ^{108}Sn and ^{108}In are 10.3 min and 58.0 min, ⁷⁸ respectively. In addition, radioactive nuclei ^{56}Ni ($\tau_{1/2} = 6.075 \text{ d}^{78}$) and ^{57}Co ($\tau_{1/2} = 271.75 \text{ d}^{78}$) are produced just after the formation of ⁴He in the extremely high density region with $\eta_{high} \geq 10^{-3}$ like the beginning of supernova explosions.³⁷

Figure 14 shows the comparison between the average mass fraction produced in IBBN calculation and the solar system abundances by Anders & Grevesse.³⁸ There are over-produced elements around A = 150 ($\eta_{high} = 10^{-4}$) and A = 80($\eta_{high} = 10^{-3}$). Although it seems to conflict with the chemical evolution in the universe, this problem could be solved by the careful choice of f_v and/or $R.^{57}$

In IBBN model, the lithium-7 can be synthesized in both regions depending on f_v and R as shown in Tables 5.4 and 5.4. For $\eta_{high} = 1.0 \times 10^{-5}$, the averaged value of ⁷Li/H is 1.5×10^{-9} , which is higher than the predicted value in SBBN with $\eta_{10} = 6.1$. On the other hand, in cases of $\eta_{high} = 5.1 \times 10^{-4}$ and 1.0×10^{-4} , the average of ⁷Li/H is lower than the SBBN value. Although these ⁷Li/H values is still higher than the results of recent observation (13), there remains possibility to solve the "Lithium problem" by extending our IBBN model to another kind of model such a multi-zone model.

6. Brans-Dicke cosmology with a variable cosmological term

6.1. Field equation

The action in the Brans Dicke theory modified with a variable cosmological term Λ (BD Λ) which is a function of a scaler field ϕ , is given by Endo & Fukui⁵⁹ as

$$S = \int d^4x \sqrt{-g} \left[(R - 2\Lambda) \phi - \frac{\omega}{\phi} \phi_{,\nu} \phi^{,\nu} + 16\pi L_m \right], \qquad (23)$$

where R, L_m and ω are the scalar curvature, the Lagrangian density of matter , and the dimensionless constant of Brans-Dicke gravity, respectively. The field equations for $BD\Lambda$ are written as follows:⁶⁰

$$R_{\mu\nu} - \frac{1}{2}g_{\mu\nu}R + g_{\mu\nu}\Lambda = \frac{8\pi}{\phi}T_{\mu\nu} + \frac{\omega}{\phi^2}\left(\phi_{,\mu}\phi_{,\nu} - \frac{1}{2}g_{\mu\nu}\phi_{,\alpha}\phi^{,\alpha}\right) + \frac{1}{\phi}\left(\phi_{,\mu;\nu} - g_{\mu\nu}\Box\phi\right),$$
(24)

$$R - 2\Lambda - 2\phi \frac{\partial \Lambda}{\partial \phi} = \frac{\omega}{\phi^2} \phi_{,\nu} \phi^{,\nu} - \frac{2\omega}{\phi} \Box \phi, \qquad (25)$$

where \Box is the d'Alembertian.

The expansion is described by the following equation derived from the (0,0) component of Eq. (24):

$$\left(\frac{\dot{a}}{a}\right)^2 = \frac{8\pi\rho}{3\phi} - \frac{k}{a^2} + \frac{\Lambda}{3} + \frac{\omega}{6} \left(\frac{\dot{\phi}}{\phi}\right)^2 - \frac{\dot{a}}{a}\frac{\dot{\phi}}{\phi}.$$
(26)

We adopt the simplest case of the coupling between the scalar and matter field

$$\Box \phi = \frac{8\pi\mu}{2\omega+3} T^{\nu}_{\nu},\tag{27}$$

where μ is a constant. Original Brans-Dicke theory is deduced for $\mu = 1$.

Assuming a perfect fluid for $T_{\mu\nu}$, Eq. (27) reduces to the following:

$$\frac{d}{dt}\left(\dot{\phi}a^3\right) = \frac{8\pi\mu}{2\omega+3}\left(\rho-3p\right)a^3.$$
(28)

Then, Eq. (28) is integrated to give

$$\dot{\phi} = \frac{1}{a^3} \left[\frac{8\pi\mu}{2\omega + 3} \rho_{m_0} t + B \right],$$
(29)

where B is an integral constant and from now on we use the normalized value of B: $B^* = B/(10^{-24} \text{g s cm}^{-3}).$

A particular solution of Eq. (25) is obtained from Eqs. (24) and (27):

$$\Lambda = \frac{2\pi \left(\mu - 1\right)}{\phi} \rho_{m_0} a^{-3}, \tag{30}$$

where ρ_{m_0} is the matter density at the present epoch.

Fig. 15. Time evolution of G in BDA with $\mu = 0.6$. G_0 is the present value: $G_0 = 6.6726 \times 10^{-8} \text{ cm}^3 \text{g}^{-1} \text{s}^{-2}$

The gravitational "constant" G is expressed as follows,

$$G = \frac{1}{2} \left(3 - \frac{2\omega + 1}{2\omega + 3} \mu \right) \frac{1}{\phi}.$$
(31)

The difference of G between the BDA and the Friedmann model appear at 0.01 sec < t < 1000 sec as shown in Fig. 15. It suggests that the expansion rate in the BBN epoch is markedly different.

It is reduced to the Friedmann model when $\phi = \text{constant}$ and $\omega \gg 1$. Physical parameters have been used to solve Eqs. (26), (29), and (30): $G_0 = 6.6726 \times 10^{-8} \text{cm}^3 \text{g}^{-1} \text{s}^{-2}$, and $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$.

