ABSTRACT

We present the results of photometric observations of three TeV blazars, 3C 66A, S5 0954+658 and BL Lacertae, during the period 2013–2017. Our extensive observations were performed in a total of 360 nights which produced \sim 6820 image frames in BVRI bands. We study flux and spectral variability of these blazars on these lengthy timescales. We also examine the optical Spectral Energy Distributions of these blazars, which are crucial in understanding the emission mechanism of long-term variability in blazars. All three TeV blazars exhibited strong flux variability during our observations. The colour variations are mildly chromatic on long timescales for two of them. The nature of the long-term variability of 3C 66A and S5 0954+658 is consistent with a model of a non-thermal variable component that has a continuous injection of relativistic electrons with power law distributions around 4.3 and 4.6, respectively. However, the long-term flux and colour variability of BL Lac suggests that these can arise from modest changes in velocities or viewing angle toward the emission region, leading to variations in the Doppler boosting of the radiation by a factor \sim 1.2 over the period of these observations.

Key words: galaxies: active – BL Lacertae objects: general – quasars: individual (3C 66A, S5 9854+658, BL Lac) – galaxies: photometry

1 INTRODUCTION

Blazars are well known for their rapid flux variability across the whole electromagnetic spectrum, strong optical and radio polarization and non-thermal anisotropic emission (Ulrich, Maraschi & Urry 1997). The dominant radiation properties of blazars are interpreted by the relativistically beaming effects which are believed to originate from strongly Doppler boosted relativistic jets that are being viewed at angle $\leqslant 10^\circ$ with respect to the line of sight (Urry & Padovani 1995). Flat spectrum radio quasars along with the BL Lacertae objects are now normally said to constitute the blazar class of active galactic nuclei (AGN). The Doppler beaming effects of blazar jets viewed at small angles can strongly

amplify the perceived luminosity and simultaneously shorten their apparent time-scales; this property makes blazars ideal targets to use flux variability studies to probe their central engines.

The broad band spectral energy distribution (SEDs) of blazars are characterized by double peaked structures. The low energy peak is dominated by the synchrotron radiation from relativistic electrons. In the leptonic scenarios, the high energy peak can be due to the inverse Compton scattering of lower energy synchrotron photons from the same electron population in synchrotron-self-Compton (SSC scenario; e.g. Kirk, Rieger & Mastichiadis 1998) or of external photons from broad line region, accretion disc or dusty torus in an external Compton (EC) scenario (e.g., Sikora, Begelman & Rees 1994). In the hadronic scenarios, it could be due to synchrotron emission from protons or, more likely from secondary decay products of charged pions (e.g. Atoyan & Dermer 2003; Böttcher et al. 2013). Based on the location of the synchrotron peak, blazars are classified into low, intermediate and high energy peaked blazars (LBL, IBL and HBL, respectively; Padovani & Giommi 1995). Abdo et al. (2010) classified blazars based on the location of the synchrotron peak frequency, ν_s . If $\nu_s \leq 10^{14}$ Hz (in the infrared), it is classified as a low spectral peak (LSP) source; if it is in the optical–ultraviolet range ($10^{14} \le \nu_s \le 10^{15}$ Hz), it is classified as an intermediate spectral peak (ISP) source, and if it lies in the X-ray regime ($\nu_s \ge 10^{15}$ Hz), it is classified as a high spectral peak (HSP) source.

Blazars are variable on diverse time-scales ranging from minutes through months to even decades. Their variability timescales can be broadly divided into three classes. Intraday variability (IDV) timescales range from a few minutes to several hours and flux changes by a few tenths of magnitude (e.g. Wagner & Witzel 1995). Short term variability (STV) and Long Term variability (LTV) have timescales ranging from several days to months and months to decades, respectively (Fan et al. 2009; Gaur et al. 2015a, b; Gupta et al. 2016).

IDV in blazars almost certainly arises due to purely intrinsic phenomenon such as the interaction of shocks with small scale particle or magnetic field irregularities present in the jet (e.g. Marscher 2014; Calafut & Wiita 2015) or the production of ultrarelativistic mini-jets within the jet (e.g. Giannios et al. 2009). When the viewing angle to a moving, discrete emitting region changes, it causes variable Doppler boosting of the emitting radiation (e.g. Larionov et al. 2010; Raiteri et al. 2013). LTV is usually attributed to a mixture of intrinsic and extrinsic mechanisms. Here we consider intrinsic mechanisms to involve shocks propagating down twisted jets or plasma blobs moving through some helical structure in the magnetized jets (e.g. Marscher et al. 2008). Extrinsic mechanisms would involve the geometrical effects that result in an overall bending of the jets, either through instabilities (e.g. Pollack et al. 2016), or through orbital motion (e.g., Valtonen & Wiik 2012).

