Abstract

Telescopes – 'far seeing' – have since centuries revealed insights to objects at cosmic distances. Adopted for gamma-ray-astronomy, ground based Cherenkovtelescopes image the faint Cherenkov-light of air-showers induced by cosmic gammarays rushing into earth's atmosphere. In the race for the lowest possible energythreshold for cosmic gamma-rays, these Cherenkov-telescopes have become bigger, and now reached their physical limits. The required structural rigidity for image-quality constrains a cost-effective construction of telescopes with apertures beyond 30 meter in diameter. Moreover, as the aperture increases, the narrower depth-of-field irrecoverably blurs the images what prevents the reconstruction of the cosmic particle's properties. To overcome these limits, we propose plenopticperception with light-fields. Our proposed 71 meter Cherenkov-plenoscope requires much less structural rigidity and turns a narrow depth-of-field into threedimensional reconstruction-power. With an energy-threshold for gamma-rays of one Giga electron Volt, 20 times lower than what is foreseen for the future planned Cherenkov-Telescope-Array (CTA), the Cherenkov-plenoscope could become the portal to enter the sub second time-scale of the highly variable gamma-ray-sky. We present the Cherenkov-plenoscope in Part I of this thesis.

In Part II, we push Cherenkov-astronomy by sensing Cherenkov-light in the quantum-regime. A key ability of Cherenkov-telescopes, and our proposed Cherenkov-plenoscope, is the detection of few Cherenkov-photons within the everpresent nightly pool of photons emitted by stars, zodiacal dust, atmospheric glow, and others. Photo-sensors and electronics have made huge progress, and now reach a regime where the quantized nature of photons can be resolved. We present the identification of single-photons during regular observation-conditions with the 3.6 meter Cherenkov-telescope named FACT on Canary island La Palma, Spain. We implement a true single-photon-representation for air-shower-records and compare it to established representations which are usually highly entangled with the photo-sensors and electronics in use and thus usually do not have a quantized description. Our representation contains the arrival-times of single-photons which makes it the most natural, and arguably the most interchangeable representation possible for Cherenkov-astronomy. With the complete time-structure of the air-shower's Cherenkov-photons, our single-photon-representation has the potential to improve the reconstruction of the cosmic particle's properties.

Zusammenfassung

Das Teleskop - 'In die Ferne sehen' - gewährt seit Jahrhunderten Einblicke auf Objekte in kosmischen Distanzen. Übernommen fuer die Astronomie der Gammastrahlen bilden bodengebundene Cherenkov-Teleskope das schwache Cherenkov-Licht ab, welches von Luftschauern ausgeht. Luftschauer werden durch kosmische Strahlung erzeugt, wenn diese in die irdische Atmosphäre eindringt. Im Rennen um die kleinst mögliche Energieschwelle fuer kosmische Gammastrahlen sind Cherenkov-Teleskope immer grössser geworden und stossen nun an ihre physikalischen Grenzen. Die benötigte strukturelle Steifigkeit für die Abbildungsqualität verhindert einen kosteneffiziente Bau von Teleskopen mit Aperturdurchmessern von mehr als 30 Metern. Mehr noch, mit wachsenden Aperturen verwäscht die immer schmalere Tiefenschärfe die Bilder unwiederruflich und verhindert die Rekonstruktion der kosmischen Strahlung. Um diese Grenzen zu überwinden, schlagen wir eine plenoptische Wahrnehmung und die Verwendung von Lichtfeldern vor. Unser hier vorgeschlagenes 71 Meter Cherenkov-Plenoskop benötigt viel weniger strukturelle Steifigkeit und wandelt eine schmale Tiefenschärfe in drei dimensionale Rekonstruktionskraft um. Mit einer Energieschwelle von einem Giga Elektronen Volt für Gammastrahlen, 20 mal geringer als die voraussichtliche Energieschwelle für das geplante Cherenkov-Telescope-Array (CTA), könnte unser Cherenkov-Plenoskop das Portal werden um in den höchst variablen Gammastrahlenhimmel auf Zeitskalen unterhalb einer Sekunde vorzudringen. In Teil I dieser Arbeit präsentieren wir das Cherenkov-Plenoskop. In Teil II dieser Arbeit treiben wir die Gammastrahlungsastronomie weiter voran indem wir Cherenkov-Licht im Quantenbereich erfassen. Eine Schlüsselfähigkeit von Cherenkov-Teleskopen und unserem vorgeschlagenen Cherenkov-Plenoskop ist die Detektierung von wenigen Cherenkov-Photonen inmitten des allgegenwärtigen Sees aus nächtlichen Photonen ausgesandt von Sternen, Zodiakstaub, atmosphärischem Glühen und anderem. Photosensoren und Elektronik haben gewaltige Fortschritte gemacht und erlauben es nun, die quantisierte Natur von Photonen aufzulösen. Wir präsentieren die Identifikation von Einzelphotonen während regulären Beobachtungsbedingungen auf dem 3,6 Meter Cherenkov-Teleskop namens FACT auf der kanarischen Insel La Palma, Spanien. Wir implementieren eine echte Einzelphotonendarstellung für Luftschaueraufnahmen und vergleichen diese mit etablierten Darstellungen, welche für gewöhnlich hochgradig mit den jeweilig verwendeten Photosensoren und Elektroniken verstrickt sind und darum in der Regel keine quantisierte Darstellung haben. Unsere Darstellung enthält die Ankunftszeiten von Einzelphotonen was sie zur natürlichsten und best austauschbaren Darstellung für die Cherenkov-Astronomie macht. Mit der vollständigen Zeitstruktur der Cherenkov-Photonen im Luftschauer hat unsere Einzelphotondarstellung das Potential, die Rekonstruktion der kosmischen Strahlung zu verbessern.

Introduction

Earth is not the center of the universe. A simple conclusion drawn from observations of the night-sky that changed a complete society and marked the starting point of our modern quest for knowledge. During this quest, the fields of physics, astronomy, and cosmology merged closer together. Observations of the sky, beyond earth, became important for scientific progress in seemingly opponent fields which investigate the innermost structure of matter. So let us take a closer look into the sky. Already with our eyes we see structures like stars, the moon, the sun, and our home galaxy named Milky-Way. With telescopes ('far seeing') we see more complex structures like moons of planets, nebulae, and foreign galaxies. It is the light which provides us with insights as it travels from distant objects to our eyes.

However, there is light which the human-eye can not see. New windows beyond the visible-light were opened in the past 100 years. For example, the window of invisible radio-light was opened and became a pillar of modern astronomy. Now, a young, and novel window of high energetic gamma-rays is about to open to astronomy. And we do what we can to tear open this window.

Gamma-ray-astronomy

Gamma-rays are single photons so energetic that they can disrupt the nuclei of an atom with bounding-energies of MeV or even GeV. Although gamma-rays are electromagnetic radiation as visible- or radio-light, the term gamma-*ray* already implies that their wave-character is hardly recognizable in most interactions. At energies onwards from some MeV, the particle-character dominates and so we often call it gamma-ray instead of gamma-radiation. Beside the gamma-rays produced on earth by nuclear decay, there are also gamma-rays of cosmic origin. In fact, there are not only cosmic gamma-rays but also other high-energetic particles of cosmic origin like protons, electrons, and heavy ions. On earth, the atmosphere shields us from cosmic particles but when we go up in altitude the increase in flux of cosmic particles becomes evident [Hess, 1912]. In todays gamma-rayastronomy, high energetic charged particles create great challenges in the observations of gamma-rays and have to be distinguished from gamma-rays. Even more challenging, charged particles are much more abundant and outshine even the brightest sources of gamma-rays. With this said, the three ¹ goals of gamma-ray-astronomy today are to measure

- the incident-direction of a gamma-ray,
- the energy of a gamma-ray,
- and the type of particle to assert that the cosmic particle actually was a gamma-ray.

All these three measurements must be done for each individual event of an incoming cosmic gamma-ray or incoming cosmic-ray which is different from opticaland radio-astronomy. In optical- and radio-astronomy, many cosmic photons contribute to a single measurement. Cosmic particles can either be detected directly outside earth's shielding atmosphere, or indirectly by observing the interactions of the cosmic particles in the atmosphere. Both of these methods are currently being investigated for gamma-ray-astronomy, and both have exclusive advantages above the other. Similar to the spectrum [Olive et al., 2014] of energies of cosmicrays, the spectrum of energies of gamma-rays decreases rapidly towards higher energies. In the case of the Crab Nebula, one of the brightest known sources of cosmic gamma-rays in the sky, gamma-rays with energies of 100 GeV are two to three orders-of-magnitude more abundant than gamma-rays with energies of 1 TeV [Aleksić et al., 2015]. This steep decrease of the spectrum of the energy causes the observations of gamma-rays to be dominated by particles with energies close to the lower energy-threshold of the detectors.

Detecting gamma-rays directly

The direct detection of gamma-rays takes place in space, outside of earth's atmosphere. Detectors in space wait for cosmic gamma-rays to interact in their mass. Detectors in space have typically three components of which each one is dedicated to measure one of the three important properties of cosmic particles. First, there is a tracker that reconstructs the trajectories of electrons and positrons created via pair-production $\gamma \rightarrow e^+ + e^-$ to estimate the direction of the initial gammaray. The trajectory of charged cosmic-rays can even be reconstructed directly by the tracker from the initial particle itself. Second, there is a calorimeter where the secondary interaction-products can deposit all their energy in order to estimate the energy of the cosmic particle. And third, there is an anti-coincidence-detector wrapped around the inner tracker and calorimeter. The anti-coincidence-detector measures the type of the particle by distinguishing electrically charged cosmicrays from neutral gamma-rays. Figure 2 shows all three components on the very successful Fermi-Large-Area-Telescope.

 $^{^1\}mathrm{In}$ the regime of MeV-energies, even the polarization [Dean et al., 2008] of a gamma-ray can be measured.

Figure 1: The inert, but full-solid-angle sky of gamma-rays seen by the Fermi-LAT detector [Acero et al., 2015]. AGN is short for Active-Galactic-Nucleus, PWN is short for Pulsar-Wind-Nebula, and SNR is short for Super-Nova-Remnant.

So detectors in space fulfill all demands of gamma-ray-astronomy. However, detectors in space are limited in mass and volume and are unfortunately not expected to become any bigger in the foreseeable future of space-travel. Since the mass of the detector is mandatory for the tracker and especially for the calorimeter, the effective areas for the detection of gamma-rays today are below 1 m². Today, detectors in space are excellent to create static and wide field-of-view surveys of the inert gamma-ray-sky with years of exposure-time, see Figure 1. Only in rare cases of an excessively high emission of gamma-rays from a temporarily flaring source, detectors in space are able to resolve time structures on the time-scale of days² [Tavani et al., 2011, Abdo et al., 2011].

Detecting gamma-rays indirectly

Indirect detectors make use of the atmosphere of the earth. When a cosmic particle or cosmic gamma-ray enters the atmosphere, it can interact with the molecules in the atmosphere. Due to the high kinetic energy of the cosmic particle, the fragments and the newly created particles of such interactions travel further down the atmosphere almost parallel to the trajectory of the cosmic particle. This interaction of particles continues in a cascade until the kinetic energies of the interaction-products are not sufficient anymore to further create new particles.

 $^{^{2}}$ This excludes assumptions about pulsed emission as it is commonly assumed for pulsars. The emission-period of pulsars is typically tens of milliseconds, but a deviation from this pulsation will still only be detected after days of exposure-time.

Figure 2: The Large-Area-Telescope (LAT) for gamma-rays named after Enrico Fermi. The LAT is dedicated to measure the three properties: Direction, energy, and type of cosmic particles. Schematics is inspired by two separate figures provided by www.nasa.gov/glast.

Figure 3: The dominant interactions inside an air-shower. The hadroniccomponent is red, the electro-magnetic-component is blue, and the weak-decaycomponent is green. Figure is not to scale. For cosmic particles of electromagnetic type, the air-shower starts directly inside the blue branch on the left.

For energies below ≈ 80 MeV ionization becomes more likely than bremsstrahlung which effectively ends the cascade. This destructive and cascaded process is called air-shower. Depending on the initial kinetic energy of the cosmic particle, airshowers can be several kilometers long. At energies above $10^{12} \,\mathrm{eV}$, air-showers can reach the ground before the cascade reaches its climax. There are two different types of air-showers. First, there are air-showers which are dominated by electromagnetic interactions. Such air-showers are induced by cosmic particles of electromagnetic type like the gamma-ray, or the electron. Second, there are air-showers which have both hadronic and electro-magnetic interactions. Those air-showers are induced by cosmic particles of hadronic type like the proton or the ironnucleus. Figure 3 shows the two different air-shower types. The momentum of secondary particles perpendicular to the trajectory of the cosmic particle, is larger in hadronic interactions than it is in electro-magnetic interactions. Therefore, air-showers with hadronic components have a wider spread of secondary particles perpendicular to the trajectory of the cosmic particle. The different geometry of narrow electro-magnetic air-showers, and wide and bushy hadronic air-showers allows us to reconstruct whether the cosmic particle was of hadronic, or of electromagnetic type. On ground, indirect detectors have sensors to detect the particles and radiations which are created in the air-shower and have not yet been absorbed again in the atmosphere. Five types of interaction-products are likely to reach ground before they get absorbed in the atmosphere themselves. First, blueish, visible Cherenkov-photons that are produced by charged particles in the airshower that traverse the air faster than the local speed of light in this air. Second, charged muons that originate from hadronic interactions in the air-shower are unlikely to undergo further interactions in the air. Third, ultra-violet and visible photons produced by atoms and molecules which got ionized by the air-shower and later recombine. Fourth, radio-waves which are produced by the separation of electric charges in the air-shower due to the magnetic-field of the earth, and the Askaryan-effect. Fifth, neutrinos produced in e.g. the decay of pions and muons. Only if the energy of the cosmic particle is high enough, the creation of new, short lived, particles might not have come to an end before the air-shower reaches the ground. When the energies are high enough, any particle might be found in the so called air-shower-tail on ground. As only secondary particles reach the sensors on ground, the measurement of the direction, the energy and the type of the cosmic particle, is not straightforward. To measure the three properties, indirect detectors try to reconstruct the spatial geometry of the airshower. There are indirect detectors that only detect the charged particles which reach the ground [Allekotte et al., 2008] and are therefore referred to as airshower-tail-detectors. Dedicated air-shower-tail-detectors have a dense coverage on ground optimized to tell apart the type of the cosmic particle to do gamma-rayastronomy [DeYoung et al., 2012]. Other indirect detectors are telescopes which record the photons produced by florescence in the air-shower horizontally from the side [Abraham et al., 2010]. Even a detector for florescence-photons which records air-showers from space while looking down onto earth is proposed [Ebisuzaki et al., 2014]. And then there are telescopes that record the bluish Cherenkov-photons produced in the air-shower. For gamma-rays with energies above several 10 GeV, Telescopes for Cherenkov-photons can measure the three features important to gamma-ray-astronomy (direction, energy, and type) and offer large collectionareas for gamma-rays of $> 10^4 \text{ m}^2$ [Bernlöhr et al., 2013].

The Cherenkov-telescope

Cherenkov-telescopes³ measure the energy and direction of cosmic gamma-rays and other cosmic particles. During the night, Cherenkov-telescopes record the incident-directions c_x , c_y and the arrival-times t of both night-sky-backgroundphotons and Cherenkov-photons produced in the air-shower. The short but intense time-structure of the flash of Cherenkov-photons on ground of ~ 5 ns allows the Cherenkov-telescope to trigger and record the Cherenkov-photons within the pool of night-sky-background-photons. By reconstructing the geometry of the air-shower from the recorded incident-directions and arrival-times of the photons, Cherenkov-telescopes estimate the three properties important to gamma-

³Also called Imaging-Atmospheric-Cherenkov-Telescope (IACT).

ray-astronomy: Direction, energy and type of the cosmic particle. The more Cherenkov-photons a Cherenkov-telescope can record of an individual air-shower, the better the properties of the cosmic particle can be reconstructed. Larger but costly apertures for Cherenkov-photons allow Cherenkov-telescopes to reconstruct air-showers induced by cosmic particles with lower energies. Today, small Cherenkov-telescopes have $\approx 10 \text{ m}^2$ apertures for Cherenkov-photons and are able to detect gamma-rays with energies down to $\sim 1 \text{ TeV}$ [Temme et al., 2015]. Large Cherenkov-telescopes have $\approx 200 \text{ m}^2$ apertures for Cherenkov-photons and are able to detect gamma-rays with energies down to $\sim 100 \text{ GeV}$ [Tridon et al., 2010]. So far Cherenkov-telescopes opened the high-energy > 100 GeV window of gamma-rays to astronomy [Kildea et al., 2007] and have found ≈ 200 sources of gamma-rays [Wakely and Horan, 2008]. To further open the gamma-ray-window, we have to make gamma-ray-astronomy more powerful and cost effective.