The parameter ω is an intrinsic parameter in the Brans-Dicke gravitational model, and it determines the expansion rate of the early universe. In our study, we set $\omega = 10000$. Although the variations are limited to the earlier ara, still larger value of ω can be permitted for our BDA model (see Fig. 15). Recent observations by the Cassini measurements of the Shapiro time delay suggested that the lower limit of ω is very large: $\omega \geq 4 \times 10^4$ (Berti et al.,⁶³ Bertotti et al.⁶⁴).

Figure 16 shows the evolution of the scale factor in $BD\Lambda$ for the several values of B^* . We identify considerable deviations in $BD\Lambda$ from the Friedmann model at t < 100 s, which depends on the specific parameters. We note that the evolution of the scale factor depends on both the initial value of ϕ and a parameter μ . This is the reason why the scale factor evolves rather differently compared to the Friedmann model.

Fig. 16. Time evolutions of the scale factor in $BD\Lambda$ with $\mu = 0.6$ which are compared to the Friedmann model.

6.2. Parameter constraints from Big Bang nucleosynthesis

Big-Bang nucleosynthesis provides powerful constraints on possible deviation from the standard cosmology.⁶⁵ Changes in the expansion as shown in Fig. 16 affects the abundances of light elements, because the n/p ratio is sensitive to the expansion rate in the BBN epoch.

Figure 17 shows the calculated abundances of ⁴He, D, and ⁷Li for $B^* = 2$ and $\mu = 0.6$. The $\pm 2\sigma$ uncertainties in nuclear reaction rates are indicated by the dashed lines. The horizontal dotted lines indicate the observational values of ⁴He, D/H, and ⁷Li/H as follows: $Y_{\rm p} = 0.2516 \pm 0.0080$, ⁶⁶ $Y_{\rm p} = 0.326 \pm 0.075$, ¹⁸ D/H = $(2.82 \pm 0.21) \times 10^{-5}$ (Pettini et al.⁵⁶), ⁷Li/H = $(2.34 \pm 0.32) \times 10^{-10}$ (Melendez & Ramirez.⁶⁷). Here two observational values of ⁴He are used. The solid vertical lines indicates the WMAP constraint of the baryon-to-photon ratio, $\eta = (6.19 \pm 0.15) \times 10^{-10}$ (Komatsu et al.¹⁸).

The intersection range of the two observational values of ⁴He is used to constrain the parameters. It is found that the values of η derived from ⁴He and D/H are tightly consistent with the value by WMAP, while that from ⁷Li/H is barely consistent. We have a very small parameter region for ⁷Li/H where the bands of the theoretical abundance, the observational abundance, and the WMAP eta overlap. These agreements lead us to the parameter ranges of $0.0 \leq \mu \leq 0.6$ and $-2 \leq B^* \leq 2$.

Fig. 17. Light element abundances of ⁴He, D, and ⁷Li vs. η for $B^* = 2$, $\mu = 0.6$, and $\omega = 10^4$. Dashed lines indicate the $\pm 2\sigma$ uncertainties in nuclear reaction rates in each abundance. The horizontal dotted lines indicate the regions of observational abundances. The solid vertical lines indicate the baryon-to photon ratio η .

7. Summary and discussions

We have reviewed the SBBN, BBN with the neutrino degeneracy, IBBN, and BBN in the Brans-Dicke cosmology. First, we have compared the results of SBBN with the current observations of light elements. Considering the uncertainties in the nuclear reaction rates and the observed errors, we can summarize as follows:

- (1) The consistency is confirmed as far as 4 He and D are concerned.
- (2) Large uncertainties of He observations still allow the possibility that some unknown processes beyond SBBN affected the primordial abundance. For example, a large value of $Y_{\rm p} \simeq 0.3$ has been reported in low metallicity stars in globular clusters.⁴⁰ This large amount of He could be ascribed to the local neutrino degeneracy.
- (3) The significant discrepancy concerning ⁷Li remains to be solved.

Second, consistency between IBBN and the observations of ⁴He and D/H abundances has been investigated under the thermal evolution of the standard model with η_{WMAP} . We have examined the two-zone model, where the universe has the high and low baryon density regions separately at the BBN epoch. We have calculated nucleosynthesis that covers 4463 nuclei in the high density region. Below we summarize our results and give some prospects.

- (1) There are significant differences of the evolution of the light elements between the high and low density regions; In the high density region, nucleosynthesis begins at higher temperature. ⁴He is more abundant than that in the low density region.
- (2) Both *p* and *r*-elements are synthesized simultaneously in the high density region with $\eta_{high} \simeq 10^{-4}$. Total mass fractions of nuclides heavier than ⁷Li amount to 10^{-7} for $\eta_{high} = 10^{-4}$ and 10^{-5} for $\eta_{high} = 10^{-3}$. The average mass fractions in IBBN are comparable to the solar system abundances.
- (3) Heavy elements beyond Fe surely affects the formation process of the first generation stars due to the change in the opacity. Therefore, it may be also necessary for IBBN to be constrained from the star formation scenarios.
- (4) The observed abundances of ⁷Li⁴⁹ cannot be explained in terms of SBBN. Although our IBBN model is also inconsistent with ⁷Li observations, the theoretical value of ⁷Li is lower than that of SBBN. Modifications of IBBN model may conduce to the answer.

Third, we show a possible alternate theory of gravity, Brans-Dicke theory with a variable Λ term. Even for a very large coupling constant ω , this theory can explain the observed primordial abundances of the light elements. Therefore, it is still worthwhile to continue to explore some non-standard cosmology.