Photometry is a powerful tool to study the structure and radiation mechanism of blazars by measuring their variability timescales, amplitude and duty cycle. In this work, we performed extensive optical observations of three TeV blazars, 3C 66A, S5 0954+658 and BL Lac to study their flux and colour variability on long-term time scales. We also studied the Spectral Energy Distributions (SEDs) of these

blazars across optical bands. Our photometric observations were made at several telescopes during the period 2013–2017. A total of 360 nights of observations are reported here allowing us to search for and characterize their variability on rather long timescales. This study is a follow up of our earlier extensive optical monitoring of TeV blazars covering the period 2010–2012 (Gaur et al. 2015a,b; Gupta et al. 2016). Two of these sources, S5 0954 +658 and BL Lac were also observed for IDV on many nights and those data have been studied in Bachev (2015) and Gaur et al. (2017), respectively. In Section 2 we briefly describe our observations and data reductions. We present our results in Section 3. Sections 4 gives a discussion and conclusions.

2 OBSERVATIONS AND DATA REDUCTION

Our observations of three TeV blazars, 3C 66A, S5 0954+658 and BL Lacertae began in January 2013 and concluded in June 2017. The logs of observations for these blazars are provided individually in Table 1. Complete observation log of these three sources are provided in Supplementary Material. Our observations were made using seven telescopes in Bulgaria, Georgia, Greece, Serbia and Spain. For 3C 66A, we also used archival data of the Steward Observatory (Smith 2009) in V band for a total of 165 nights. Details about the telescopes in Bulgaria, Greece and Georgia are given in Gaur et al. (2012, 2015a); details about Serbian Telescope are described in Gupta et al. (2016, Table 1) and details about the telescope in Spain are provided in Gupta et al. (2016). The standard data reduction methods we employed on all observations are described in detail in Section 3 of Gaur et al. (2012). Typical seeing varied between 1-3 arcsec during these measurements.

To summarize, standard data reduction was performed using \mathtt{IRAF}^1 , including bias subtraction and flat-field division. Instrumental magnitudes of the source as well as comparison stars in its field (Villata et al. 1998) were produced using the \mathtt{IRAF} package $\mathtt{DAOPHOT}^2$; normally an aperture radius of 6 was used along with a sky annulus of 7.5–10 arcsec.

Data from the different telescopes are collected as instrumental magnitudes of the blazar and reference stars so that we can apply the same analysis and calibration procedures to all the datasets. Instrumental magnitudes are obtained by the above mentioned standard aperture photometry procedures by the observers. Data from one observatory (35.6 cm Telescope, Spain) was provided in calibrated magnitudes. During the compilations of light curves, we discarded a small number of clearly bad and unreliable points.

 $^{^{\}rm 1}$ IRAF is distributed by the National Optical Astronomy Observatories, which are operated by the Association of Universities for Research in Astronomy, Inc., under cooperative agreement with the National Science Foundation.

3 RESULTS

3.1 3C 66A

3C 66A is one of the most luminous blazars at TeV γ -rays (Very High Energy (VHE) , E > 100 GeV). It was detected at VHE γ -rays by VERITAS (Acciari et al. 2009). It is classified as a BL Lac object (Maccagni et al. 1987). Recently, it has been proposed that this blazar is hosted in a galaxy belonging to a cluster at z=0.340 (Torres-Zafra et al. 2016). The synchrotron peak of 3C 66A is located between 10^{15} and 10^{16} Hz and hence it is best classified as an intermediate frequency peaked BL Lac object (Perri et al. 2003; Fan et al. 2016).

3C 66A was the target of the multi-wavelength campaign carried out by the Whole Earth Blazar Telescope (WEBT) during its optically bright state in 2003-2004, involving observations at radio, infrared, optical, X-ray and γ -ray bands (Böttcher et al. 2005). At optical frequencies, it showed several flaring events on time-scales of days and flux changes of $\sim 5\%$ on timescales of hours. Again, WEBT organized a multi-wavelength campaign in 2007-2008 in the high optical state of the source and it exhibited several bright flares on time-scales of days and even on hours (Böttcher et al. 2007). This campaign caught an exceptional outburst around September 2007 reaching peak brightness at R \sim 13.4, with a lack of spectral variability in this high state. Abdo et al. (2011) also used multi-wavelength observations of this source to study its behaviour in flaring and quiescent states. Recently, Kaur et al. (2017) studied the optical IDV of 3C 66A over more than 10 years (from 2005-2016) and found significant variations in the optical flux on long-term time-scales with a large number of flares superimposed on the slowly varying pattern.

Table 2. Spectral indices of 3C 66A and S5 0954+658 for various flux states.

Source	Flux (mJy)	Spectral Index
3C 66A	7.75 4.76 3.68	1.64 1.66 1.68
S5 0954+658	18.01 4.31 0.34	1.84 1.90 2.72

3.1.1 Long term flux and colour variability

The LTV light curve (LC) of 3C 66A is shown in Fig. 1 for a total of 295 nights over nearly four years from January 2013-January 2017. The B, V, R and I LCs are shown from top to bottom panels. We observed this source on 130 nights for a total of 697 photometric frames with maximum sampling in V and R bands. We averaged the magnitudes on the daily basis to understand the long-term behaviour of the source. We also used the archival data of the Steward Observatory (Smith 2009) available online in V band for 165 nights. In order to visualize the nature of variability more clearly, we plot the R band LC in the upper panel of Fig. 2. It can be seen that the R band LC shows many small sub-flares superimposed on the long-term trends. First, there is a decaying trend in the LC from JD 6400-6830 where the magnitude drops by 0.62. There is one major outburst during JD 6830-7370, peaking at around JD=7200 with R=14.07. The source magnitude changes by 0.64 from $m_R=14.7$ to 14.1 and back again during this outburst over about 370 days. After that, there is again an overall rising trend during JD 7370-7800 by $\Delta m = 0.53$.