Part I

Cherenkov-Plenoscope

A ground-based Approach in One Giga Electron Volt One Second Time-To-Detection Gamma-Ray-Astronomy

Chapter 1

Introduction

Ground based Cherenkov-telescopes measure the energy and incident-direction of cosmic gamma-rays and other cosmic particles, such as protons and electrons. Cosmic particles induce air-showers in earth's atmosphere where in turn Cherenkov-photons are emitted. During the night, Cherenkov-telescopes record the incident-angles c_x , c_y and the arrival-times t of these Cherenkov-photons in a three-dimensional intensity-histogram $\mathcal{I}[c_x, c_y, t]$ called image-sequence. To sense the quick ~ 1 ns flash of Cherenkov-photons within the pool of night-skybackground-photons, the Cherenkov-telescope records an image-sequence with ~ 1 billion images per second. By reconstructing properties of the air-shower from the image-sequence [Hillas, 1985], Cherenkov-telescopes gather information about the cosmic particle to do astronomy.

The high energy-threshold of Cherenkov-telescopes is the main limit for studying astronomical emitters of gamma-rays. For example, the study of pulsars is limited because for most of them the emission of gamma-rays is cut off at and above $\sim 10 \,\text{GeV}$ [The MAGIC Collaboration, 2008a, Abdo et al., 2009b]. And in general the study of sources at cosmological distances like active-galactic-nuclei and gamma-ray-bursts is limited due to the absorption of high energetic gammarays in the extra-galactic background-light [The MAGIC Collaboration, 2008b]. For example, the gamma-ray-horizon [The MAGIC Collaboration, 2008b] in the universe contains ~ 4.7 times more observable volume when being able to detect gamma-rays with energies as low as 100 GeV instead of 200 GeV. Furthermore, the study of transient sources benefits from a low energy-threshold [Aharonian et al., 2001]. Currently the only way to measure gamma-rays with energies below a few tens of GeV are telescopes in space, e.g. Fermi-LAT [Acero et al., 2015, which measure gamma-rays before they interact with earth's atmosphere. The predominant limiting factor for space-telescopes is their small collection-area which unfortunately is not expected to become far bigger within the near future. Beside their costs, space-telescopes with their wide coverage of the sky are great for static sources of gamma-rays and year long exposures [Acero et al., 2015], but their $\sim 1 \,\mathrm{m}^2$ collection-area limits their abilities to resolve the highly variable gamma-ray-sky.

The energy-threshold of Cherenkov-telescopes itself is limited by the efficiency to detect Cherenkov-photons, as the number of the Cherenkov-photons is roughly proportional to the cosmic particle's energy [de Naurois and Mazin, 2015]. Therefore, Cherenkov-telescopes have put great effort into lowering their energythresholds, mainly by moving onto mountains to be closer to the air-shower, or by enlarging their aperture for Cherenkov-photons. This way, current and upcoming Cherenkov-telescopes reach energy-thresholds as low as $\sim 20 \,\mathrm{GeV}$ [The MAGIC Collaboration, 2008a, Bernlöhr et al., 2013], while the most ambitious proposals for Cherenkov-telescopes, on the frontier of low energy-thresholds, strives to reach 5 GeV [Aharonian et al., 2001]. However, two physical limits reduce the maximum aperture for Cherenkov-photons on a single Cherenkov-telescope to below $\sim 30 \,\mathrm{m}$. First, the square-cube-law [Galilei, 1638] makes building bigger Cherenkov-telescopes increasingly difficult due to the need for mechanical rigidity in order to keep the targeted optical geometry for the imaging-reflector and the image-sensor. Second, the depth-of-field induced by larger apertures renders more and more parts of the recorded images blurred and thus erodes the power to reconstruct the particle type, energy and direction from the recorded Cherenkov-photons [Hofmann, 2001, Mirzoyan et al., 1996]. We discuss the origin and limitations of a narrow depth-of-field in Chapter 6. The depth-of-field-limit is a central reason why the next generation of Cherenkov-telescopes will not exceed ~ 23 m aperture-diameter [Bernlöhr et al., 2013]. Furthermore there is the technological challenge of signal processing and routing which prevents us from combining individual Cherenkov-telescopes before the trigger-level into an array to lower the energy-threshold. With todays electronics the trigger-decision in an array of Cherenkov-telescopes can not be taken on the combined aperture for Cherenkov-photons provided by all the Cherenkov-telescopes in the array, but has to be taken on each Cherenkov-telescope individually. Although impressive efforts were made [Jung et al., 2005, López-Coto et al., 2016] to take the triggerdecision based on combined information beyond the aperture of the individual Cherenkov-telescope, still the mayor part of information-reduction is made on the individual Cherenkov-telescope before the overall trigger of the array [Bulian et al., 1998, Funk et al., 2004, Weinstein et al., 2007, López-Coto et al., 2016].

The potential of reaching $> 10^4 \text{ m}^2$ collection-areas for gamma-rays with the atmospheric Cherenkov-method motivated us to overcome these physical limits and technological challenges. We propose to combine the atmospheric Cherenkov-method with the plenoptic-method [Lippmann, 1908, Adelson and Wang, 1992, Ng et al., 2005, Wilburn et al., 2005] to build the Cherenkov-plenoscope, a telescope for cosmic gamma-rays with the large collection-areas of Cherenkov-telescopes on ground and the low energy-threshold of telescopes in space.

Chapter 2

Results

The Cherenkov-plenoscope measures the incident-direction and energy of individual cosmic gamma-rays and cosmic-rays. During the night, the Cherenkovplenoscope records the air-showers induced by these cosmic particles from ground by measuring the entire (plenary) extrinsic state of the Cherenkov-photons. It bins the photons depending on their incident-directions (c_x, c_y) , their supportpositions on the aperture-plane (x, y) and their arrival-times t into a five-dimensional intensity-histogram $\mathcal{L}[c_x, c_y, x, y, t]$ called light-field-sequence. By reconstructing the air-shower from the light-field-sequence, the Cherenkov-plenoscope gathers information about the cosmic particle to do astronomy. To record light-fields, the Cherenkov-plenoscope uses a large imaging-reflector in combination with a light-field-sensor, see Figure 2.1.

2.1 Introducing the plenoscope's optics

The large imaging-reflector of the plenoscope reflects an incoming photon towards the light-field-sensor, see Figure 2.2. Just as in a classic telescope, the large imaging-reflector reflects a photon towards a certain position on the sensorplane depending on the photon's incident-direction. On the classic image-sensor in a telescope, the photon was now absorbed by a photo-sensor and added to the recorded image. However, the light-field-sensor of the plenoscope is a twodimensional array of N small cameras, in contrast to a classic image-sensor which is just an array of N photo-sensors. Each small camera is made out of a hexagonal lens and an image-sensor composed from M photo-sensors right behind the hexagonal lens. In the Figures 2.2, and 2.3, we demonstrate the observation of the three photons A, B, and C. The photons A and B have different incidentdirections and therefore are reflected onto different positions on the sensor-plane, where they enter different lenses of different small cameras. Photon A enters the lens at n = 2, and photon B enters the lens at n = 1, see Figure 2.3. However, since the support-positions of A and B are close together, they are both absorbed in the right most photo-sensor at m = 3 on the image-sensor in their

Figure 2.1: To scale illustration of the proposed Cherenkov-plenoscope Portal. Its light-field-sensor and large imaging-reflector are suspended by cables.

small cameras. Photon C has a similar incident-direction as photon A and thus enters the same small camera at n = 2. However, since photon C has a different support-position than photon A, photon C is not absorbed by the right-most photo-sensor in its small camera, but in the photo-sensor at m = 0. Each photosensor (n, m) corresponds to one specific bin in the light-field-intensity-histogram $\mathcal{L}[c_{xn}, c_{y_n}, x_m, y_m]$, i.e. one specific light-field-cell. Each of these light-field-cells (n, m), or lixels for short, describe a bundle of photon-trajectories which can be approximated by a three-dimensional ray

$$\vec{r}_{n,m}(\lambda) = \left(x_m, y_m, 0\right)^T + \lambda \left(c_{xn}, c_{y_n}, \sqrt{1 - c_{xn}^2 - c_{y_n}^2}\right)^T.$$
 (2.1)

Bins with the same incident-direction $n(c_{xn}, c_{yn})$ in the light-field are called a picture-cell, or a pixel for short. And bins with the same support-position m (x_m, y_m) in the light-field are called a principal-aperture-cell, or a paxel for short. The plenoptic perception of photons has severe consequences, of which we introduce the very basics in Chapter 6. In Chapter 10 we show how plenoptic perception can enlarge the field-of-view by overcoming the aberrations of imagingoptics [Hanrahan and Ng, 2006]. Such aberrations are inevitable limits to imaging on telescopes. In Chapter 11 we show how plenoptic perception loosens the constrains for the rigid alignment between the imaging-reflector and the sensor-plane. Rigid alignment is a strong technological challenge on large telescopes. In Chapter 8 we show how we calibrate the response of the light-field-sensor in order to obtain a light-field-sequence \mathcal{L} which describes photons in three-dimensional space and time. In the Chapters 9, and 15 we describe the rich and powerful ways to interpret the light-field-sequence \mathcal{L} in order to reconstruct air-showers. Finally in Chapter 19 we compare the perception of established methods in Cherenkovastronomy to the Cherenkov-plenoscope's perception.

In general, the light-field $\mathcal{L}[c_x, c_y, x, y]$ recorded by a single plenoscope is equiv-

alent to M images $\mathcal{I}_m[c_x, c_y]$ recorded by an array of M telescopes located at different support-positions (x, y). Thus in the general case, a plenoscope and a dense array of telescopes can record the light-field in the same way. However, in the particular case of quick flashes of Cherenkov-photons produced in air-showers, the Cherenkov-plenoscope has one crucial advantage over the array of Cherenkovtelescopes: Its trigger.

2.2 Going around the trigger-challenge

In an array of Cherenkov-telescopes, combining the intensity of close-by pixels (c_x, c_y) from different Cherenkov-telescopes located at different positions (x, y)would be crucial for the trigger-decision on the lowest possible energies. Unfortunately this is very difficult to do. The image-sensors of the individual Cherenkovtelescopes are separated by at least the diameter of their imaging-reflectors. The trigger for an array of Cherenkov-telescopes needs time-delays which depend on the pointing-direction of the telescopes, and it has to reorganize all the signals from the individual telescopes from being bundled into near-by support-positions (x, y) to being bundled into near-by incident-directions (c_x, c_y) . The Cherenkovplenoscope on the other hand has the ideal arrangement for a trigger that takes into account the full aperture of the large imaging-reflector. In contrast to an array of Cherenkov-telescopes, the photo-sensors which represent similar incidentdirections in c_x , and c_y , but belong to different support-positions in x, and y are mechanically very close together inside the light-field-sensor ($< 15 \,\mathrm{cm}$, see later Figure 5.11). The plenoscope does neither need time-delays which depend on the pointing, nor does it need external, and flexible routing of signals. In Chapter 12 we motivate the need for a trigger in Cherenkov-astronomy, and describe a possible implementation in a Cherenkov-plenoscope. In the Sections 19.7, and 19.8 we show how this trigger-challenge is currently addressed on arrays of Cherenkov-telescopes.

2.3 Deferring the square-cube-law

Since the light-field-sensor records three-dimensional trajectories of photons rather than just the absorption-positions of photons, the alignment of the light-fieldsensor with respect to the imaging-reflector is less constrained than the alignment of a conventional image-sensor. As long as the actual misalignment of the light-field-sensor with respect to the imaging-reflector is known, the light-fieldsensor can still record trajectories of photons. It just samples a different region of the light-field. And when the Cherenkov-photons of an air-shower are still within the sampled region of the light-field, a misalignment does not harm the observation-power for gamma-rays. In Chapter 11 we discuss how the plenoscope can compensate misalignments between its light-field-sensor and its large

Figure 2.2: The optics of the plenoscope. On the bottom is the large imagingreflector, on the top is the light-field-sensor. Here the light-field-sensor has N = 3small cameras with M = 4 photo-sensors in each small camera. We demonstrate the trajectories of the photons A, B, and C. Photo-sensors are red, and walls in between small cameras are green.

Figure 2.3: Close-up on the optics of the light-field-sensor shown in Figure 2.2. The photo-sensors can be addressed in two dimensions (n, m), see table on the right. The first index n addresses the incident-direction. The second index m addresses the support-position.

imaging-reflector. We further demonstrate that sharp images can still be obtained with strong misalignments.

The reduced demand for rigid alignment allows the Cherenkov-plenoscope to mechanically decouple the light-field-sensor from the imaging-reflector. This way the Cherenkov-plenoscope can defer the physical limit of the square-cube-law and have larger, and more cost-effective apertures for Cherenkov-photons. In Chapter 16, we propose a dedicated mount for the Cherenkov-plenoscope which explicitly takes advantage of these reduced demands for rigidity.

2.4 Turning depth-of-field into tomography

Again, since the Cherenkov-plenoscope records three-dimensional trajectories of photons rather than only the photons absorption-positions, the plenoscope overcomes the physical limit of the depth-of-field, as we motivate in Section 6.4. However, the plenoscope not only overcomes the depth-of-field-limit but it turns the tables on it. The narrow depth-of-field gives the plenoscope its three-dimensional reconstruction-power. The recorded trajectories of the Cherenkov-photons can directly be used for a tomographic reconstruction of the air-shower, similar to reconstructions in light-field-microscopy¹ [Levoy et al., 2006]. We discuss our first experiences with tomographic reconstructions of air-showers in Chapter 15. Above this, all the established reconstruction-methods for air-showers can be applied as well. For example we can project the light-field onto images focused to different object-distances [Ng et al., 2005], see Section 9.4. On refocused images, the established [Hillas, 1985] reconstruction of air-showers can be used with the Cherenkov-plenoscope. We can project the light-field onto the areal intensity histogram in x, and y to reconstruct the air-showers, as shown in [Chantell et al.,

¹Also called focus-stack-deconvolution, or narrow-angle-tomography.

1998, Lizarazo et al., 2006]. And we can reconstruct the Cherenkov-light-front's three-dimensional structure in the moment when it rushes into the aperture-plane, as shown in [Fontaine et al., 1990].

2.5 Entering the Portal, entering the 1 GeV, 1 s gamma-ray-sky

To explore plenoptic perception in gamma-ray-astronomy, we propose a specific Cherenkov-plenoscope with an aperture-diameter of 71 m which we name Portal, see Figure 2.1. With Portal we introduce the cable-robot-mount to take advantage of the relaxed rigidity-constrains between the light-field-sensor and the imaging-reflector, see Chapters 11, and 16. The cable-robot-mount extensively uses computer-control to reduce the need for rigid and heavy structures. It is inspired by the cable-suspended radio-receiver of the Arecibo-Observatory [Altschuler and Nieves, 2002], the initial robot-crane-manipulator [Albus et al., 1993], and the fast cable-robot-simulator [Miermeister et al., 2016].

Portal uses first, a large, cable-suspended imaging-reflector with 71 m diameter and 106.5 m focal-length. Second, Portal uses a mechanically separated, cablesuspended light-field-sensor with 12.1 m diameter corresponding to 6.5° field-ofview. The two moving components are suspended independently of each other, such that the forces holding the light-field-sensor do not have to run through the large imaging-reflector and its mount. Portal's light-field-sensor has 515,023 light-field-cells (lixel) formed by N = 8,443 small cameras equivalent to classical picture-cells (pixel) with M = 61 principal-aperture-cells (paxel) each, see Chapter 7. Portal reaches zenith-distances up to 45° without the zenith-singularity of altitude-azimuth-mounts [Borkowski, 1987], and has only thin cables shadowing its aperture. During the day, Portal's light-field-sensor is parked on a pedestal next to the large imaging-reflector to ease service. The independent pointing of both light-field-sensor, and large imaging-reflector without a zenith-singularity allows Portal to point fast and hunt transient-sources.

Portal's goal is to drive the energy-threshold for gamma-rays down to 1 GeV to become the 'gamma-ray-timing-explorer' [Aharonian et al., 2001]. To minimize losses of Cherenkov-photons [Aharonian et al., 2001], and to maximize the threedimensional reconstruction-power of air-showers, we propose to install Portal high in altitude $\sim 5,000$ m a.s.l². Such exceptional dry, dark, and high sites with transparent atmospheres are already being used for astronomical instruments, such as the Llano de Chajnantor, Andes [Wootten, 2003], for the southern hemisphere and Ali, Himalaya [Kuo, 2017, Ye et al., 2015], for the northern hemisphere. In Chapter 5, we show pictures of the Portal Cherenkov-plenoscope.

 $^{^{2}}$ A.s.l. is short for above sea level.

Figure 2.4: Effective collection-area of Portal's trigger for gamma-rays coming from a point-source within the field-of-view. At 1 GeV, Portal effectively collects gamma-rays with an area of $\approx 30,000 \text{ m}^2$.