To set some context, 3C 66A exhibited an exceptional outburst around September 2007, reaching peak brightness at ~ 13.4 (Böttcher et al. 2009). Also, Kaur et al. (2017) presented a decade long LC of 3C 66A and found this source reaching a peak brightness of 13.40 in R band on 1st November 2010 with a minimum magnitude of only 15.1 in August 2011. During our observing campaign, the average R band magnitude is 14.4 with a maximum of 14.07 magnitude on JD=7200 and a minimum of 14.72 magnitude on JD=7340. Hence, we can say that the source is mostly in a relatively high state during our observing campaign. LCs in other bands also shows similar behaviour. The mean magnitudes in the B, V and I bands are 15.43, 14.80 and 13.83, respectively. The maximum and minimum brightness magnitudes are: in B band, max=15.07, min=15.80; V band, max=14.36, min=15.23; and I band, max=13.50, min=14.16. While Fig. 1 makes it clear that we have many fewer data points in the B and I bands, fortuitously, several were taken close to both the minima and greatest maxima.

We estimated the average spectral indices as calculated in Wierzcholska et al. (2015):

$$\alpha_{BR} = \frac{0.4(B-R)}{\log(\nu_B/\nu_R)},\tag{1}$$

where ν_B and ν_R are the effective frequencies of the respective bands. We calculated the spectral index for only those nights of our observation where we have simultaneous data

4 Gaur et al.

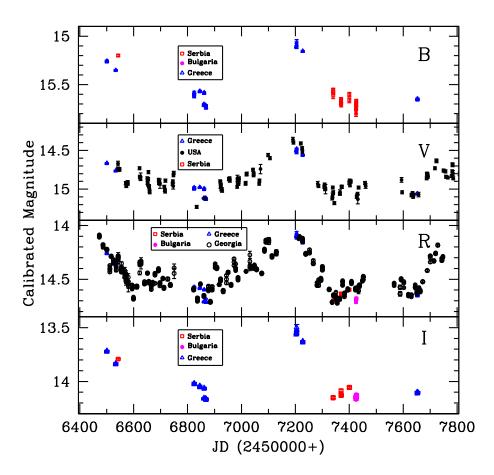

Figure 1. Long term light curve of 3C 66A during the period 2013–2017. The top to bottom panels respectively show B, V, R and I calibrated magnitudes and different symbols indicate data from different telescopes as defined in each peanel separately.

Table 3. Properties of variable emission components of 3C 66A and S5 0954+658

Source	Band	Number of Observations	log (m)
3C66A	I R	65 _	+0.114
	V B	66 65	-0.081 -0.265
S5 0954+658	I R V B	43 - 26 38	+0.110 - -0.096 -0.320

in B and R bands and they are shown in the lower panel of Fig. 2. The α_{BR} slope is very steep during the observing period and varies between 2.1–2.7. This plot again indicates that the emission is dominated by synchrotron emission.

We searched for a relationship between colour-index with respect to magnitude which is needed to ascertain whether flux changes are associated with the spectral changes. We used the simultaneous observed data in B, V and R bands for a particular night. Figure 3 shows the color variability diagram during the period 2013–2017. The color bar indicates the progression of time in JD

(2450000+). We have fitted straight lines (CI = $m \times R + c$) to colour index, CI, versus R magnitude plot. We found $m=0.021\pm0.019$; $c=1.30\pm0.29$, with linear Pearson correlation coefficient r=0.13 indicating p=0.069. Here a positive correlation is defined as a positive slope between the colour index and magnitude of the blazar which implies that the source tends to be bluer when it brightens or redder when it dims. An opposite correlation with negative slope implies the source follows a redder when brighter behaviour. As the nominal values of the slopes are small and do not exceed twice the errors, we did not find any significant correlation between magnitude and colour index for this blazar. In the previous studies of spectral variability, Böttcher et al. (2005) found a weak positive correlation between (B-R) versus R magnitude when the source was in a low brightness state with $R \ge 14.0$ but no clear correlation was found in brighter states of the source. Also, this source was a target of WEBT campaign again in 2007–2008 when it was in a high optical state, reaching a peak brightness of R \sim 13.4 but then it did not display spectral variability (Böttcher et al. 2009).

3.1.2 Spectral Energy Distribution (SED)

To learn about the origin of variability on longer timescales, we studied the SED in optical bands in different flux states. We adopted the assumption by Hagen-Thorn et al. 2004

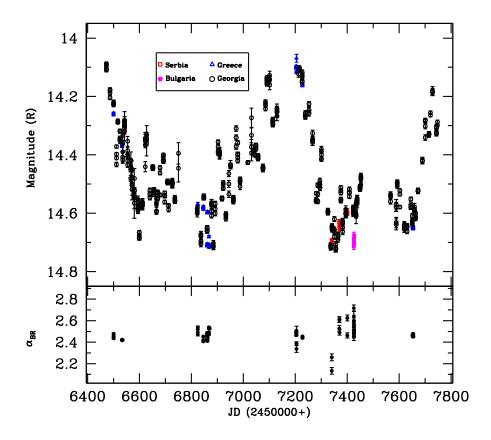

Figure 2. R band LC of 3C 66A (upper panel) and the variation of spectral indices α_{BR} with respect to JD (lower panel). Spectral indices are calculated for those nights where we have quasi-simultaneous data in B and R bands.

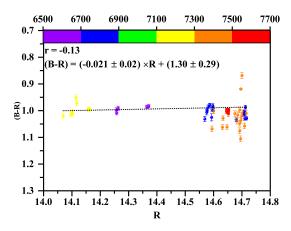

Figure 3. Colour versus magnitude relation for 3C 66A

(and considered later by Larionov et al. 2008; 2010) that the flux changes over the relevant set of observations arise from a single variable source (or multiple sources with similar SED). Hence, if the relative SEDs do not change and the variability is caused only by flux variations in that source region, then if n is the number of bands in which observations are made, the measured points should lie on straight lines in the n-dimensional flux density space. As noted by

Larionov et al. (2010), the converse would also be true, so that an observed linear relation between flux densities at two different wavelengths while the brightness varied means that the flux ratio, or slope is invariant. If linear relations were detected between multiple bands that would mean that the slopes of those lines could yield the constant relative SED of that variable source component.

Hence we searched for the flux-flux relations between the B, V, R and I bands. First, we transformed magnitudes into de-reddened flux densities using the Galactic absorption from Schlegel, Finkbeiner & Davis (1998); see Bessell et al. (1998). The flux-flux relations are shown in Fig. 4. it can be seen from the figure that flux ratios follow linear dependencies, and we used R band data to obtain relations as: $F_i = c_i + m_i F_R$ where i = B, V and I bands. These linear regressions are used to construct the SED during different flux states of the source observed during our campaign i.e., maximum (7.75 mJy); average (4.76 mJy) and minimum (3.68 mJy) fluxes. All the three curves are fitted with a power law, i.e., $F_{\nu} \propto \nu^{-\alpha}$, for the spectral index α . Spectral indices for all the mentioned flux states are provided in the upper part of Table 2 and are constant at $\simeq 1.66$. As mentioned above, slopes of the linear regressions can also be used to construct the relative SED of the variable source. The values of these slopes and the number of observational points used in producing them are provided in Table 3. A

6 Gaur et al.

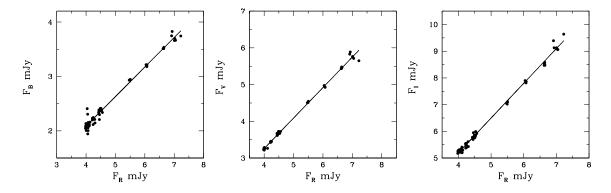

Figure 4. Flux–flux dependence of 3C 66A, where the B (left), V (center) and I (right) band fluxes are plotted against the R flux; lines represent linear regressions.

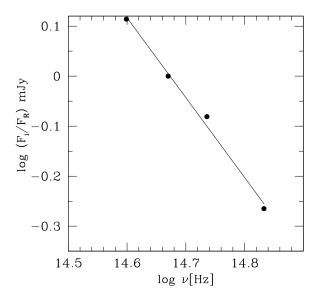

Figure 5. Relative SED of the variable component of 3C 66A, normalized with respect to R band.

SED of 3C 66A which is normalized to the R band is shown in Fig. 5. We derive a power law slope of the variable component to be $\alpha=1.60\pm0.09$. As long as we can assume that additional components are responsible for the observed variability and the relative SED of this variable portion is not varying, it can be concluded that the origin of variability of this blazar is intrinsic. It then can be accommodated within a non-thermal variable component which has a continuous injection of relativistic electrons with a power law energy distribution of $p \simeq 4.3$ as $\alpha \simeq (p-1)/2$.

3.2 S5 0954+658

S5 0954+658 is a BL Lac object with a claimed redshift of z=0.367 (Stickel et al. 1993); however, Landoni et al. (2015) found a featureless spectrum and a limit of z>0.45, which is based on non-detection of the host galaxy. This source is optically active and its optical variability was first studied by Wagner et al. (1993). Raiteri et al. (1999) studied a four year

long optical light curve and detected fast large amplitude variations. They also found that the variations over long time-scales for this source were not associated with spectral variations. Papadakis et al. (2004) studied intra-day flux and spectral variability of this source during 2001–2002. Hagen-Thorn et al. (2015) studied the optical flux and polarization variability of this blazar during 2008–2012. They found flux variations exceeded 2.5 mag and a degree of polarization that reached 40%. Larionov et al. (2011) also performed photopolarimetric observations of S5 0954+658 during 2011 and found it to have been in a faint state in mid-January 2011 with a brightness level R \sim 17.6, but by the middle of March the optical brightnes rose up to ~ 14.8 mag, showing flare-like behaviour. During the rise of the flux, the position angle of the optical polarization rotated smoothly over more than 200 degrees. Bachev (2015) presented the intra-night monitoring of the blazar during February 2015 and found violent variations on very short timescales of ~ 0.1 mag within ~ 10 min.