2.6 Estimating Portal's sensitivity

We give a first estimate on Portal's sensitivity for cosmic gamma-rays by simulating the observations of air-showers induced by gamma-rays and charged cosmicrays. We run a simulation, see Chapter 18, for the observation of individual air-showers which returns us the response of Portal's light-field-sensor. Only if the Cherenkov-photons together with the night-sky-background-photons fulfill the trigger-criteria, the response of the light-field-sensor is read-out, see Chapter 12. We set the trigger-threshold such that the accidental trigger-rate caused by fluctuations of the night-sky-background-photons during the dark night is far ($\sim 10^{-2}$) below the expected trigger-rate for air-showers, see Figure 12.10. With this trigger-threshold we estimate Portal's instrument-response-functions for a point-source of gamma-rays, see Figure 2.4, a diffuse pool of electrons, and a diffuse pool of protons, see both in Figure 2.5. We take the measured fluxes of cosmic electrons [Aguilar et al., 2014] and protons [Aguilar et al., 2015] and

Figure 2.5: Effective collection-area and solid-angle of Portal's trigger for cosmic-rays with a diffuse distribution of incident-directions.

Figure 2.6: Figure provided by Adrian Biland. The geomagnetic cut-off-rigidity estimated based on the measured earth's magnetic-field and the simulation of cosmic-ray-trajectories. Different locations on earth have different cutoff-rigidities. In Atacama-desert in South-America, cutoff-rigidities of $\approx 10 \,\text{GV}$ can be reached.

combine these with models [Lipari, 2002, Zuccon et al., 2003] regarding their efficiencies to produce air-showers in earth's atmosphere. The earth's magnetic field effectively deflects low energetic charged particles before they can penetrate the atmosphere deep enough to interact with the air and initiate air-showers [Supanitsky and Rovero, 2012]. Figure 2.6 shows earth's cut-off-rigidity for cosmic-rays. This way, we estimate not the flux of charged particles, but the flux of air-showers initiated by these charged particles in earth's atmosphere, see Figure 2.7. Knowing the true incident-directions of the simulated gamma-rays, we estimate Portal's angular resolution for a diffuse source, see Chapter 14. Portal's angular resolution reaches $\approx 0.31^{\circ}$ for an 68% containment-radius for gamma-rays at energies between 750 MeV and 1,500 MeV. Such an angular resolution of Portal would be good, but is still within the expected regime of former studies and other instruments, see Figure 2.8. In this first estimate for the sensitivity we neglect that Portal's angular resolution will be better for higher energies. We simulate a counting-experiment with an on-off-observation. We define five circular regions in Portal's field-of-view which all have a radius equal to the estimated angular resolution. We choose one on-region, which is centered around a hypothetical gamma-ray-source, and four additional off-regions which are centered at positions where no gamma-ray-sources are expected. Then we count the number of events reconstructed to originate in the on- and off-regions. With the off-regions, we estimate the expected number of background events in the on-region. Only if the number of events in the on-region exceeds the expected fluctuations of the background by at least a factor of five standard-deviations, we claim a detection for the hypothetical source. Figure 2.9 shows the expected trigger-rates for air-showers induced by gamma-rays and charged cosmic-rays when observing

Figure 2.7: The flux of air-showers initiated by charged particles in earth's atmosphere for a geomagnetic cutoff-rigidity of 10 GV. We chose a cutoff-rigidity of 10 GV as it is representative for a potential site in South-America, see Figure 2.6. We are conservative and estimate that the flux of air-showers initiated by cosmic-rays with rigidities below 10 GV does not vanish completely, but is reduced to 5%. Initial flux of cosmic-rays is taken from AMS-02's precision measurements [Aguilar et al., 2014] and, [Aguilar et al., 2015]. For the flux of airshowers below the rigidity-cutoff we follow the ideas discussed in [Lipari, 2002], and [Zuccon et al., 2003].

Figure 2.8: The angular resolution for the reconstructed incident-directions of gamma-rays. The angular resolution of Fermi-LAT [Abdo et al., 2010], the predicted angular resolution of the proposed 5@5 Cherenkov-telescope-array [Aharonian et al., 2001], and the estimated limits for the angular resolution of ground based air-shower-observations using reconstruction-methods from the year 2006 [Hofmann, 2006].

the quasar and bright gamma-ray-source 3FGL- $J2254.0+1608^3$. In Figure 2.9 we find that Portal indeed reaches its design-energy-threshold, as its differential trigger-rate for gamma-rays peaks at 1 GeV. With the expected trigger-rates for gamma-rays and charged cosmic-rays, we are now able to estimate Portal's sensitivity for the worst-case-scenario in which we do not have any separation-power to tell apart air-showers induced by gamma-rays from air-showers induced by protons. Figure 2.10 shows the sensitivities of the Portal Cherenkov-plenoscope, the Fermi-LAT satellite and other Cherenkov-telescopes. Beware, as we have no energy-reconstruction for Portal yet, we represent the sensitivity using the integral-spectral-exclusion-zone [Ahnen, 2017b]. This is different from the more common differential representation provided for most Cherenkov-telescopes. In Figure 2.10 we show Portal's sensitivity for two scenarios. First, a thin red curve shows Portal's sensitivity without any separation-power for gamma-rays and protons. This corresponds directly to the rates shown in Figure 2.9 without further cuts. Second, a wide red band shows Portal's sensitivity in the case that Portal could separate air-showers induced by hadronic particles from air-showers induced by electromagnetic particles with similar precision as it is possible on established Cherenkov-telescopes. The lower border of the wide red band corresponds to a rejection of 99% of the hadronic air-showers. At this point, the air-showers induced by electrons and positrons become the relevant fraction of the background. Although a basic separation of electrons from gamma-rays [Hofmann, 2006] might be possible on Portal, we did not investigate this option yet.

Note that in Figure 2.10, the ground based instruments are listed with 50 h exposure-time, while the satellite Fermi-LAT is listed with its full 10 years exposure-time. Since Portal's light-field-sequence $\mathcal{L}[c_x, c_y, x, y, t]$ contains multiple image-sequences $\mathcal{I}[c_x, c_y, t]$ of e.g. a dense array of seven large sized Cherenkov-telescopes, see Section 6.5, Portal can always fall back to the performance of Cherenkov-telescope-arrays for energies above the geomagnetic cut-off. In general, it can be assumed that Portal will reach at least the sensitivity of MAGIC for energies $\gtrsim 100 \text{ GeV}$. But in this estimate Portal does not make use of the established analysis for air-showers on Cherenkov-telescopes which is why Figure 2.10 does not show a smooth transition of Portal's sensitivity into the sensitivity of MAGIC at energies $\gtrsim 100 \text{ GeV}$.

³Also known as 3C454.3

Figure 2.9: The expected trigger-rates on Portal when observing the bright gamma-ray-source 3FGL-J2254.0+1608. The trigger-rates here are only for the on-region which on the sky-dome where we expect the source. The on-region's radius of 0.31° is based on Portal's angular-resolution, see Figure 2.8. The expected trigger-rates are based on the fluxes of air-showers presented in Figure 2.7, the flux of gamma-rays coming from 3FGL-J2254.0+1608 [Acero et al., 2015], and Portal's instrument-response-functions shown in the Figures 2.4, and 2.5. For energies below the rigidity-cutoff, Portal can observe the gamma-ray-sky signal dominated. The integrated rates in the on-region are: 94.2 s^{-1} for gamma-rays, 74.9 s^{-1} for electrons, and 458 s^{-1} for protons. This gives us a total trigger-rate of about $59 \times 10^3 \text{ s}^{-1}$ in the entire 6.5° field-of-view. From the peak of the expected differential trigger-rates for gamma-rays, we find that Portal indeed reaches an energy-threshold of 1 GeV. For more details on the trigger see Chapter 12.

Figure 2.10: The integral-spectral-exclusion-zones for the Portal Cherenkovplenoscope, the Fermi-LAT satellite, the MAGIC Cherenkov-telescopes, and the future planned Cherenkov-Telescope-Array (south). Note the different exposuretimes listed in the legend. Every point-like gamma-ray-source with a powerlaw like energy-spectrum (a straight line in this log-log-scale) that touches the integral-spectral-exclusion-zones of the instruments will be detected within the listed exposure-time. MAGIC: [Ahnen, 2017b], Fermi-LAT: [Wood et al., 2016], CTA-south: [Fioretti et al., 2016], and [CTAO gGmbH, 2018], Crab Nebula: [Aleksić et al., 2015].
Chapter 3

Outlook

Since satellites such as Fermi-LAT and the Portal Cherenkov-plenoscope share the same energy-range, it would be a great opportunity for gamma-ray-astronomy to have both such complementary observatories. All the gamma-ray-sources found in satellite-surveys in the full but inert gamma-ray-sky taken over years of exposure, are potential targets for observations with Portal, see Figure 3.1. For instance Fermi-LAT, with $\approx 20\%$ of the sky field-of-view, can observe a large number of sources with a simple monitoring strategy. The pointing-strategy of the Portal Cherenkov-plenoscope with only $\approx 0.1\%$ of the sky field-of-view on the other hand would best be guided to observe dedicated sources with a very large statistics of gamma-rays in a short period of time. This is a complementary observation not possible with satellites [Aharonian et al., 2001]. To point out the complementary nature of e.g. the Fermi-LAT satellite and Portal, consider the following: The ratio $\frac{100\%}{0.0804\%} = 1,244$, see Figure 5.12 by which Fermi-LAT's field-of-view exceeds Portal's field-of-view, is roughly the ratio $\frac{10 \text{ years}}{50 \text{ h}} = 1,752 \text{ by}$ which Portal's time-to-detections undercut the time-to-detections of Fermi-LAT. Today, we face the challenge of the cosmic-rays origin. We face the challenge of dark-matter-phenomena. We face the challenge of asymmetry between matter and anti-matter. We face the challenge of extra-galactic-background-light and extra-galactic magnetic-fields. We face the challenge of the rapid transientphenomena like gamma-ray-bursts, and fast-radio-bursts. We face the challenge of electromagnetic counterparts for gravitational-waves in rapid cosmic mergers. Designed to take on the challenges of our generation, Portal is the most powerful gamma-ray-timing-explorer proposed yet. As Felix Aharonian said:

'...the scientific reward of the implementation of ground based approach in GeV gamma-ray-astronomy will be enormous' [Aharonian, 2005]

3.1 Searching for dark matter

The velocity-dispersions of stars in galaxies and the separation of baryonic matter from gravitational-lensing matter, which was observed in the colliding galaxies in

Figure 3.1: The flux of gamma-ray-sources above one GeV versus the time-todetections with Portal. These are the gamma-ray-sources listed in Fermi-LAT's 3FGL catalog [Acero et al., 2015], and the flux (Flux1000) listed in the catalog. Vertical black line marks 50 h. Almost all sources in the Fermi-3FGL-catalog can be detected by Portal in less than 50 h, see dotted vertical line on the right. This figure corresponds to Portal's thin, red integral-spectral-exclusion-zone without any gamma-hadron-separation in Figure 2.10. With gamma-hadron-separation, the times-to-detection reduce by a factor of ≈ 6 .

the Bullet-Cluster [Clowe et al., 2006], suggest the existence of a dark type of matter. Together with the prediction of a lightest super-symmetric particle and the cosmological evolution of the early universe, today the scenario of the so called weakly interacting massive particle (WIMP) is frequently debated. The non baryonic, and dark WIMP would have been created thermodynamically in the early universe and is now assumed to form gravitationally bound clumps in galaxies. The WIMP scenario predicts gamma-ray emission from annihilation which could be visible as a halo-emission in such clumps of dark matter, and is already investigated by current instruments [Aharonian et al., 2006a, Bertone, 2010]. Portal would be ideal to not only support Fermi-LAT's quest for upper limits on such annihilation features from the WIMP but to take over and push the sensitivity-frontier since Portal's unmatched low energy-threshold for cosmic gamma-rays in combination with its large collection area are the key features [Bergström et al., 2011,Bergström, 2013] to reveal the heavy sector of dark matter in an indirect search.

3.2 Resolving Crab-Nebula-flares

The discovery of powerful gamma-ray-flares above 0.1 GeV of the nearby supernova-remnant SN 1054 (Crab-Nebula) [Tavani et al., 2011] are indicating that shorter time-to-detections will potentially reveal further insights into the production and acceleration of cosmic-rays, and the emission of gamma-rays in such extreme environments.

3.3 Investigating massive black holes

Relativistic plasma-jets driven by super massive black holes inside active-galacticnuclei are believed to result from the conservation of angular-momentum of in falling matter. Although these jets extend up to distances which usually are found in between galaxies, their creation in the vicinity of the black hole remains unresolved by todays imaging-instruments. However, fast variability in the emission of gamma-rays from these objects give hints to the particle accelerations at the base of the jets. Only short after the first sighting of gamma-rays from Markarjan 421 with a ground based telescope [Punch et al., 1992], the Whipple Observatory was able to reveal flux-doubling-timescales in the 1 hour regime [Gaidos et al., 1996]. Latest observations made by the MAGIC Cherenkov-telescope with its lower energy-threshold for gamma-rays on IC 310 were already able to reveal time-structures in the 1 minute regime [Aleksic et al., 2014]. The flux of IC 310 rose up to between 1 and 5 times the flux of the Crab Nebula, and MAGIC was able to provide estimates for the flux within time-bins of only ~ 120 s. The observation of flux-variabilities on such small time-scales allow insights into the structure of the bases of the jets close to the black holes which are far more precise than the structures resolved by any imaging method. Further, flaring activegalactic-nuclei can serve as a lab to probe the energy-dependence of the speed of light as done by the H.E.S.S. Cherenkov-telescopes on PKS 2155-304 [Aharonian et al., 2008], and the MAGIC Cherenkov-telescopes on Markarjan 501 [Albert et al., 2008a]. Time structures in the 1 minute regime were reported on PKS 2155-304 [Aharonian et al., 2008]. The Portal Cherenkov-plenoscope will detect the active-galactic-nuclei Markarjan 421 in ≈ 4.0 s, PKS 2155-304 in ≈ 7.5 s, and Markarjan 501 in ≈ 33.7 s when these are not flaring, but in their average, low states of activity which is below 0.5 times the flux of the Crab Nebula [Acero et al., 2015]. These time-to-detections are without any gamma-hadron-separation and correspond to the solid, red line in Figure 2.10, and the time-to-detections in Figure 3.1. However, these time-to-detections go down to 0.8 s for Markarjan 421, 1.6 s for PKS 2155-304, and 6.4 s for Markarjan 501 if gamma-hadron-separation was implemented and could be made as powerful at the low energies of the Portal Cherenkov-plenoscope, as it has been made at $\sim 100 \,\text{GeV}$ on todays Cherenkovtelescopes.

3.4 Sneaking below the gamma-ray-horizon – Probing extra-galactic-background-light

The red-shifted light emitted by early stars and galaxies is supposed to be the second brightest [Dole et al., 2006] diffuse background-radiation after the cosmic microwave-background, and yet we only know little about it. Direct observations of this infra-red, so called extra-galactic background-light, are difficult because it is out shined by the zodiacal light and other nearby sources including the instruments themselves. However, the attenuation of gamma-rays which interact with the extra-galactic background-light via pair production ($\gamma_{\text{high energy}} + \gamma_{\text{infra-red}} \rightarrow e^+ + e^-$) serves as an indirect measurement of the density of the extra-galactic background-light [The MAGIC Collaboration, 2008b, Aharonian et al., 2006b]. Figure 3.2 shows the attenuation of gamma-rays in the extra-galactic-background-light. With its low energy-threshold for gamma-rays, the Portal Cherenkov-plenoscope will not only be able to look deeper and see more sources in the gamma-ray-sky [Taylor, 2017] than any other existing or proposed ground based instrument.

3.5 Probing extra-galactic magnetic-fields

The strength and the origin of extra-galactic magnetic-fields might give valuable insights to the early formation of galaxies, but direct measurements are be-

Figure 3.2: Figure taken from [Fermi-LAT Collaboration et al., 2018]. The gamma-ray-horizon measured by Fermi-LAT. Here $\tau_{\gamma\gamma} = 1$ indicates the point after which the universe becomes opaque for gamma-rays. To see distant sources, the energy-threshold must be low.

yond our current reach. However, gamma-rays can serve as an indirect probe to the strength of extra-galactic magnetic-fields [Neronov and Vovk, 2010]. Strong extra-galactic magnetic-fields are expected to cause a diffuse halo-emission around distant point-sources as high energetic gamma-rays are expected to undergo pair-production with the extra-galactic-background-light to create electrons and positrons which in turn create lower energetic gamma-rays due to inverse Comptonscattering in the extra-galactic magnetic-fields. The trajectories of the charged electrons and positrons in between this conversion are bend by the magnetic-fields, so that the extension of the halo-emission observed on earth gives an estimate on the column density of the extra-galactic magnetic field's strength.