3.2.1 Long term flux and colour variability

The LTV LC of S5 0954+658 is shown in Fig. 6 for a total of 170 nights over nearly four years from February 2013-June 2017. B, V, R and I LCs are respectively shown from the top to the bottom panels of the above figure. To understand the long-term behaviour of this source it was observed for a total of 1756 photometric frames with maximum sampling in V and R bands. In order to visualize the nature of variability more clearly, we replot the R band LC on an expanded scale in upper panel of Fig. 7; it displays many short subflares superimposed on the longer term trends. The source was in a low optical state during the period MJD 6400-7000, with the mean magnitude of this source during this period ~ 17 . After this period, the source flux increased significantly and reached up to an R magnitude of ~ 13 as was also reported by Bachev (2015). Until MJD=7600 this source displayed many flare-like events. There also was a strong flare peaking around MJD=7810 which was only caught in V band measurements; it involved a rise of ~ 2 mag over ~ 100 days and a more rapid decline. During our observing campaign, the faintest R band magnitude was 17.40 at MJD=6640 and the brightest was 13.19 magnitude on MJD=7070. LCs in other bands also show similar behaviours. The faintest and

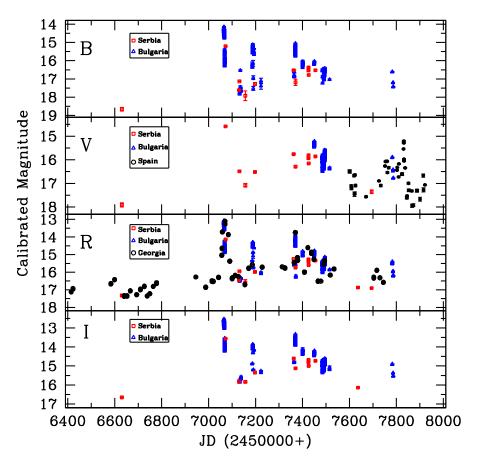

Figure 6. Long term LC of S5 0954+658 during the period 2013-2017, with symbols as in Fig. 1.

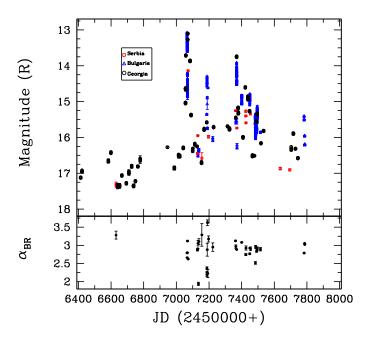

Figure 7. R band LC of S4 0954+658 (upper panel) and the variation of spectral indices α_{BR} (lower panel) with respect to JD. (lower panel).

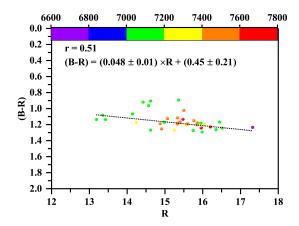

Figure 8. Colour versus magnitude relation of S4 0954+658

brightest magnitudes, respectively in B band were 18.65 and 14.15; in V band, 17.91 and 15.31; and in I band, 16.66 and 12.64. Hence, during our campaign we observed the source in its low state as well as in its high state.

In order to search for the relationship between colour index with respect to the magnitude, we used the simultaneous data in B and R bands. A color variability diagram is shown in Figure 8 where the color bar indicates the progression of time in JD(2450000+). The straight line fitted to colour index versus R magnitude gives $m=0.048\pm0.010$; $c=0.45\pm0.21=0.337$; p=0.51 which indicates a positive correlation between colour and magnitude. Raiteri et al. (1999) studied the long term light curve of this source and detected large amplitude variations but they were not associated with the spectral variations.

3.2.2 Spectral Energy Distribution

As we did for 3C 66A, we examined the flux-flux relations of S5 0954+658, shown in Fig. 9 and found that they follow linear regressions. Using the slopes of these linear regressions, we constructed SEDs at maximum (18.01 mJy); average (4.31 mJy) and minimum (0.34 mJy) levels, respectively. We fitted these SEDs using $F_{\nu} \propto \nu^{\alpha}$ and their respective slopes are provided in Table 2. These indicate that the slope is flatter when the flux increases, which is a common property of High Synchrotron Peaked blazars (e.g., Vagnetti et al. 2003; Hu et al. 2006; Gaur et al. 2012). According to Hagen-Thorn et al. (2004), if such flux-flux relations are linear, a variable emission component is likely to be responsible for the variability. Hence, we constructed the relative SED of the variable emission in Fig. 10 using the slopes of flux-flux relations provided in Table 3. These indicate that the slope of the variable component is 1.82 ± 0.15 . Hence, the variability of S5 0954+658 can be interpreted in terms of a non-thermal variable component that has a continuous injection of relativistic electrons with a steep power-law energy distribution of $p \sim 4.64$.

3.3 BL Lacertae

BL Lacertae is a prototype of the blazar class (at the redshift z=0.069; Miller & Hawley 1977) and is classified as

low frequency peaked blazar (LBL). BL Lac has long-known strong variability in optical bands and is one of the favorite targets of multi-wavelength campaigns, such as those carried out by the Whole Earth Blazar Telescope (WEBT/GASP; Böttcher et al. 2003; Villata et al. 2009; Raiteri et al. 2009, 2010, 2013 and references therein). It displays intense optical variability on short and intra-day time-scales (e.g. Clements & Carini 2001; Agarwal & Gupta 2015; Gaur et al. 2014). It also shows strong polarization variability (Marscher et al. 2008; Gaur et al. 2014, and references therein). In previous studies, it has been found that flux variations are associated with spectral changes (Villata et al. 2002; Papadakis et al. 2003; Hu et al. 2006). Most of the observed properties of this source can be attributed to synchrotron emission from highly relativistic electrons within a helical jet (Raiteri et al. 2009). BL Lac is within a relatively bright host galaxy and we removed its contribution from the observed magnitudes by following the method provided in Gaur et al. (2015a).

3.3.1 Long term flux and colour variability

The LTV LC of BL Lac is shown in Figure 11 for a total of 73 nights over nearly three years spanning 2014 through 2016. The source displayed significant flux changes on long-term time-scales in all the bands we measured (B, V, R and I). The variability amplitudes seen in the B, V, R and I bands are 263, 260, 254, and 251 per cent, respectively. The equivalent total changes in magnitudes are ΔB =1.31, ΔV =1.28, ΔR =1.15 and ΔI =1.12.

Our entire set of observations can be divided into three seasons. The first observation season covered the period 23 May 2014–30th September 2014, during which BL Lac was observed for a total of 14 nights. The second cycle spanned 20 February 2015-14 December 2015 when the source was observed on 36 nights. The third season covers the period from 30 June 2016-1 October 2016 when BL Lac was observed for a total of 23 nights. The magnitude of BL Lac ranged between 13.4-12.3 in the R band during this three year span. In some of the nights, observations were performed using two telescopes and we found good agreement between them. This source was extensively observed in the past by the WEBT collaboration and they found the magnitude to vary between 14.8-12.5 in the R band (Villata et al. 2002; 2004; Raiteri et al. 2010, 2013, and references therein). Hence, we can conclude that we observed BL Lac in a relatively high state, as noted above.

We calculated the spectral index for each night of our observations and they are shown in the lower panel of Fig. 12. The α_{BR} slope is very steep during the observing period and varies between 2.4–3.5. This plot again indicates that the emission is dominated by synchrotron emission and shows strong bluer-when-brighter trends.

A mildly chromatic behaviour is found for the LTV, with a slope of 0.072 ± 0.02 ; intercept of 0.14 ± 0.21 ; r=0.468; p=3.3e-05 for the (B-R) CI versus R magnitudes shown in Figure 13. This is in accordance with Villata et al. (2004) where they found a similar slope between (B-R) versus R during the period 1997–2002; the mildly chromatic long-term variations were simply explained in terms of changes in Doppler factors. Also, it can be seen from Fig. 12 that there are various outbursts superimposed on the long term trends which vary over time and the chromatism is also variable.

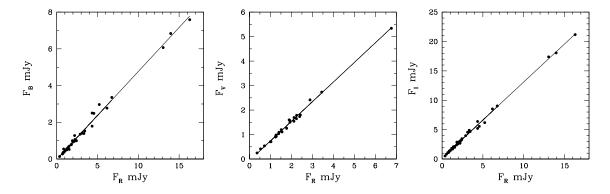

Figure 9. Flux-flux dependence of the blazar S5 0954+658, where the B (left), V (center) and I (right) band fluxes are plotted against the R flux; the lines represent linear regressions.

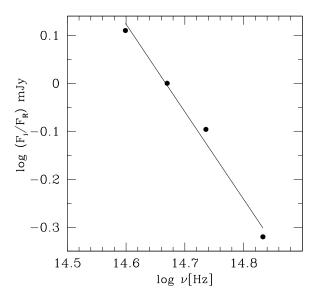

Figure 10. Relative SED of S5 0954+658, normalized to R band.

The slope of 0.1 should be considered to represent only a mean value.

It can seen that the the smaller flares/brightness changes on time-scales of days are superimposed on the longer term trends. In previous studies of BL Lacertae it was argued that much of the variability can be explained by changes in the Doppler factor of the jet emission region (e.g., Villata et al. 2004; Larionov et al. 2010).

3.3.2 Spectral Energy Distribution

We calculated the flux-flux dependencies for the B, V, R and I bands and these are shown in Figure 14. The relations are not very well fit by linear functions and hence the spectra are far from power-laws. So we fit them with second order polynomials, i.e., $a+b\times F+c\times F^2$. We then produced continuum spectra of BL Lacetae by using these polynomial regressions and these are shown in Fig. 15 for R band fluxes of 15, 25 and 35 mJy, which are within the range of our measurements.