3.6 Resolving gamma-ray-bursts on the 10^{-5} s time-scale

Thanks to the tremendous efforts [Aasi et al., 2015] put in the detection of gravitational waves, we are now able to identify the merging of e.g. two neutron-stars at cosmic distances when these heavy objects spiral into each-other. Right from the start, electromagnetic counterparts for the short-lived gravitational-wavetransients were looked after [Aasi et al., 2014]. After the first limits [Savchenko et al., 2016], finally the coincident detection of gravitational wave GW 170817 and the short gamma-ray-burst GRB 170817A [Abbott et al., 2017b] was made. Most likely all our current models and theories approach their limits in the extraordinary environments of cosmic mergers which makes the observation of gammarays emitted in e.g. neutron-star-neutron-star-mergers an outstanding probe. Already the current generation 'Advanced-LIGO' of gravitational-wave-detectors

Figure 3.3: Figure taken from [Cannon et al., 2012]. Advanced-LIGO's expected detection-rate versus the time before a neutron-star-neutron-star-merger. The thick line marks the most probable detection-rate, and the shaded areas represent its 5% to 95% confidence-interval.

is expected to observe about one neutron-star-neutron-star-merger per year with an alert-time of about 100s before the actual merger, see Figure 3.3 [Cannon et al., 2012]. With future gravitational-wave-detectors [Abbott et al., 2017a] there might be the opportunity of having enough early alerts, so that a guided observation for ground based instruments such as the Portal Cherenkov-plenoscope becomes feasible. For gamma-ray-bursts that emit gamma-rays with energies above $\sim 1 \,\text{GeV}$, Portal's collection-area will allow to have about four ordersof-magnitude more statistics and thus time-resolution than any space-born instrument. For example, in the long gamma-ray-burst GBR-130427A, the Fermi-LAT satellite detected [Ackermann et al., 2014] over 500 gamma-rays with energies above 100 MeV, and still 15 gamma-rays with energies above 10 GeV. If this bright, and long gamma-ray-burst happened within Portal's field-of-view, Portal would have detected it within 4.3×10^{-5} s, and Portal would have detected gamma-rays at a rate of up to $1.7 \times 10^5 \,\mathrm{s}^{-1}$. From [Ackermann et al., 2014], we conclude that the gamma-ray-flux of GBR-130427A above $^1 \; 1 \, {\rm GeV}$ is $\sim 10^{-4} \,\mathrm{cm}^{-2} \,\mathrm{s}^{-1}$. Compare this flux and our estimated time-to-detection to the steady gamma-ray-sources shown in Figure 3.1.

Today, it is not known if the short gamma-ray-bursts coincident with neutronstar-neutron-star-mergers emit gamma-rays with energies above $\sim 1 \text{ GeV}$, such as it was observed in the long gamma-ray-bursts coincident with hyper-novae. But Portal is a good way to find out. Assuming, without any particular model in mind, that the flux of a short gamma-ray-burst above 1 GeV is large enough for a satellite with $\sim 1 \text{ m}^2$ collection-area to detect 0.01 gamma-rays, Portal will still detect a flood of 300 gamma-rays. Gamma-ray-bursts also serve as test for

¹Called 'Flux1000' in 3FGL [Acero et al., 2015], see Figure 3.1.

variations of the speed-of-light [Abdo et al., 2009a] where Portal's high timingresolution is key to push the frontier of our models.

3.7 Seeing pulsars below the 10 GeV cut-off

When stars run out of light elements to fuse, the outwards pushing pressure of the fusion-heat can not longer outbalance the inward pulling gravitational binding. When gravitational pressure takes over, the electron-nuclei-plasma in the star's core condenses to neutrons while the outer shell of the star is blown away in what we observe as a super nova. The remnant is a compact neutron-star with high magnetic field densities on its surface which rotates rapidly inside a nebula of the former outer shell. On earth, we observe a pulsating emission of photons timed in phase with the rotation of these neutron-stars. Therefore, we call them pulsars. For most pulsars, the gamma-ray-emission shows a steep cutoff below 10 GeV [Aharonian et al., 2012]. At least for the pulsar inside the Crab-nebula the energy extends, barely visible with todays instruments after 320 h of exposure, into the 1,000 GeV range [Ansoldi et al., 2016]. Portal is the first ground based instrument to measure high gamma-ray statistics in short periods of times of pulsars far below the 10 GeV cutoff. In addition, Portal at the same time can observe the high energy emission in the 1,000 GeV range using classic Cherenkov telescope analysis. Portal is ideal to extend our knowledge on the gamma-rayemission from pulsars.

3.8 Searching for nearby pulsars and antimatteranisotropy

An excess of positrons in the cosmic-rays at energies above 10 GeV was measured by space born instruments [Adriani et al., 2009] and was not expected from the positron-production-efficiency of galactic propagation-models for cosmic-rays. Beside the hype on possible explanations using dark matter, this excess might be explained with existing knowledge on nearby pulsars such as Geminga and Monogem [Linden and Profumo, 2013]. There might also be unknown pulsars even closer to us which we did not detect yet because their beamed emissions are missing earth. A strong indication for the nearby-pulsar-theory would be an anisotropy in the arrival-directions of the positron flux here on earth. Such anisotropy might be measured by current and future Cherenkov-telescopes [Linden and Profumo, 2013] using years of exposure-time. Portal on the other hand can exploit the geomagnetic cutoff to have a rather pure sample of positrons [Supanitsky and Rovero, 2012]. The remaining background of gamma-rays could be subtracted using the static gamma-ray-sky observed by Fermi-LAT [Acero et al., 2015]. As the earth with its magnetic field and Portal rotate below the sky, the flux of positrons can be probed over a wide range of galactic directions. This combination makes Portal an unique instrument to investigate the anisotropy of the anti-matter-positron-sky.

3.9 Imaging bright stars with milli arcsecondresolution

Beside observing the gamma-ray-sky, the Cherenkov-plenoscope can at the same time image bright stars with angular resolutions approaching 10^{-3} arcseconds. Its plenoptic-perception and 1 ns arrival-time-resolution for single-photons offer a unique opportunity for stellar-intensity-interferometry. Currently, the proposed implementations of stellar-intensity-interferometers in arrays of Cherenkovtelescopes [Dravins et al., 2012, Dravins et al., 2013], face large technological challenges for signal-processing and signal-transmission. Like the trigger in Cherenkovastronomy, a stellar-intensity-interferometer needs instant access to the photosensors that sample nearby incident-directions (c_x, c_y) , but separate supportpositions (x, y). In telescope-arrays, such photo-sensors are housed in separate telescopes. To correlate their signals, flexible, high bandwidth cables need to be routed over large distances. In addition, the signals need adjustable timedelays to correct for the pointing of the telescopes. All of this either limits the field-of-view, this is the number of photo-sensors used in each telescope, or the exposure-time. In the Portal Cherenkov-plenoscope on the other hand, photosensors that sample same incident-directions, but separate support-positions are already $\approx 15 \,\mathrm{cm}$ close together inside the light-field-sensor's small cameras. In the Cherenkov-plenoscope there is no need for adjustable time-delays, and no need for signals to leave the protective housing of the light-filed-sensor. The unique geometry of the Cherenkov-plenoscope potentially allows to cost-efficiently install signal-correlations for stellar-intensity-interferometry in each small camera in the light-field-sensor, thus offering huge field-of-views. Compared to Cherenkovtelescope-arrays, the Portal Cherenkov-plenoscope can only offer a 71 m baseline for correlations, what is potentially enough for resolving $\approx 2 \times 10^{-3}$ arcseconds. Still, this resolution is in the regime of the European-Extremely-Large-Telescope, and the Very-Large-Telescope- Interferometer [Dravins et al., 2012].

The Cherenkov-plenoscope offers a novel and unique trade-off for stellar-intensityinterferometry: A limited baseline, and thus a limited angular resolution on the one hand, but much less challenging signal-transmission and signal-processing, much wider field-of-views, and unlimited exposure-times on the other hand.

3.10 Probing the chemical composition of cosmicrays

To constrain the origin and the propagation of cosmic-rays, their chemical composition at energies of $\sim 10^6 \,\text{GeV}$ is of great interest. At this energy, the cosmic-rayspectrum has one of its few features, the so called knee. Space-born detectors like AMS-01 [Aguilar et al., 2010], and AMS-02 can measure the chemical composition of cosmic-rays precisely. But, at energies of above $\sim 10^3 \,\text{GeV}$, their small collection areas leave the chemical composition of cosmic-rays unresolved. Ground based air-shower-tail-detectors have large collection-areas to observe cosmic-rays at energies around the knee. They can even estimate the cosmic-ray's charge by measuring the air-shower's muon-multiplicity. But muon-multiplicity depends on hadronic interaction-models. Today these hadronic models need to be extrapolated far beyond the energies reached in particle-colliders. A model-independent alternative is to observe the direct Cherenkov-light emitted by the cosmic-ray to deduce its charge [Kieda et al., 2001]. Direct Cherenkov-light-observations with Cherenkov-telescope-arrays have large collection-areas of $\sim 10^5 \,\mathrm{m^2}$. But measuring the cosmic-ray's first-interaction-altitude, at which the emission of direct Cherenkov-light stops, is challenging [Aharonian et al., 2007].

In a first attempt [Engels, 2017], Axel Arbet Engels simulates an idealized Cherenkovplenoscope with the goal to estimate the cosmic-ray's first-interaction-altitude in each individual air-shower. He reconstructs the emission-positions of the Cherenkov-photons in three spatial dimensions from the light-field-sequence using tomography. He uses a simple filtered-back-projection implemented by the author of this thesis (S.A.M.), see Figure 15.4 in Chapter 15. Axel's first findings indicate a potential to resolve the first-interaction-altitude within $\approx 1,000$ m. This would allow a charge-resolution of 14.3% for iron. Tomographic reconstructions of airshowers with either a Cherenkov-plenoscope or an array of Cherenkov-telescopes, have the potential to reveal insights beyond the simple ellipse-models [Hillas, 1985] often discussed in reconstructions based on imaging.

Chapter 4

Conclusion

Before this thesis, the 1 GeV gamma-ray-sky with its high variability and fast transient-phenomena at and below the \sim 1 second-time-scale has been far out of reach for astronomy. But this is about to change now.

Our proposed 71 m Portal Cherenkov-plenoscope offers $30,000\,\mathrm{m^2}$ collection-area^1 for cosmic gamma-rays at 1 GeV. It can detect several sources in the steady, non-flaring gamma-ray-sky within seconds². It can, for the first time, study the gamma-ray-emission of pulsars below the crucial $10 \,\mathrm{GeV}$ cutoff-energy³. It can look deeper into the universe, and thus choose from more potential sources, than any existing or proposed ground based instrument⁴. Portal can sneak below the geomagnetic cutoff for charged $cosmic-rays^5$ and study the positronsky's anisotropy⁶. Its novel cable-robot-mount has no near-zenith-singularity⁷ and thus can point the Cherenkov-plenoscope intrinsically faster during its hunt for transient-phenomena. The Cherenkov-plenoscope can reconstruct the inner structures of air-showers in three spatial dimensions⁸, which potentially opens a window for particle-physics. Portal's field-of-view is 170% the solid-angle of current Cherenkov-telescopes⁹. And dedicated Cherenkov-plenoscopes can be build to push the current generation's field-of-view by more than one order-ofmagnitude¹⁰. Portal can potentially run 8,443 stellar-intensity-interferometers simultaneously across its field-of-view¹¹, each having 61 support-positions on the aperture-plane. Portal's field-of-view is, for the first time in Cherenkovastronomy, free¹² of aberrations and distortions and thus allows a more precise reconstruction of cosmic gamma-rays than any other existing or proposed Cherenkov-telescope. Portal can be build now using established technology¹³. And it costs¹⁴ only $\approx 218.5 \times 10^6$ CHF, a fraction of the costs for a satellitemission.

Chapter 5

Meeting Portal

Figure 5.1: The logo of the Portal Cherenkov-plenoscope.

To meet the Portal Cherenkov-plenoscope, we take you on a picture-tour. Figure 5.1 shows Portal's logo. Since the word telescope is about far seeing, it contradicts the plenoptic method which is about close seeing in the vicinity of the aperture. Therefore, we do not use the term 'light-field-telescope'. Instead, we propose to call this novel class of instrument: Plenoscope. The term is first used by Fredrik Bergholm [Bergholm et al., 2002] to describe a hand-held optics with an eyepiece to explore light-fields and plenoptic-perception. During this thesis, we created the term independently ourselves again.

The pictures of Portal shown here are rendered with the same program which we use to propagate Cherenkov- and night-sky-background-photons, see Section 18.2. Here we see Portal with its dedicated cable-robot-mount which we discuss in Chapter 16. The author of this thesis (S.A.M.) proposes the concept of a cablerobot-mount. And in his master-thesis [Daglas, 2017], civil-engineer Spyridon Daglas works out the details of the cable-robot-mount shown here.

Figure 5.2 shows the Portal Cherenkov-plenoscope from the side in a distance of $\sim 1 \text{ km}$. The four 162 m tall masts supporting the light-field-sensor potentially will become quite a landmark. In Figure 5.3 we see Portal from $\sim 1 \text{ km}$ above. The large 71 m imaging-reflector is enclosed by rectangular concrete-pillars in a circle with 128 m diameter. The four outer masts are on a circle with 336 m diameter. In Figure 5.4 we see Portal's large, 71 m diameter imaging-reflector. It is composed from small 2 m^2 mirror-facets mounted on a three layer space-truss made out of carbon-fiber-tubes. Figure 5.5 shows the interplay of imaging-

reflector and light-field-sensor from the top, and Figure 5.6 shows it from the side. The two independent mounts supporting the two components always try to establish the desired target-geometry between the two. Depending on the desired default-focus, see Section 12.6, the light-field-sensor is $\approx 105 \,\mathrm{m}$ away from the imaging-reflector. The light-field-sensor looks red, because we can see the red photo-sensors through the lenses. The light-field-sensor is 12.1 m in diameter what corresponds to 6.5° field-of-view. In Figure 5.7 we see the space-truss structure of a mast, and the light-field-sensor in the background. The space-truss-design is adopted from wide spread overhead-power-lines. Figure 5.8 shows the light-fieldsensor inside its icosahedron-shaped cage and one of the four masts supporting it in the background. The cage-design is adopted from the cable-robot-simulator, see Figures 16.1, and 16.2. Figure 5.9 shows the densely packed small cameras inside Portal's light-field-sensor. Same as in the conceptual Figures 2.2, and 2.3, the photo-sensors are red, and the walls separating the small cameras are green. In Figure 5.10 we look straight into the light-field-sensor from a close distance of $\sim 2 \,\mathrm{m}$. Through the lenses, we see the red photo-sensors and the green walls. A single, isolated small camera is shown in Figure 5.11. The dimensions of the small camera are discussed in Chapter 7, and shown in Figure 7.2.

In Figure 5.12 we compare the field-of-views of current Cherenkov-telescopes, the Fermi-LAT satellite, and the Portal Cherenkov-plenoscope. Using plenopticperception to overcome aberrations, see Chapter 10, Portal's field-of-view could be made even larger. The only reason here to limit Portal's field-of-view is costefficiency for being a gamma-ray-timing-explorer that will focus on individual sources. In Figure 5.13 we compare the aperture of Portal's imaging-reflector to past and present apertures in Cherenkov-telescopes.

Figure 5.3: The Portal Cherenkov-plenoscope, seen from the top. Outer mast-circle is 336 m in diameter, and inner concrete-pillar-circle is 128 m.

Figure 5.4: The large, 71 m diameter imaging-reflector. Zenith-distance is 30°. Space-truss-design by civil-engineer Spyridon Daglas.

Figure 5.5: Light-field-sensor and imaging-reflector seen from the top. The light-field-sensor looks red, because we can see the red photo-sensors through the lenses.

Figure 5.6: Light-field-sensor and imaging-reflector seen from the side.

Figure 5.7: Masts and light-field-sensor in the background. The space-truss-design is adopted from overhead-power-lines. It is a fractal design composed from repeatable modules.

Figure 5.8: Light-field-sensor and mast in the background. Compare the icosahedron-shaped cage in Figures 16.1, and 16.2. The red light-field-sensor has 12.1 m diameter corresponding to 6.5° field-of-view.

Figure 5.9: Inside the light-field-sensor. Close-up on small cameras.

Figure 5.10: Looking into the light-field-sensor. Looking into the densely packed array of small cameras.

Figure 5.11: A small camera of Portal's light-field-sensor. A single biconvex lens with a hexagonal aperture in front of an image-sensor made out of M = 61 hexagonal photo-sensors. The photo-sensors on the image-sensor are red. Surfaces touching neighboring small cameras are green. The red and green color-scheme allows to compare the Figures 2.2, and 2.3. For dimensions see Figure 7.2.

Figure 5.12: The field-of-views of Cherenkov-telescopes, the Portal Cherenkovplenoscope, and Fermi-LAT. Here 100% is the full 4π sr. H.E.S.S. Chapter 6

Focusing and a narrow depth-of-field

Every telescope with an extended aperture has the limitation of focusing and the limitation of a narrow depth-of-field. The bigger the aperture, the narrower becomes the depth-of-field, and the bigger becomes the need for focusing. In this Chapter we demonstrate and discuss the shortcomings of imaging on Cherenkovtelescopes. First, we remind ourselves what imaging is all about. Second, we discuss the theory behind focusing and the depth-of-field. And third, we present example air-shower-images recorded with different aperture-sizes and different focuses.