If the intrinsic spectrum is a power law, $F_{\nu} \propto \nu^{\alpha}$ and α is taken as independent of wavelength over this modest range, then the flux-flux plots would have shown linear dependencies; however, this is not quite the case in our observations as shown in Fig. 14. Following Larionov et al. (2010), if we assume that the flux variations arise from changes in the viewing angle which lead to changes in the Doppler factor, δ , then in the observer's rest frame, the flux density is $F_{\nu} = \delta^p F_{\nu}'$ (Rybicki & Lightman 1979; Urry & Padovani 1995), where primed quantities refer to the source rest frame; p=3 for the situation where the radiation comes from a moving source with a compact emission zone (shock/knot), while p = 2 is appropriate for a smooth continuous jet (Begelman et al. 1994). Also, the frequencies are affected by the doppler shift as $\nu = \delta \nu'$. Hence, in Fig. 15, a logarithmic plot, the variation in the Doppler factor by $\Delta \log \delta$ leads to a shift in flux as well as in frequency in the following form: $\Delta \log F_{\nu} = p \Delta \log \delta$ and $\Delta \log \nu = \Delta \log \delta$. Here, we calculate the shift in the Doppler factor which is required to obtain the spectrum corresponding to 15 mJy from the highest flux spectrum of 35 mJy. We can roughly reproduce (as shown by the coloured lines in Fig. 15) the lower spectrum from the higher one by lowering δ by a factor of 1.19 for p=3 or by a factor of 1.25 assuming p=2, but given the very modest curvature over our limited range of bands, we cannot really distinguish between these possibilities. Hence, the most plausible explanation to describe the overall flux and colour variability during 2013-2017 is in terms of modest Doppler factor variations which affect the observed radiation coming from a jet. But, due to the limited range of frequencies, we can not completely ruled out the possibility of other variability models.

Larionov et al. (2010) found a somewhat larger shift in the Doppler factor by a factor of 1.58 with p=3 to fit a wider range of flux variations in data taken between 2000 and 2008. Because they had measurements in more IR bands they argued that they could distinguish between the shock/knot and smooth jet possibilities and favored the former.

4 DISCUSSION AND CONCLUSIONS

We have presented the results of photometric monitoring of three TeV blazars, namely, 3C 66A, S4 0954+658 and BL

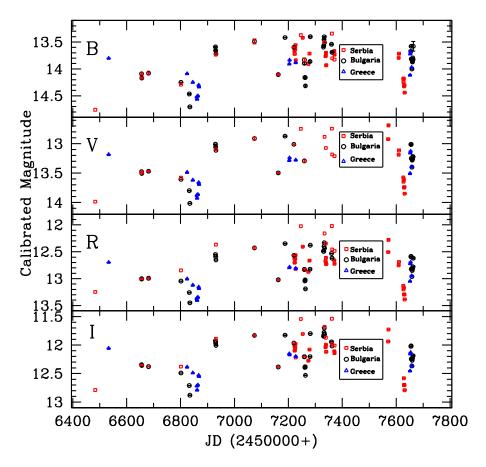

Figure 11. Long term light curve of BL Lacertae during the period 2014–2016; labels as in Fig. 1.

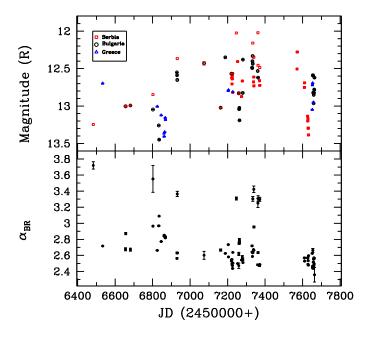

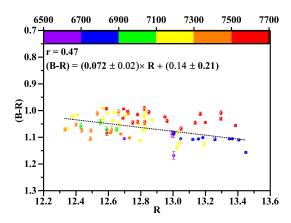

Figure 12. R band LC of BL Lac (upper panel) and the variation of spectral indices α_{BR} with respect to JD (lower panel).

 $\mbox{\bf Figure 13.} \ (\mbox{B-R}) \ \mbox{colour-index versus R magnitude of BL Lac on longer timescales}$

Lacertae over nearly four years in 2013–2017 for a total of 536 nights in B, V, R and I bands. We studied their flux and spectral variability on these long timescales. All three sources showed significant variability during our observing runs with the maximum variability shown by S5 0954+658 ($\Delta R \sim 4$). BL Lac revealed a more moderate variation of around $\Delta R \sim 1.12$ while weaker variations of $\Delta R \sim 0.65$ were displayed by 3C 66A. Comparison of our photometric observations with the earlier observations of same sources indicates that we observed the blazars 3C 66A and BL Lac in high states. However, the blazar S5 0954+658 was observed in low as well as high states. This source underwent many strong flares during our observations and reached a maximum brightness of around ~ 13 magnitude in February 2015.