6.1 Defining imaging

Imaging is about filling an intensity-histogram based on the incident-directions of incoming photons. The resulting intensity-histogram is called image or picture and its bins are often called picture-cells, or pixels for short¹. The most simple model for imaging is the pin-hole-camera.

Point like apertures

In a pin-hole-camera, all photons pass through a single point in the apertureplane, see Figure 6.1. The intercept-theorem tells us where a photon is going to hit the sensor-plane when we know the photon's incident-direction. On the pinhole-camera, the image is sharp for all objects in the scenery. Regardless of the object-distance g of the object, the object will only illuminate a single point on the sensor-plane. Since all objects in all object-distances are always sharp, there is no need for focusing, and there is no narrowing of the depth-of-field. There is

¹Many imaging-systems, e.g. Cherenkov-telescopes are designed so that the photo-sensors in their image-sensors directly correspond to a pixel. However, we define a pixel to be a bin in an intensity-histogram based on the incident-directions of photons, and not to be a physical device like a photo-sensor.

Figure 6.1: The pin-hole-camera. Long horizontal line is the optical-axis, point a is the hole in the aperture. Thin vertical line in distance d is the sensor-plane. A photon emitted in object-distance g passes through point a on the aperture-plane and is absorbed on the sensor-plane in point i.

just one problem with the pin-hole-camera. A point like aperture will not collect any photons. To collect photons, we need an extended aperture.

6.2 Extended apertures

Real telescopes have extended apertures. And when the aperture is extended, photons with same incident-directions, this is photons which will be assigned to the same pixel in the image, might enter the aperture at different supportpositions. Such two parallel photons can not be emitted from the same point in space (from the same object). Thus the image will be blurred. The extension of the aperture allows us to collect photons, but it is the reason why not all objects in an image can be sharp at the same time. Extended apertures are described by the Thin-lens-equation

$$\frac{1}{f} = \frac{1}{g} + \frac{1}{b},$$
 (6.1)

and the intercept-theorem, see Figure 6.2. The Thin-lens-equation describes in which image-distance b the sensor-plane must be in order to record a sharp image of an object in object-distance g when the focal-length of the imaging-system is f. An image of an object is sharp when the sensor-plane is positioned such that all the photons which passed the aperture and came from the object (from a point in space), converge on the sensor-plane. In Figure 6.2 we find that the image i, i', i'' is a scaled projection of the aperture-function a, a', a''. We can describe the images of objects that are not in focus as a sharp image, recorded by a pin-hole-camera, that got convolved with the scaled aperture-function of the extended camera. This blurring caused by the aperture-function is often discussed as Bokeh [Merklinger, 1997, Ahnen et al., 2016a], where the author of this thesis (S.A.M.) took the leadership of the investigations for [Ahnen et al., 2016a]. In Figure 6.2, the narrowness of the depth-of-field can be described as

Figure 6.2: An imaging-system with focal-length f. Long horizontal line is the optical-axis, thick vertical line is the principal-aperture-plane. The three principal-rays of a light-source in object-distance g are shown to converge in image-distance b. However, the principal-rays do not converge on the sensorplane since it is in sensor-plane-distance $d \neq b$. The image of the object is not sharp as it stretches from i to i''. Here the imaging-system passes the photons through the principal-aperture-plane, like a lens. For imaging-reflectors, the figure is mirrored along the principal-aperture-plane.

the angle between the line \overline{ai} and the line $\overline{a''i''}$. If the angle between \overline{ai} and $\overline{a''i''}$ is small, the depth-of-field is wide. Objects in a wide range of object-distances will appear sufficiently sharp in the image. On the other hand, if the angle between \overline{ai} and $\overline{a''i''}$ is large, only objects from a narrow region of object-distances (depth-offield) will appear sufficiently sharp in the image. So we find that focusing is about adjusting the distance between the sensor-plane and the principal-aperture-plane such that a desired object is 'sharp' in the image. And a narrow depth-of-field is about the problem that we can not have all objects from different object-distances sharp in the image at the same time. In the introduction of [Bernlöhr et al., 2013], we find² an estimate

$$g_{\pm} = g(1 \pm pg/(2fD))$$
 (6.2)

for the start-object-distance g_{-} and end-object-distance g_{+} of the depth-of-field on a Cherenkov-telescope which is based on the thoughts of [Hofmann, 2001] where also the Thin-lens-equation 6.1 is used. Here p is the extent of a pixel projected onto the image-sensor, and D is the aperture-diameter of the imaging-reflector. A Cherenkov-telescope of the same size of Portal would have a depth-of-field extending from $g_{-} = 9.2 \,\mathrm{km}$ to $g_{+} = 10.8 \,\mathrm{km}$ for an focus set to an objectdistance of $g = 10.0 \,\mathrm{km}$. It means, that only the narrow range of an air-shower between 9.2 km and 10.8 km above the principal-aperture-plane will be 'sharp', and the rest is blurred. Here the depth-of-field is only 1.6 km. Depending on the energy, air-showers can have extensions in the atmosphere which exceed the depth-of-field by about an order-of-magnitude.

 $^{^2\}mathrm{In}$ [Bernlöhr et al., 2013], the authors use d instead of g as variable-name for the object-distance.

6.3 The Cherenkov-telescope's perception

Imaging with Cherenkov-telescopes runs into a physical limit when we want to lower the energy-threshold for cosmic particles. To lower the energy-threshold for cosmic particles, Cherenkov-telescopes need larger apertures, need to move further up in altitude to get closer to the air-shower, and need higher angular resolution. But all these three measures:

- larger apertures
- closer to the air-shower
- higher angular resolution

are also the key measures to narrow the depth-of-field which will blur the images. First, in Figure 6.2 we see that when the aperture is enlarged, the points a, a', and a'' will move further apart, and thus the image i, i', and i'' will be spread out even more to blur the image. Second, in the Depth-of-field-equation 6.2 we find that the depth-of-field, this is the difference between g_+ and g_- , becomes narrower the closer we move the Cherenkov-telescope to the air-shower, this is the smaller the object-distance g becomes. And third, from Figure 6.2 we conclude that when the angular resolution of the pixels is increased, a spreading of the points i, i', and i'' will be more apparent and thus renders the additional angular resolution useless by blurring the image.

Imaging itself becomes a physical limit which prevents us from observing low energetic cosmic gamma-rays in the regime below 25 GeV with Cherenkov-telescopes.

6.4 The Cherenkov-plenoscope's perception

But what if the sensor-plane in Figure 6.2 not only knew that three photons arrived in the points i, i', and i''. What if it knew that these three photons traveled on the trajectories ia, i'a', and i''a''. In this case we knew based on the Thin-lens-equation 6.1, and the intercept-theorem that the photons approached the aperture on the trajectories ae, a'e, and a''e. In this case we had a strong hint that there were photons produced in the point e.

This is plenoptic perception [Lippmann, 1908], this is what the Cherenkov-plenoscope senses. With plenoptic perception, the Cherenkov-plenoscope turns the limitations of imaging into three-dimensional reconstruction-power. With the Cherenkovplenoscope, the three measures needed for lowering the energy-threshold (larger apertures, closer to the air-shower, higher angular resolution), all improve the three-dimensional reconstruction-power for air-showers. First, when the aperturediameter of the imaging-reflector is increased, the baselines for three-dimensional reconstructions are enlarged. This extends the reconstructible volume of atmosphere further up in front of the aperture-plane. Second, when the Cherenkovplenoscope is build higher in altitude, the air-shower will be closer to the aperture where the three-dimensional reconstruction-power is largest due to the finite baseline and finite angular resolution. Third, when the angular resolution of the pixels in increased, again the reconstructible volume of atmosphere extends further up in front of the aperture-plane.

Where the telescope works best with small apertures, the plenoscope works best with large apertures. The Cherenkov-plenoscope will probably take over the performance of Cherenkov-telescopes at aperture-diameters of about 25 m for the reasons of limited perception due to imaging discussed in [Bernlöhr et al., 2013], and [Hofmann, 2001].

6.5 Example images of air-showers

We demonstrate the need for focusing and the limitations of a narrow depthof-field using five simulated observations of air-showers. For each of the five simulated gamma-ray-events, we compile a collection of four different classes of figures.

The first class of figures shows the image of the air-shower recorded with a giant Cherenkov-telescope of the same size of Portal with an aperture-diameter of 71 m. The second class of figures shows an array of seven images from the same airshower recorded by a dense array of seven large Cherenkov-telescopes with an aperture-diameter of 23.7 m each. Figure 6.3 shows how the apertures of the seven large Cherenkov-telescopes are positioned in the aperture of the giant Cherenkovtelescope. The third class of figures shows eight images from the same air-shower again recorded with the giant 71 m Cherenkov-telescope, but this time the focus is set to eight different object-distances. The fourth class of figures shows the distribution of the true emission-positions of the Cherenkov-photons which were detected by the instruments. The example figures are grouped as shown in Table 6.1. Such high energetic air-showers will be rare in the observations of Portal, but serve well as a demonstration for imaging. If not explicitly stated differently, the images of the Cherenkov-telescopes shown here are focused to an object-distance of 10 km. The figures show only the intensity of photons which were classified to be Cherenkov-photons, see Chapter 13.

Redefining imaging – Cherenkov-plenoscope

All the figures in this chapter show the images of air-showers exactly the way a classic Cherenkov-telescope would have observed them. However, we create these images from projections of the light-field observed by our Portal Cherenkovplenoscope. As we discuss in Chapter 9, we can project the light-field of the Cherenkov-plenoscope onto images which correspond to images of Cherenkovtelescopes with different support-positions, different aperture-diameters, and different focuses. For the demonstration of the effects of a narrow depth-of-field on

Figure 6.3: To demonstrate the effect of different aperture-sizes and different support-positions, we comfortably fit seven 23 m Large-Size-Telescopes [Acharya et al., 2013] of the upcoming Cherenkov-Telescope-Array into the aperture of Portal. The numbers of the seven large Cherenkov-telescopes (0 to 6) correspond to the numbers in the lower left corners of the images in the Figures 6.5, 6.9, 6.13, 6.17 and 6.21.

images of air-shower taken by Cherenkov-telescopes, it is not relevant that the images were actually projections of a light-field recorded by a Cherenkov-plenoscope. But we point this out here to demonstrate that the Cherenkov-plenoscope can always fall back to all the reconstruction-methods for air-showers which were developed for Cherenkov-telescopes and arrays of Cherenkov-telescopes. Our Portal has not only seven but 61 paxels to segment its aperture. But for the purpose of this demonstration we integrate over these 61 paxels using the mask shown in Figure 6.3 to obtain seven paxels corresponding to an array of seven 23.7 m Cherenkov-telescopes. Compare this to the 23 m Large-Size-Telescope [Acharya et al., 2013] of the upcoming Cherenkov-Telescope-Array.

gamma-ray	energy/GeV	$x/{ m m}$	$y/{ m m}$	Figures 71 m telescope	Figures 23 m telescope-array	Figures 71 m telescope refocused	Figures true emission-positions
1	121.8	-69.7	4.5	6.4	6.5	6.7	6.6
2	113.6	14.0	69.7	6.8	6.9	6.11	6.10
3	197.1	51.8	-1.0	6.12	6.13	6.15	6.14
4	230.0	-10.2	56.4	6.16	6.17	6.19	6.18

Table 6.1: Basic properties of the gamma-rays shown in the example images. All gamma-rays come from zenith, and run parallel to the optical-axis of the telescopes. Here x, and y is the positions where the elongated trajectory of the cosmic gamma-ray intersects the principal-aperture-plane. Also the corresponding figure-numbers are shown.

6.6 Discussion

In the images recorded by a giant 71 m telescope shown in the Figures 6.4, 6.8, 6.12, 6.16, and 6.20, we find that the air-showers do not look like ellipses anymore as it is described by Hillas' model [Hillas, 1985]. Depending on the distance between the cosmic particle's trajectory and the optical-axis, the air-shower-images either have a triangular, or a circular shape, but not the shape of an ellipse. On the other hand, the air-shower-images recorded by the seven 23 m telescopes in the Figures 6.5, 6.9, 6.13, 6.17, and 6.21, do look much more like symmetric ellipses according to Hillas. In the seven images recorded by the seven 23 m telescopes we find, as expected from stereoscopic arrays of Cherenkov-telescopes, that the main-axes of the ellipses in the individual images intersect in one point. Since the seven 23 m telescopes are located at different support-positions, see Figure 6.3, they observe the air-showers from different perspectives which allows for stereoscopic reconstructions of the air-showers. Now the images of the giant 71 m telescope are blurred and difficult to interpret because these are the sum of those seven images recorded by seven individual 23 m telescopes. The image of the 71 m telescope, can not be separated again into the individual images of the seven 23 m telescopes. All this information about the individual main-axes of the ellipses, which is so powerful to reconstruct the incident-direction of the cosmic gamma-ray, is lost in the image of the 71 m telescope.

In the Figures 6.7, 6.11, 6.15, 6.19, and 6.23, we show how drastically the air-

shower-images change when we choose to focus the 71 m telescope to different object-distances. To be clear, on a real Cherenkov-telescope there is no way to record such a series of images with the focus set to different object-distances. But here we can simulate the same air-shower multiple times, while the telescope focus is varied. Now when we look at the stack of refocused air-shower-images, we find that there are images in the middle of these stacks where the density of Cherenkov-photons is highest, while in return the density is lowest for the images at the lower and upper end of the stack. When we look at the density of the true emission-positions of these photons in the Figures 6.6, 6.10, 6.14, 6.18, and 6.22, we find that the object-distances for the air-shower-images in the focusstack with the highest photon-densities, correlate with the object-distances for the highest density of true emission-positions. Although all images in the focusstack contain the same Cherenkov-photons, these images look different because each one focuses to just one thin slice of the air-shower along the optical-axis. A stack of refocused images can be used for the three-dimensional, tomographic reconstruction of air-showers, see Chapter 15.

6.7 Conclusion

The Cherenkov-plenoscope not only overcomes the physical limit of the narrow depth-of-field, but it turns the tables on it. All the three measures proposed to lower the energy-threshold on Cherenkov-telescopes: Larger apertures, closer to the air-shower, and higher angular resolution; all toughen the depth-of-field-limitations on Cherenkov-telescopes, but strengthen the reconstruction-power of the Cherenkov-plenoscope.

Chapter 7

Introducing Portal's optics

Although the Cherenkov-plenoscope's perception is fundamentally different from the Cherenkov-telescope's perception, its optical components are not. There are only two different types of optical components in Portal. First mirror-facets, and second lenses. Both are mass fabricated with purely spherical surfaces. Their identical copies are used over and over again. We list optical properties and motivate design-choices.

7.1 Imaging-reflector

Portal's large imaging-reflector has f = 106.5 m focal-length and D = 71 m outer diameter resulting in a focal-ratio F = f/D = 1.5. Because of the lenses in the light-field-sensor, we do not want to go much below this focal-ratio, see later Section 7.3. To be light-weight and cost-efficient, Portal has a segmented imagingreflector which is composed from many identical mirror-facets. These mirrorfacets are the first of the two optical components used in Portal. The Figures 2.1, 5.2, and 5.4 show schematics and renderings of Portal's large imaging-reflector.

Mirror-facets

The 1,842 mirror-facets are also imaging-reflectors themselves with the same focal-length f as the overall large imaging-reflector. The reflective surface of each mirror-facet has the shape of a sphere with a curvature-radius of 2f. The perimeter of the mirror-facets is hexagonal to fill the overall aperture with only small gaps in between the edges of the facets. The outer perimeters of all mirror-facets are fully enclosed by the 71 m diameter of the large imaging-reflector. Since the center of the large imaging-reflector is shadowed by the light-field-sensor, we do not put mirror-facets within an inner diameter of 5 m but leave room for e.g. calibration-equipment. Each mirror-facet provides 1.97 m^2 reflective area, compare CTA-LST-facet in Table 16.1. Between the edges of neighboring mirror-facets is a gap of 2.5 cm for clearance. In total, the reflective area of Portal's large imaging-reflector is $3, 628.7 \text{ m}^2$. Figure 7.1 shows the mirror-facets reflectivity

used in the simulations. This is the reflectivity of a durable coating for mirrorfacets developed for the upcoming Cherenkov-Telescope-Array (CTA) [Pareschi et al., 2013a]. We choose a large 1.97 m² mirror-facet which can be mass produced today in a cost-efficient way [Pareschi et al., 2013a]. Larger mirror-facets reduce the complexity of their orientational fine alignment, and are favored by the supporting space-truss-lattice, see Figure 16.9.

Principal-aperture-plane

Without loss of generality, we describe the geometry of Portal's imaging-reflector with respect to the principal-aperture-plane [Wöhler, 2012, Forsyth and Ponce, 2003], compare Figure 6.2. The principal-aperture-plane in x and y, together with the optical-axis of the imaging-reflector in z define the origin of the imagingreflector's frame. We describe the geometry of the imaging-reflector with respect to the principal-aperture-plane, because the principal-aperture-plane is also our reference to describe the light-field, see Chapter 8, and Figure 8.1 in particular. Describing the light-field with respect to the principal-aperture-plane simplifies the representation of the light-field, as it abstracts away the complex surfacegeometry of the imaging-reflector, see Chapter 8. For reasons that we will discuss next, all of the mirror-facets of Portal's imaging-reflector are positioned above the principal-aperture-plane. The principal-aperture-plane is not the surface of the mirror-facets, but an abstract plane.

Geometry

The center-positions of the mirror-facets are embedded on a paraboloid to optimize isochronous imaging as much as possible before we have to fall back to the novel reconstruction-methods for the photon-arrival-times which are possible with the light-field-sensor, see Section 8.3. In contrast to embedding the mirror-facets center-positions on a sphere with the focal-point $\vec{f} = (0, 0, f)$ in its center, as it is done in the Davis-Cotton-geometry [Davies and Cotton, 1957], the paraboloid induces a wider spread in photon-incident-directions, but a narrower spread in photon-arrival-times. For Portal, we choose to go for the smallest possible spread in photon-arrival-times.

On Portal's imaging-reflector, the center-position of the i-th mirror-facet

$$\vec{m_i} = \left(x_i, y_i, \frac{r_i^2}{4f} + c\right)^T \tag{7.1}$$

is restricted in its x, and y-component by the hexagonal grid of the mirror-facets. The z-component depends on the distance $r_i = \sqrt{x_i^2 + y_i^2}$ of the mirror-facet to the optical-axis, the focal-length f, and an offset c which is chosen globally for

Figure 7.1: The reflection-coefficient used to simulate the mirror-facets on the imaging-reflector of Portal. This is the measured reflection-coefficient of the so called 'dielectric' mirror-facets of the Medium-Size-Telescope (MST) in the Cherenkov-Telescope-Array (CTA) [Pareschi et al., 2013a, Pareschi et al., 2013b].

all mirror-facets to fulfill

$$f \stackrel{!}{=} \frac{1}{Q} \sum_{i=0}^{Q} \left| \vec{f} - \vec{m_i} \right|_2.$$
 (7.2)

Here Q is the number of mirror-facets. The offset c rises all the mirror-facets along the optical-axis up and above the principal-aperture-plane so that the average of all the distances from the mirror-facets to the focal-point equals the focal-length. The target-orientations of the mirror-facets are such that the central spot on each mirror-facet reflects photons running parallel to the optical-axis towards the focal-point \vec{f} .

7.2 Aligning the mirror-facets on Portal

Just as on Cherenkov-telescopes, orientation-alignment for the 1,842 mirror-facets is needed in a regime of $\approx 0.035^{\circ}$, which is half a pixel's field-of-view. Since Portal uses many more mirror-facets than existing telescopes, the alignmentmethod for Portal must have an execution-time which does not scale too fast with the number of mirror-facets. Fortunately, the alignment-methods for Cherenkovtelescopes [McCann et al., 2010, Ahnen et al., 2016b] which are based on the characterization of solar-concentrators during the night [Arqueros et al., 2003], have a constant execution-time with respect to the number of mirror-facets. The author of this thesis (S.A.M.) took the leadership in the investigations of [Ahnen

Figure 7.2: Dimensions in millimeter. The geometry of the small cameras inside Portal's light-field-sensor. On the left is the view from the front, on the right is the view from the side. Just as in the Figures 2.2, 2.3, and 5.11, the sensitive surfaces of the photo-sensors are red and the faces of the lens which are touching neighboring lenses are green.

et al., 2016b]. We propose to adopt such alignment-methods, and increase the robustness by using more cameras, if needed. Currently these alignment-methods only use a single CCD-camera¹ in the focal-point of the imaging-reflector. But alignment-methods can use plenoptic-perception as well by e.g. replacing the single CCD-camera with an array of CCD-cameras. This way, a wider range of possible miss-orientations of the mirror-facets could be covered in shorter time, and possible misalignments between the large imaging-reflector and the light-field-sensor could be compensated.

7.3 Light-field-sensor

The light-field-sensor of Portal is a dense, two-dimensional array of identical, small cameras. Figure 7.2 shows the dimensions of one of these small cameras. Each small camera consists out of first a bi-convex, spherical lens made out of silica-glass, and second a two-dimensional array of photo-sensors. This lens is the second of the two optical components used in Portal. In Figure 7.2 the faces of the lens which touch neighboring lenses of neighboring small cameras are shown in green. The green faces of the lens are opaque. The sensitive surfaces of the photo-sensors are shown in red. The lens in the small camera is positioned such that its projection of incoming photons is sharpest in the outer region on the photo-sensors, and not in the center. Figure 7.3 shows the point-spread-functions inside a small camera for different incident-directions of photons coming from different positions on the large imaging-reflector. Because the lens has a rather

¹These cameras do not necessarily have a Charged-Coupled-Device (CCD). The term CCDcamera just happens to be often used for industrial cameras with sizes similar to the human eye. We use it here to prevent naming-collisions with the small cameras in the light-field-sensor of Portal.

wavelength/nm	transmission through $1{\rm cm}/\%$
193	98.5
249	99.5
266	99.9

Table 7.1: Transmission-probability of photons going through a 1 cm thick plate of Suprasil silica-glass made by Heraeus [Heraeus, 2018] excluding losses due to Fresnel-reflection. For wavelength above 266 nm and until $\approx 1,100$ nm, the attenuation seems to be negligible for the simulations of Portal. The lenses in Portal are at most 1.5 cm of path-length.

strong aberration in the outer region of its projection, we made the inner walls of the small camera reflective. These inner walls have the same reflectivity as the mirror-facets of the large imaging-reflector, see Figure 7.1. In the Figures the walls are green as they also touch neighboring small cameras just like the green surfaces of the lens. These reflective walls actually reduce more artifacts than they create. In Figure 7.3 for small incident-angles up to 11.1°, we find that caustics are running out of the point-spread-function's core towards the outside. Now with reflective inner walls, these caustics are thrown back towards the inside when the incident-angles become larger. In any case, this correction is only minor as it effects only a small fraction of the photons.

Bi-convex lens with hexagonal perimeter

The bi-convex lenses are made out of silica-glass. Because of its high transmission for bluish and ultra-violet photons, we choose a silica-glass called Suprasil 311/312/313 made Heraeus [Heraeus, 2018]². The Figures 7.4 and the Table 7.1 show the transparency of the silica-glass. The lenses are so transparent that at most $\approx 1\%$ of the photons with wavelengths below 250 nm is absorbed inside of them. Of course our simulation handles the Fresnel-reflections which are much more relevant here. Figure 7.5 shows the refraction-index of the lenses.

Focal-ratio for small lenses and large imaging-reflector

For image-quality and ease of manufacturing, we want the largest possible focalratios for the lenses. But in Figure 7.6 we find that the largest focal-ratio for the lenses is determined by the intercept-theorem

$$\frac{f_{\rm lens}}{D_{\rm lens}} = \frac{f}{D},\tag{7.3}$$

²Also other flavors of silica-glass made by other manufactures seem to have comparable properties for our needs. But we give credits to Heraeus here because their specifications are well documented.

Figure 7.3: Point-spread-functions inside the small cameras. From the top left to the bottom right the incident-angles of the photons are 0.0°, 3.7°, 7.4°, 11.1°, 14.7°, and 18.4°. Square grid has 20 mm spacing. Large hexagon is the perimeter of the small camera, compare Figure 7.2. Small hexagons are the individual photo-sensors, compare Figure 5.11. Darkening is proportional to the cube-root of the intensity.

Figure 7.4: The transmission-probability of photons going through a 1 cm thick plate of Suprasil silica-glass made by Heraeus [Heraeus, 2018]. Reconstructed from the specifications by Heraeus based on the transmission including losses due to Fresnel-reflection, and the transmission with only the losses expected due to Fresnel-reflection. See also Table 7.1.

Figure 7.5: The refraction-index used to simulate the lenses in Portal. This is the measured refraction-index of 'Suprasil' silica-glass produced by the Heraeus company [Heraeus, 2018].

Figure 7.6: The focal-ratio of the lenses should be the same as the focal-ratio of the large imaging-reflector. This way, the array of photo-sensors in the small camera is fully covered by the projection provided by the lens.

where we assume that $f \gg f_{\text{lens}}$. Since we want the small cameras to fill the sensor-plane without gaps, the array of photo-sensors in a small camera can not be larger than the lens' diameter D_{lens} . Thus the projection provided by the lens has to fit onto an area not exceeding the lens' diameter D_{lens} .

However, Equation 7.3 is only valid for the one-dimensional case. In the twodimensional implementation used in Portal's light-field-sensor there is an additional quirk. In Figure 7.2 we find, that the projected image of the large imagingreflector has to fit inside the inner-diameter of the hexagonal aperture of the lens. But the lens' optical diameter D_{lens} is the outer diameter of the hexagonal aperture of the lens. This is one of two reasons why on Portal the focal-ratio for the lenses is $F_{\text{lens}} = 1.22$ instead of the F = 1.5 of the large imaging-reflector. This is also the reason why the lenses have hexagonal apertures. Square, or triangular apertures cause even smaller focal-ratios F_{lens} because their inner and outer diameters deviate even more. Figure 7.2 not only implies that an hexagonal aperture for the lenses is optimal, but also that the large imaging-reflector should have a hexagonal aperture, and not a circular one. This way, the large imaging-reflector could be projected onto the full hexagonal array of photo-sensors inside the small camera. In Portal, we did not yet implement this.

Afterthought – Curving the sensor-plane

The Portal Cherenkov-plenoscope simulated here uses a light-field-sensor with all its small cameras positioned in a flat plane, and with all small cameras facing parallel. However, we see benefits for future studies when the small cameras do not face parallel, but do face towards the center of the large imaging-reflector. This way, the projections provided by the lenses always cover the entire array of photo-sensors in each small camera. Otherwise the projections move further off the photo-sensors the further the small cameras are off the optical-axis of the large imaging-reflector. On Portal this is not yet a problem because Portal's fieldof-view is not this large, and because we naively shortened the focal-ratio of the lenses to compensate for this off-axis-effect. This shrinks the projections provided by the lenses and is the second reason why the lenses in Portal have smaller focalratios than Portal's large imaging-reflector. But shortening the focal-ratios of the lenses hurts optical quality and should be avoided. In general, and especially when going for larger field-of-views, tilting the small cameras to make them face the center of the large imaging-reflector should be a beneficial workaround. We propose to achieve this individual tilt for the small cameras by not arranging them on a flat plane, but on a sphere. The center of this sphere is the center of the large imaging-reflector. And the curvature-radius of this sphere is the focallength f of the large imaging-reflector. This way, the small cameras are all tilted to face the center of the large imaging-reflector, and the small cameras do not interferer mechanically. The fact, that there is no flat sensor-plane anymore is fully compensated using the light-field-geometry for the same reasons we discuss in Chapter 11. Figure 7.7 shows our proposed curved light-field-sensor side-byside to a flat light-field-sensor.

Photo-electric-conversion

In Portal we simulate photo-sensors which have the photon-detection-efficiency of the Hamamatsu R11920-100-05 photo-multiplier-tubes designed for the Large-Size-Telescope (LST) in the Cherenkov-Telescope-Array (CTA), see Figure 7.8. This photo-sensor is optimized to detect bluish Cherenkov-photons and to reject reddish night-sky-background-photons. Rejecting reddish night-sky-background photons eases the trigger-decision for air-showers. For the read-out of the signals, we assume that Portal has the read-out of the FACT³ Cherenkov-telescope which is discussed in Part II of this thesis.

7.4 Conclusion

The Portal Cherenkov-plenoscope only uses two types of optical components. First, mirror-facets, and second lenses. Both these components have purely spherical surfaces to ease their production. Both these components are mass produced to populate the plenoscope with identical copies. The optics of Portal can be produced today using established methods developed for Cherenkov-telescopes.

 $^{^{3}}$ This is not because we think that the read-out of the FACT Cherenkov-telescope is the best read-out possible, but because we know its shortcomings and artifacts and how to represent those in a simulation.

Figure 7.7: We propose to curve the light-field-sensor in future studies to ease the implementation of larger field-of-views, and to allow larger focal-ratios of the lenses. On the left side, the plenoscope shown here has a flat light-field-sensor. The projections provided by the lenses are shown in dark blue. On the left, flat part of the light-field-sensor, these projections do not cover all photo-sensors. The projections move more and more to the outside the further the small camera is away from the optical-axis of the large imaging-reflector. On the right, curved part of the light-field-sensor, the projections still cover all the photo-sensors in the small cameras. Compare to the plenoscope in Figure 2.2 which has a much smaller field-of-view.

Figure 7.8: The photon-detection-efficiency used to simulate the photo-sensors in the light-field-sensor of Portal. This is the measured photon-detection-efficiency of the photo-multiplier-tube R11920-100-05 by manufacturer Hamamatsu developed for the Large-Size-Telescope (LST) in the Cherenkov-Telescope-Array (CTA) [Toyama et al., 2013].

Chapter 8

Estimating the light-field-geometry

Here we describe in a quantitative way how the plenoscope perceives the light-field. We do this by describing the geometry of the light-field perceived by each photo-sensor in the plenoscope. Based on this description, we can reconstruct the three-dimensional trajectories and arrival-times of photons. In Section 8.1, we introduce two addressing schemes for the photo-sensors in the light-field-sensor. In Section 8.2, we present our implementation of an approximative description for the geometry of the light-field. In Section 8.4, we visualize this approximative description for Portal. We name this approximative description the light-field-geometry of the plenoscope.

Further in Section 8.3, we present perfect isochronous imaging with the Cherenkovplenoscope, which overcomes a fundamental shortcoming of Cherenkov-telescopes, and is useful when projecting the light-field onto images.

8.1 Addressing photo-sensors and lixels

When we first introduce an addressing scheme for the photo-senors in the Portal plenoscope in Equation 2.1 we chose a two-dimensional scheme (n, m) where n loops over all the N = 8,443 small cameras and m loops over the M = 61 photo-sensors in each of those small cameras. In this first introduction, the small cameras can be identified as pixels, and the individual photo-sensors in the small cameras can be identified as paxels. We did so to stress the hierarchy between the photo-sensors in the light-field-sensor presented in Figure 2.2. However, the fact that such a two-dimensional addressing is possible goes back two the specific design of Portal's light-field-sensor. But in general one does not have to group the photo-sensors into clusters of pixels and paxels. For Portal the two-dimensional addressing is only adequate as an approximation. In general, we identify each photo-sensor with a light-field-cell (lixel) and address those in a one-dimensional

scheme. For Portal, the number of lixels is

$$K = M \times N, \tag{8.1}$$

and the address of the lixel is composed as

$$k = m + n \times M \tag{8.2}$$

such that in turn the addresses of the pixel and paxel are

$$n = \text{floor}(k/M) \tag{8.3}$$

$$m = k - n \times M. \tag{8.4}$$

The one-dimensional addressing is more natural when we describe advanced reconstructions such as tomography or the refocusing of images in post, while the two-dimensional addressing can be more accessible for the very basic imaging and areal sampling without corrections of the shortcomings introduced by real optical components. The naive two-dimensional addressing of lixels can be more accessible because it allows to identify parts of the hardware as 'pixels' as it is often done in Cherenkov-telescopes. However, prepare to break with this established mindset because otherwise we can not overcome aberrations in Chapter 10, compensate misalignments in Chapter 11, or refocus images in post in Section 9.4.