We also studied the correlation between R magnitude and the colour indices. We did not find any correlation for 3C 66A but found weak positive correlations for S5 0954+658 and BL Lac. It can be seen that the spectra of S5 0954+658 are getting flatter as the flux increases (Table 2) which indicates a bluer-when-brighter trend. For BL Lacertae, we found a positive slope of 0.1 between the (B-R) colour-index and R magnitude, again indicating a similar trend, which is commonly seen for LBL blazars. Bluer-when-brighter chromatism can be explained with a one-component synchrotron model in that the more intense the energy release, the higher the typical particle's energy and the higher the corresponding frequency (Fiorucci et al. 2004). It can also be result from the injection of fresh electrons with an energy distribution harder than that of the previously cooled ones (e.g., Kirk, Rieger & Mastichiadis 1998; Mastichiadis & Kirk 2002). The long-term trends we saw are generally mildly chromatic. The flatter slope of the colour-magnitude diagram could be revealing the presence of multiple variable components, each evolving differently. Hence, superposition of different spectral slopes from multiple components leads to a general reduction of the colour-magnitude correlations (Bonning et al. 2012, Bachev 2015). It has been found in previous studies that the slope of the optical spectrum is often only weakly sensitive to the long-term trends while strictly following the bluer when brighter trends on short timescales (Villata et al. 2002; Larionov et al. 2010; Gaur et al. 2012, 2015a).

IDV of two of these sources, S5 0954+658 and BL Lac, were investigated in Bachev (2015) and Gaur et al. (2017), respectively. S5 0954+658 was observed by Bachev (2015) during its unprecedented high state in 2015 February when it reached a maximum brightness of $\sim\!13$ magnitude. Rapid, violent variations of 0.1–0.2 mag h $^{-1}$ were observed on intraday timescales and favour a geometrical scenario to account for this variability. The IDV of BL Lacertae was observed by Gaur et al. (2017) over a total of 45 nights and they found strong variability of $\sim\!0.1$ mag over a few hours on several nights. The IDV of BL Lacertae can be associated with models based on shocks moving through a turbulent plasma jet.

Models that have been proposed to explain optical variability of blazars generally involve one or more of the following processes: changes in the electron energy density distribution of the relativistic particles producing variable synchrotron emission; inhomogeneities in magnetic fields; shocks accelerating particles in the bulk relativistic plasma jet; turbulence behind an outgoing shock in a jet; and irregularities in the jet flows (e.g., Marscher, Gear & Travis 1992; Giannios et al. 2009; Marscher 2014; Gaur et al. 2014; Calafut & Wiita 2015; Pollack et al. 2016). The flux variations in blazars on longer timescales can also be explained by the launching of new components (or shocks) (e.g., Marscher & Gear 1985, Hughes et al. 1989) or mechanisms involving geometrical effects such as modestly swinging jets, for which the path of the relativistically moving source regions along the jet deviates a bit from the line of sight, leading to a changing Doppler factor (e.g., Gopal-Krishna & Wiita 1992; Pollack et al. 2016) or in a helical jet model where the orientation changes though the rotation about the helix (Villata et al. 2009).

In order to try to understand the origin of variability of these blazars during our observations, we studied fluxflux relations of these sources, based on the assumption that linear relations between observed fluxes at different wavelengths suggest that the slope does not change during the period of flux variability. And, if the variability arises from a single variable source (or multiple components with similar SEDs) then its slope can be derived from the slopes of the flux-flux relations. Hence, we calculated the flux-flux relations of these three blazars and found that those of 3C 66A and S5 0954+658 followed linear regressions. Hence, a single variable source (or multiple components with similar SEDs) are probably responsible for the variability we are seeing. Using the slopes of the flux-flux relations, we constructed the relative SED of this variable components. The slopes of the variable emitting region of 3C 66A and S5 0954+658 are found to be $\simeq 1.65$ and 1.8, respectively. Hence, using the flux-flux relations we suggest that the variability in these two sources can be interpreted in terms of a non-thermal variable component which has a continuous injection of relativistic electrons with a power law energy distributions around 4.3 and 4.6, respectively.

The flux-flux relations of BL Lac are better fitted with a second order polynomial which implies that the observed flux variations more likely arise from the changes in the Doppler factor of the relativistic jet, as suggested earlier (Villata et al. 2002; Larionov et al. 2010, and references therein). Hence, we calculated the optical spectra of BL Lac at different flux states between 15 mJy and 35 mJy.

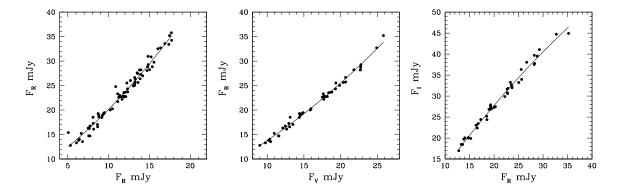

Figure 14. Flux-flux dependence of the BL Lac, where the R flux is plotted against the B (left), V (center) and I (right) band fluxes. The lines represent second-order polynomial regressions.

We found that the lowest spectrum could be reasonably reproduced from the highest flux spectrum by decreasing the Doppler factor by a factor of ~ 1.2 . These observations of long-term flux and mildly achromatic BL Lac variability might be explained to arise from changes in the viewing angle, which lead to the Doppler factor becoming variable (Larionov et al. 2010 and references therein).

Our observations of these three blazars allow us to make plausible inferences about the origins of variability in optical bands. However, as we are dealing with very narrow range of frequencies in the optical SEDs and we have limited data set which is simultaneous in B, V, R and I bands needed to properly study flux–flux relations the conclusions must be used with caution. Even larger datasets and broader multi-wavelength modelling of SEDs are required to firmly constrain various blazar jet parameters.

We would like to thanks the anonymous reviewer for the constructive comments which helped us to improve the manuscript scientifically.