8.2 Approximating lixels using rays

To interpret the photon-intensity recorded by a photo-sensor in the plenoscope, we have to know which part of the light-field is sampled by this photo-sensor. We have to know the light-field-cell (lixel) to each photo-sensor. We use the ray $\vec{r}_k(\lambda)$ from Equation 2.1 to approximate how photo-sensor k samples the light-field. This is an approximation because a ray only samples a singular incident-direction and a singular support-position. But actual photo-sensors always sample an extended region of incident-directions and an extended region of support-positions. For Portal we estimate the rays $\vec{r}_0(\lambda)$ to $\vec{r}_{K-1}(\lambda)$ in a computer-simulation, where we throw many photons into the plenoscope. We randomly draw the supportposition of each photon on the principal-aperture-plane, and we randomly draw the incident-direction of each photon. All the photons are emitted so that they would travel the same distance before they intersect the principal-aperture-plane. When the photon is absorbed by a photo-sensor, we append the geometry of the trajectory of the photon to the according photo-sensor. Finally we approximate the light-field-geometry of each individual photo-sensor with the 12 properties shown in Table 8.1. Here we estimate the ray $\vec{r}_k(\lambda)$ using the mean supportpositions $\overline{x}, \overline{y}$ and the mean incident-direction $\overline{c_x}, \overline{c_y}$ of all photons which are

	mean	uncertainty
Support-position in x	\overline{x}	σ_x
Support-position in y	\overline{y}	σ_y
Incident-direction in x	$\overline{c_x}$	σ_{c_x}
Incident-direction in y	$\overline{c_y}$	σ_{c_y}
arrival-time-delay (w.r.t. principal-aperture-plane)	$\overline{t}_{\mathrm{pap}}$	$\sigma_{t\mathrm{pap}}$
Collection-efficiency	$\overline{\eta}$	σ_η

Table 8.1: Light-field-geometry of a single photo-sensor in the plenoscope approximated using 12 values.

detected by photo-sensor k. To describe the lixels in more detail, higher order statistics of the photons detected by a photo-sensor k might be used such as the uncertainties listed in Table 8.1. Here the collection-efficiency η is proportional to the ratio of the number of all the photons that got thrown to the number of all the photons that got absorbed in the photo-sensor. Now we can use the resulting table

$$G = \begin{cases} \overline{x}_{0} & \overline{y}_{0} & \overline{c_{x}}_{0} & \overline{c_{y}}_{0} & \overline{t}_{\text{pap}}_{0} & \overline{\eta}_{0} \\ \overline{x}_{1} & \overline{y}_{1} & \overline{c_{x}}_{1} & \overline{c_{y}}_{1} & \overline{t}_{\text{pap}}_{1} & \overline{\eta}_{1} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ \overline{x}_{K-1} & \overline{y}_{K-1} & \overline{c_{x}}_{K-1} & \overline{c_{y}}_{K-1} & \overline{t}_{\text{pap}}_{K-1} & \overline{\eta}_{K-1} \end{cases}$$

$$(8.5)$$

of all the K photo-sensors to approximate the light-field-geometry of the plenoscope. The first four columns of G define the support-positions and incidentdirections of the rays in Equation 2.1. So we can also think of

$$G = \begin{cases} \vec{r}_0(\lambda) & \bar{t}_{\text{pap}_0} & \bar{\eta}_0 \\ \vec{r}_1(\lambda) & \bar{t}_{\text{pap}_1} & \bar{\eta}_1 \\ \vdots & \vdots & \vdots \\ \vec{r}_{K-1}(\lambda) & \bar{t}_{\text{pap}_{K-1}} & \bar{\eta}_{K-1} \end{cases}$$

$$(8.6)$$

as a table of rays, arrival-time-delays, and collection-efficiencies for all the K lixels in the plenoscope. The light-field-geometry G allows us to calibrate the responses of the plenoscope to abstract away from the optics, so that we only need to think about photons arriving on the flat surface of the principal-aperture-plane. Figure 8.1 shows how we can think of the calibrated light-field-sequence \mathcal{L} . All our further interpretation of the light-field-sequence \mathcal{L} are based on the mindset presented by the Equation 8.6, and Figure 8.1.

8.3 Isochronous imaging

We defined the light-field-geometry G with respect to the principal-apertureplane. However, if one intends to calculate classic image-sequences \mathcal{I} from the

Figure 8.1: The photons in the light-field-sequence \mathcal{L} . Black dots are photons with arrows indicating their direction of motion along their dashed trajectories. The calibration of the plenoscope abstracts away all the quirks of the large imagingreflector, the lenses, the small cameras and the photo-sensors. What is left are single photons traveling along rays with respect to the principal-aperture-plane. Note that photon 1 and photon 2 occupy the same ray $k_1 = k_2$, but at different positions because of their different arrival-times $t_{\text{pap}_1} \neq t_{\text{pap}_2}$. Here c is the speed of light.

recorded light-field-sequence \mathcal{L} , the arrival-time-delays \bar{t}_{pap} must not be used for calibration. One can use no arrival-time-delays and just use the raw recorded arrival-times t_{raw} to get a good timing resolution for imaging. This is because the coarse surface of Portal's large imaging-reflector follows a parabola. However, a parabola can only do good isochronous imaging in the central part of the image, but the plenoscope can do better. The plenoscope can synthesize the perfect isochronous image in post for the entire field-of-view. Isochronous imaging means that incoming light-fronts, where the photons travel together in a plane perpendicular to their direction of motion, will arrive in the same pixel at the same moment. Figure 8.12 shows the path-length-delays which are added to the calibration used for the principal-aperture-plane. The Figures 8.8 and 8.9 show the time-delays \bar{t}_{img} which are added to the raw arrival-times t_{raw} in order to obtain perfect isochronous images.

8.4 Light-field-geometry of Portal

We visualize the light-field-geometry of Portal when the large imaging-reflector and the light-field-sensor of Portal are both in their target-geometry with respect to each other. We propagate 10^9 photons to estimate Portal's light-field-geometry. In Figure 8.2 we find the magnitude of the spread in incident-directions versus the magnitude of the incident-directions. This is an inverse representation of the point-spread-function discussed on telescopes. As expected from the large imaging-reflector, the inner region has a smaller spread in incident-directions. The finite aperture of the small cameras in the light-field-sensor alone is expected to induce a spread in the order ¹ of $\approx 0.02^{\circ}$. Even in the outer region of the field-of-view, the spread in incident-directions is below the spacing of the small cameras.

The Figures 8.3 to 8.11 show the arrangement of the photo-sensors inside the 12.1 m diameter light-field-sensor of Portal. We draw each photo-sensor as a small hexagon and color it according to its value. We also show close-ups of the same sensor-plane in order to see the structures inside the small cameras. Compare the arrangement of the photo-sensors with Figure 5.11, and 7.3.

Figure 8.3 shows the incident-directions in both $\overline{c_x}$, and $\overline{c_y}$ for all photo-sensors. Same as with an image-sensor in a telescope, the positions of the photo-sensors on the sensor-plane correspond directly to the incident-directions.

The Figures 8.4 and 8.5 show the support-positions \overline{x} , and \overline{y} for all the photosensors. Unlike a telescope, the additional projection provided by the lenses in the small cameras allow the photo-sensors inside a small camera to sample the support-positions across the full 71 m aperture of the large imaging-reflector. The close-ups in the Figures 8.4 and 8.5 show clearly the repeating pattern of the small

¹Standard-deviation of a uniform distribution in a limited range: $0.067^{\circ}/\sqrt{12}$.

Figure 8.2: Histogram of the mean magnitude of the incident-directions versus the spread magnitude of the incident-directions for all photo-sensors. The darkening in the histogram goes with the square-root of the number of lixels.

cameras.

Figures 8.6 and 8.7 show the collection-efficiency $\overline{\eta}$ of all the photo-sensors. As can be seen from the close-ups, the central photo-sensors inside a small camera are less efficient than the outer ones. This is because the central photo-sensor is partly blocked due to the housing of the light-field-sensor itself. Depending on the position of the small camera on the sensor-plane, the shadow of the housing of the light-field-sensor moves accordingly to the opposite direction. Since the observations of air-showers approach a single photon regime, the recorded light-field-sequences are always subject to quantization noise. This makes an application of the collection-efficiency $\overline{\eta}$ difficult or even impossible for the correction of photon-intensities. However, we use it extensively to speed up the simulations of Portal when we inject night-sky-background-photons into the light-field-sensor, see also Section 18.3.

The Figures 8.8 and 8.9 show the time-delays \bar{t}_{img} of the photo-sensors which are needed for a perfect isochronous image. The overall spread of the delays is only ≈ 1 ns and thus already sufficient for the observation of air-showers even if we do not correct for it. Just as one would expect from a telescope with a parabolic imaging-reflector, the spread in the central part of the sensor-plane is lowest.

The Figures 8.10 and 8.11 show the time-delays \bar{t}_{pap} of the photo-sensors which are needed for the principal-aperture-plane.

Figure 8.11: Same as Figure 8.10. Close-ups on left and upper regions of the sensor-plane.

Figure 8.12: Time-of-flight offsets for isochronous imaging. Parallel rays carry photons arriving on the principal-aperture-plane x, y. For isochronous imaging we add the signed time-of-flight offsets (thick arrows) between the light-front (dashed-line) and the principal-aperture-plane to the arrival-times of the photons in pixel (c_x, c_y) .

8.5 Multiple light-field-geometries on Portal

Since in Portal the geometry between the large imaging-reflector and the light-field-sensor might not be fix during all time, the light-field-geometry for Portal depends on the actual geometry between the two. This is a trade-off that we have to do in order to build a large 71 m imaging-reflector with a decoupled light-field-sensor. During the observations with Portal, the cable-robot-mount will always try to bring the large imaging-reflector and the light-field-sensor into their desired target geometry \hat{T}_{target} . However, small deviations from the desired target geometry \hat{T}_{target} , which the cable-robot-mount can not correct for fast enough, might occur. The reason for such fast deviations might be wind-gusts. The actual geometry \hat{T}_{actual} between the large imaging-reflector and the light-field-sensor is recorded during the observations so that dedicated light-field-geometries $G(\hat{T}_{actual})$ can be applied accordingly. We describe \hat{T} with the homogeneous transformation from the large imaging-reflector's frame into the light-field-sensor's frame.

8.6 Conclusion

The light-field-geometry is a powerful tool to describe and simulate any optical instrument sensing photons. The light-field-geometry allows us to mentally decouple the implementation-details of an instrument from its actual perception. With the light-field-geometry we can abstract away all the quirks and features of Portal's large imaging-reflector, and its lenses in the light-field-sensor. All these quirks and features are taken care of in the light-field-geometry. The light-field-geometry allows us to focus on what actually matters: Individual photons traveling along their trajectories in a three-dimensional space, see Figure 8.1.

Having the light-field-geometry of an instrument is enough to estimate the response of that instrument for a given light-field-input. And the other way around, when we have the response and the light-field-geometry of an instrument, we can reconstruct the light-field which the instrument observed.

Together with the operations formulated in Chapter 9, the light-field-geometry allows us to overcome aberrations, see Chapter 10, and to compensate misalignments, see Chapter 11.

Chapter 9

Interpreting the light-field-sequence

The light-field-sequence \mathcal{L} of the plenoscope can be approached in various ways to reconstruct the air-shower in order to learn about the cosmic particle. Here we demonstrate the methods we have investigated so far. First, we show three different representations of the light-field-sequence \mathcal{L} . Second, we demonstrate imaging, areal-sampling, refocused imaging, synthetic apertures, light-fronts. Threedimensional tomography we discuss separately in Chapter 15.

9.1 Representing the light-field-sequence

There are different ways to represent the light-field-sequence \mathcal{L} . We use three different representations. Each representation has certain advantages. Our three representations can be converted into each other without loss.

Lixel-time-histogram

First, we represent the light-field-sequence as a two-dimensional histogram

$$\mathcal{L}[k, t] = \begin{bmatrix} i_{0,0} & i_{0,1} & i_{0,2} & \dots & i_{0,T-1} \\ i_{1,0} & i_{1,1} & i_{1,2} & \dots & i_{1,T-1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ i_{K-1,0} & i_{K-1,1} & i_{K-1,2} & \dots & i_{K-1,T-1} \end{bmatrix}$$
(9.1)

which we call lixel-time-histogram. The columns correspond to the K lixels in the plenoscope, and the rows correspond to the T time-cells. Each entry $i_{k,t}$ is the intensity of photons which arrived in lixel k at time-cell t. On Portal the shape of $\mathcal{L}[k, t]$ is $((K = 515, 023) \times (T = 100))$. Portal uses T = 100 time-cells of 500 ps duration each. Usually the population of $\mathcal{L}[k, t]$ is very sparse.

Pixel-paxel-time-histogram

For the specific design of Portal, the two-dimensional histogram $\mathcal{L}[k, t]$ can also be written as a three-dimensional histogram $\mathcal{L}[n, m, t]$, where the lixels k are addressed using the pixels n, and paxels m which they approximatively correspond to, see section 8.1.

$$\mathcal{L}[n, m, t] = \begin{bmatrix} i_{0,0,0} & i_{0,1,0} & \cdots & i_{0,M-1,0} \\ i_{1,0,0} & i_{1,1,0} & \cdots & i_{1,M-1,0} \\ \vdots & \vdots & \ddots & \vdots \\ i_{N-1,0,0} & i_{N-1,1,0} & \cdots & i_{N-1,M-1,0} \end{bmatrix}, \quad (9.2)$$

$$\mathcal{L}[n, m, t] = \begin{bmatrix} i_{0,0,1} & i_{0,1,1} & \cdots & i_{0,M-1,1} \\ i_{1,0,1} & i_{1,1,1} & \cdots & i_{1,M-1,1} \\ \vdots & \vdots & \ddots & \vdots \\ i_{N-1,0,1} & i_{N-1,1,1} & \cdots & i_{N-1,M-1,1} \end{bmatrix}, \quad (9.2)$$

When we compute the sum along two of the three axis of the three-dimensional histogram $\mathcal{L}[n, m, t]$, we can directly obtain an image, an areal-sample, or an intensity-sequence. The Equations 9.3 to 9.9 illustrate the various processing options of summing up the photon-intensities along certain axes of $\mathcal{L}[n, m, t]$.

$$\sum_{n,m,t} \mathcal{L}[n, m, t] \rightarrow \mathcal{L}, \text{ Intensity, number of photons}$$
(9.3)

$$\sum_{m,t} \mathcal{L}[n, m, t] \rightarrow \mathcal{L}[n], \text{ Classic image of telescope}$$
(9.4)

$$\sum_{n,t} \mathcal{L}[n, m, t] \rightarrow \mathcal{L}[m], \text{ Areal intensity on aperture}$$
(9.5)

$$\sum_{n,m} \mathcal{L}[n, m, t] \rightarrow \mathcal{L}[t], \text{ Intensity sequence, light-curve}$$
(9.6)

$$\sum_{t} \mathcal{L}[n, m, t] \rightarrow \mathcal{L}[n, m], \text{ Static light-field}$$
(9.7)

$$\sum_{m} \mathcal{L}[n, m, t] \rightarrow \mathcal{L}[n, t], \text{ Classic image-sequence, video}$$
(9.8)

$$\sum_{n} \mathcal{L}[n, m, t] \rightarrow \mathcal{L}[m, t], \text{ Areal intensity-sequence on aperture} \quad (9.9)$$

On Portal the shape of $\mathcal{L}[n, m, t]$ is $((N = 8, 443) \times (M = 61) \times (T = 100))$.

Stream of photons

We can also describe the light-field-sequence \mathcal{L} as a stream

$$\mathcal{L}[j] = \begin{bmatrix} k_0 & , & t_{raw0} \\ k_1 & , & t_{raw1} \\ \vdots & & \vdots \\ k_{J-1} & , & t_{rawJ-1} \end{bmatrix}$$
(9.10)

of all the J photons in it. Here each row in \mathcal{L} describes a single photon. The first column addresses the lixel k_j which absorbed the j-th photon, and the second column is the arrival-time $t_{\text{raw}j}$ of the j-th photon. The stream of photons is practical to label individual photons as it is done in the classification of Cherenkov-photons and night-sky-background-photons. Further, the stream of photons does not assume that lixels are organized hierarchical so that the light-field $\mathcal{L}[n, m]$ becomes a rectangular histogram in n and m. Personally, we mostly ended up using the stream of photons to represent the light-field-sequence \mathcal{L} because of its generality and efficiency due to its natural zero-suppression.

9.2 Directional sampling – Imaging

The plenoscope can do imaging exactly like a conventional telescope. In the special case of Portal, we simply sum up the photon-intensities of all lixels which belong to the same pixel, see Equations 9.4 and 9.8. In words closer to the implementation of Portal, we simply sum up the photon-intensities of all photosensors inside of each small camera, see Figure 2.2. Imaging can be described as a linear-combination

$$\mathcal{I}[n] = U_{\text{imaging}}[n, k] \cdot \mathcal{L}[k]$$
(9.11)

of the photon-intensities in the light-field. Photon-intensities from several lixels k in $\mathcal{L}[k]$ are added up in a particular pixel n in the image $\mathcal{I}[n]$. This linear-combination can be described using the imaging-matrix

$$U_{\text{imaging}}[n, k] = \begin{bmatrix} u_{0,0} & u_{0,1} & \dots & u_{0,K-1} \\ u_{1,0} & u_{1,1} & \dots & u_{1,K-1} \\ \vdots & \vdots & \ddots & \vdots \\ u_{N-1,0} & u_{N-1,1} & \dots & u_{N-1,K-1} \end{bmatrix}.$$
 (9.12)

Each matrix-element $u_{n',k'}$ describes how much of the photon-intensity from the lixel k' in the light-field $\mathcal{L}[k]$ is added up into the pixel n' in the image $\mathcal{I}[n]$. In the special case of Portal, we can compute the matrix-elements using Equation

Figure 9.1: Close-up on the sensor-plane of Portal. Black photo-sensors (lixels) are summed up to synthesize the central pixel (n = 4, 221) in the image. Black is a weight of 1, and white is a weight of 0.

8.3

$$u_{n,k} = \begin{cases} 1 & \text{if } n = \text{floor}(k/M) \\ 0 & \text{else} \end{cases}$$
(9.13)

Figure 9.1 visualizes the matrix-elements on Portal to synthesize the central pixel n = 4,221 in the image. In general, the matrix-elements in $U_{\text{imaging}}[n, k]$ can be computed using the light-field-geometry G. We can compute the matrix-elements of $U_{\text{imaging}}[n, k]$ using the angular distances between the incident-directions of the pixels n in $\mathcal{I}[n]$ and a lixel k in G.

$$u_{n,k} = \begin{cases} 1 & \text{if } \sqrt{(c_{xn} - c_{xk})^2 + (c_{y_n} - c_{y_k})^2} \le c_{\text{pixel-radius}} \\ 0 & \text{else} \end{cases}$$
(9.14)

where $c_{\text{pixel-radius}}$ is e.g. the angular radius of a pixel in the image $\mathcal{I}[n]$. The matrixelements do not need to be strictly binary (0 or 1) as shown in the Equations 9.13, and 9.14. The weights can depend on the distances between the incidentdirections, or on the integrated overlap between pixels to reduce aliasing. The Figures 6.4, 6.8, 6.12, 6.16, and 6.20 show images projected from Portal's lightfield using Equation 9.13.

9.3 Areal-sampling

The plenoscope can do areal-sampling of the photon-intensities on ground similar to the modified solar-concentrators for dense areal-sampling presented in Section 19.2. An areal-sample is the photon-intensity-histogram along the supportpositions x, and y on the principal-aperture-plane. With the special design of Portal, we just sum the light-field-sequence $\mathcal{L}[n, m, t]$ according to the Equations 9.5, or 9.9. In general, areal-sampling can also be formulated as a linear-combination

$$\mathcal{A}[m] = U_{\text{areal}}[m, k] \cdot \mathcal{L}[k]$$
(9.15)

similar to Equation 9.11. Here $\mathcal{A}[m]$ is the one-dimensional photon-intensityhistogram along the *m* paxels on the principal-aperture-plane, and

$$U_{\text{areal}}[m, k] = \begin{bmatrix} u_{0,0} & u_{0,1} & \dots & u_{0,K-1} \\ u_{1,0} & u_{1,1} & \dots & u_{1,K-1} \\ \vdots & \vdots & \ddots & \vdots \\ u_{M-1,0} & u_{M-1,1} & \dots & u_{M-1,K-1} \end{bmatrix}$$
(9.16)

is the areal-sampling-matrix. The matrix-element $u_{m',k'}$ expresses how much of the photon-intensity of lixel k' from $\mathcal{L}[k]$, goes into paxel m' in $\mathcal{A}[m]$. In the special case of Portal, the matrix-elements

$$u_{m,k} = \begin{cases} 1 & \text{if } m = k - \text{floor}(k/M) \times M \\ 0 & \text{else} \end{cases}$$
(9.17)

are calculated using the Equations 8.3, and 8.4. Figure 9.2 shows the matrixelements for the particular row $U_{\text{areal}}[m = 54, k]$ in the special case of Portal. In words close to Portal's implementation, we sum up the intensities of each *m*-th photo-sensors in all small cameras, compare Figure 2.3. In general, the weights

$$u_{m,k} = \begin{cases} 1 & \text{if } \sqrt{(x_m - x_k)^2 + (y_m - y_k)^2} \le d_{\text{paxel-radius}} \\ 0 & \text{else} \end{cases}$$
(9.18)

can be estimated using the distance between the support-position of paxel m in \mathcal{A} and the support-position of lixel k in the light-field-geometry G. The radius of the paxels $d_{\text{paxel-radius}}$ can be used as a threshold here.

9.4 Refocusing images in post

The plenoscope can project its light-field onto images which are refocused to different object-distances in post, this means after the light-field was recorded. In Chapter 6 we demonstrate such refocused images on the example of the Portal Cherenkov-plenoscope, see the Figures 6.7, 6.11, 6.15, 6.19, and 6.23. Here we

Figure 9.2: Close-up on the sensor-plane of Portal. Black photo-sensors (lixels) are summed up to synthesize a single paxel (m = 54) on the principal-apertureplane. Black is a weight of 1, and white is a weight of 0.

Figure 9.3: A ray $\vec{r}(\lambda)_k$ is reflected on the principal-aperture-plane at the bottom of the figure. We call the reflected ray $\vec{\rho}(\lambda)_k$ the image-ray. Both rays share the same support-position \vec{s}_k .

present a geometric description for refocusing in post which is motivated by [Ng et al., 2005] and Figure 6.2. First, we discuss the trajectories of the photons after they passed the principal-aperture-plane and call those trajectories image-rays. Second, we use the image-rays and their intersections with virtual sensor-planes to formulate a projection of the light-field onto images focused to different object-distances.

Image-rays

Image-rays describe the trajectories of the photons after those have passed the principal-aperture-plane, see Figure 9.3. In Figure 6.2, the image-rays are defined by their support-positions on the principal-aperture-plane a, a', and a'' together with their absorption-positions on the sensor-plane i, i', and i''. Every ray $\vec{r}(\lambda)_k$ according to Equation 2.1 has a corresponding image-ray

$$\vec{\rho}(\lambda)_k = \vec{s}_k + \lambda \frac{\vec{\delta}_k}{|\vec{\delta}_k|_2}.$$
(9.19)

Both rays $\vec{r}(\lambda)_k$, and $\vec{\rho}(\lambda)_k$ share the same support-vector

$$\vec{s}_k = (x_k, y_k, 0)^T$$
 (9.20)

such that they both intersect on the principal-aperture-plane for $\lambda = 0$

$$\vec{r}(0)_k = \vec{\rho}(0)_k.$$
 (9.21)

The direction-vector $\vec{\delta}_k$ of the image-ray $\vec{\rho}(\lambda)_k$ is calculated using the Thin-lensequation 6.1 and Figure 6.2. We first calculate where the image-ray would intersect with the focal-plane in focal-distance f of the imaging-system

$$\vec{b}_k = f \left(-\tan(c_{xk}), -\tan(c_{yk}), 1 \right)^T,$$
 (9.22)

and second we calculate the direction-vector

$$\vec{\delta}_k = \vec{b}_k - \vec{s}_k \tag{9.23}$$

by subtracting the support-position \vec{s}_k from the intersection point \vec{b}_k in the sensorplane.

Refocusing on the plenoscope

We express the refocusing as a projection

$$\mathcal{I}_{g}[n] = U_{\text{imaging}}(g)[n, k] \cdot \mathcal{L}[k]$$
(9.24)

of the light-field onto an image, similar to regular imaging in Equation 9.11. However, this time the imaging-matrix

$$U_{\text{imaging}}(g)[n, k] = \begin{bmatrix} u_{0,0}(g) & u_{0,1}(g) & \dots & u_{0,K-1}(g) \\ u_{1,0}(g) & u_{1,1}(g) & \dots & u_{1,K-1}(g) \\ \vdots & \vdots & \ddots & \vdots \\ u_{N-1,0}(g) & u_{N-1,1}(g) & \dots & u_{N-1,K-1}(g) \end{bmatrix}$$
(9.25)

depends on the object-distance g where we want to focus on. The matrix-elements $u_{n,k}(g)$ are calculated using the k-th image-ray $\vec{\rho}(\lambda)_k$, and the corresponding x, and y positions of the n-th pixel on a virtual sensor-plane in image-distance b. First, we use the Thin-lens-equation and our desired object-distance g to calculate the image-distance

$$b = \frac{1}{\frac{1}{f} - \frac{1}{g}} \tag{9.26}$$

where of the virtual sensor-plane. Second, we calculate how far

$$\lambda_g = \frac{b}{\vec{z} \cdot \vec{\delta}_k} \tag{9.27}$$

we have to travel along the direction-vector $\vec{\delta}_k$ of our image-ray $\vec{\rho}(\lambda)_k$ to intersect with our virtual-sensor-plane in distance b. Third, we calculate the intersectionposition

$$\vec{i}_{k,g} = \vec{\rho}(\lambda_g)_k \tag{9.28}$$

of the image-ray on the virtual-sensor-plane. Fourth, we compute the position

$$\vec{p}_{n,g} = (x_n, y_n, b)^T$$
 (9.29)

of the *n*-th pixel in our virtual-sensor-plane. Here x_n , and y_n correspond to the x and y positions of the *n*-th pixel on the sensor-plane. Fifth, we compute the distance

$$o_{n,k,g} = |\vec{i}_{k,g} - \vec{p}_{n,g}|_2 \tag{9.30}$$

between the pixel-position $\vec{p}_{n,g}$ and the intersection-position $\vec{i}_{k,g}$ in the sensorplane. Finally, we calculate the matrix-elements

$$u_{n,k}(g) = \begin{cases} 1 & \text{if } o_{n,k,g} \leq \text{pixel-radius} \\ 0 & \text{else} \end{cases}$$
(9.31)

by comparing the distance $o_{n,k,g}$ with e.g. the pixel-radius to decide if the k-th lixel is participating to the photon-intensity in the n-th pixel. In Figure 9.1 we see a visual representation of the matrix-elements for the n-th pixel in Portal when we do not refocus. Now we can visualize the matrix-elements for the n-th pixel in Portal when we refocus in post to different object-distances g, see Figure 9.4. In Portal, the default sensor-distance d is equal to the focal-length f, such that the default object-distance where Portal focuses on is in $g = \infty$.¹ Find in Figure 9.4, that the refocusing to infinity yields exactly the same matrix-elements we obtain in the case for imaging without refocusing in Figure 9.1.

Figure 9.6 shows the interplay of neighboring pixels in the resulting refocused image. We color the photo-sensors according to the seven neighboring pixels they will be added up into in the refocused image. We find that indeed all the photosensors contribute to the resulting refocused images. In the Figures 9.4, 9.5, and 9.6 we find that the patterns of photo-sensors is not perfectly symmetric in all refocusing scenarios. Due to the binary decision made in Equation 9.31, already small statistical fluctuations in the estimation of the light-field-geometry G can cause asymmetric patterns in this first implementation.

9.5 Synthetic apertures

We interpret the plenoscope's light-field-sequence as a set of multiple imagesequences observed with an array of telescopes. In Chapter 6 we demonstrate this on the example of Portal in the Figures 6.5, 6.9, 6.13, 6.17, and 6.21. Arrays of Cherenkov-telescopes observe gamma-rays successfully and efficiently. Thus splitting the light-field-sequence into multiple image-sequences might be a first

 $^{^{1}}$ In Section 12.6, we discuss possible benefits for the Chrenkov-plenoscope's trigger when setting the default object-distance not to infinity, but to the air-shower-maximum.

Figure 9.4: Continues in Figure 9.5. Part 1 of 2. Black photo-sensors (lixels) are summed up to synthesize a single pixel focused to different object-distances. The object-distance focused to is written on the right, where the rays converge. Here we see the central pixel n = 4,221 on Portal.

Figure 9.5: Continuation of Figure 9.4. Part 2 of 2.

Figure 9.6: Same as Figure 9.4, but including the neighboring pixels. Central, black pixel id is 4, 221, green is 4, 124, blue is 4, 222 is, red is 4, 220 is, cyan is 4, 125 is, magenta is 4, 317 is, and orange is 4, 318 is.

step to approach the light-field and the plenoscope. We formulate the synthetic creation of telescope apertures as a projection of the light-field

$$\mathcal{I}_m[n] = U^m[n, k] \cdot \mathcal{L}[k]. \tag{9.32}$$

On Portal, we can slice the light-field-sequence $\mathcal{L}[n, m, t]$ along its M = 61 paxels to obtain the M = 61 image-sequences $\mathcal{I}_m[n, t]$ observed by M = 61 synthetic telescopes

$$u_{n',k}^{m'} = \begin{cases} 1 & \text{if } n' = n \text{ and } m' = m \\ 0 & \text{else} \end{cases}$$
(9.33)

Here we used the Equations 8.3, and 8.4 to compute n, and m from k.

In general we calculate the matrix-elements $u_{n,k}^m$ based on the support-positions of the rays defined in the light-field-geometry G. First, we calculate the distance

$$o_{k,m} = \sqrt{(\overline{x}_k - x_m)^2 + (\overline{y}_k - y_m)^2}$$
 (9.34)

between the support-position of the k-th ray on the principal-aperture-plane at $\overline{x}_k, \overline{y}_k$ and the center of the *m*-th synthesized telescope-aperture x_m, y_m . Second, we can compute the matrix-elements

$$u_{n',k}^{m} = \begin{cases} 1 & \text{if } n' = n \text{ and } o_{k,m} \leq r_{m} \\ 0 & \text{else} \end{cases}$$
(9.35)

by comparing the distance $o_{k,m}$ with e.g. the radius $r_{\rm m}$ of the *m*-th synthesized telescope-aperture. Again we calculate *n* from *k* using Equation 8.3. Here we describe a synthetic aperture with the shape of a disc with a radius $r_{\rm m}$, but one might also use other shapes for the synthetic apertures as e.g. hexagons, squares or triangles. In Chapter 6 we synthesize seven large telescopes by using the mask in Figure 6.3 and Equation 9.35.

9.6 Light-front

The plenoscope can reconstruct the light-front of the Cherenkov-photons in the three-dimensional space above its aperture, as it is shown in Figure 8.1. This might be obvious as the light-front corresponds to our very definition of the light-field-sequence in Chapter 8 and thus does not need further interpretation, but we list it here explicitly because it opens up so many possibilities. We use the light-front in Chapter 14 to reconstruct the incident-direction of very low energetic 1 GeV cosmic gamma-rays.

Chapter 10

Overcoming aberrations, enlarging the field-of-view

Real imaging-optics such as lenses or imaging-reflectors suffer from aberrations which reduce the angular resolution for imaging. The plenoscope can overcome these aberrations when they originate from the aperture of the imaging-optics being extended [Hanrahan and Ng, 2006]. On a perfect imaging-optics, the absorption-position of a photon on the sensor-plane only depends on the incidentdirection c_x , c_y of the photon relative to the optical-axis of the imaging-system. On real imaging-optics however, the photon's absorption-position on the sensorplane also depends on the support-position x, y where the photon passed the aperture-plane. This results in pixels to not only collect photons with incidentdirections associated with these pixels, but to also collect photons with different incident-directions.

Here we will demonstrate how far plenoptic perception can overcome aberrations on the example of a spherical imaging-reflector. We will briefly inspire the drastic implications for the enlarging of the field-of-views on e.g. Cherenkov-telescopes by about one order-of-magnitude.

Overcoming aberrations will turn out to be already included in the light-fieldgeometry G introduced in Chapter 8, and is closely related to the compensation of misalignments between the imaging-reflector and the light-field-sensor discussed in Chapter 11.

10.1 Using the light-field-geometry

Figure 10.1 shows the four parallel photons D, E, F, and G on a plenoscope. In Figure 10.1 the imaging-reflector suffers from aberrations, in contrast to the imaging-reflector shown in Figure 2.2 which is free of aberrations. The aberrations of the imaging-reflector cause the photons D, and G to enter different small cameras in the light-field-sensor although the four photons D, E, F, and G have all the same incident-directions. On a classic image-sensor, we can not resolve that

Figure 10.1: Four photons D, E, F, and G with the same incident-directions on a plenoscope. In contrast to the imaging-reflector shown in Figure 2.2, here the imaging-reflector suffers from aberrations. To visualize the slight off-axis incident-direction, we put a fifth photon in light gray close to the optical-axis of the imaging-reflector. On the imaging-reflector, short lines at the intersectionpositions of the photons indicate the surface-normal of the imaging-reflector. In Figure 10.2 we show a close-up of the light-field-sensor.

Figure 10.2: Close up of the light-field-sensor shown in Figure 10.1.

Figure 10.3: The light-field-geometry of the plenoscope shown in the Figures 10.1 and 10.2 visualized in the lightfield-sampling-graph, compare Figure 19.1 Chapter 19.

the photons D, and G have the same incident-directions as the photons E, and F. The image is blurred. But with a light-field-sensor shown in Figure 10.1 we can resolve the true incident-directions of all the photons if we know the light-fieldgeometry G of our plenoscope. The light-field-geometry G, which is introduced in Chapter 8, tells us for each photo-sensor in the light-field-sensor which solid-angle of incident-directions c_x , c_y , and which area of support-positions x, y are covered by this photo-sensor. In the close-up Figure 10.2 we see the two-dimensional addressing of the photo-sensors in the light-field-sensor. Analog to Figure 2.3, we see in Figure 10.3 how the photo-sensors sample the light-field. In contrast to the sampling of the plenoscope free of aberrations in Figure 2.3, here we find that the sampling of the photo-sensors is not a rectangular grid in the space of incident-directions and support-positions but a skewed grid instead. The exact arrangement of the photo-sensors in the space of incident-directions and supportpositions is what is stored in the light-field-geometry G. So the sampling of the photo-sensors in Figure 10.3 is a visual representation of the light-field-geometry G for the plenoscope presented in Figure 10.1 which has an imaging-reflector with aberrations. In Figure 10.3, we find that the photo-sensors (0,0), (1,1), (1,2), and (2,3) sample similar incident-directions as they are arranged on a horizontal line in the space of incident-directions and support-positions. So when we project the recorded light-field \mathcal{L} onto an image using the light-field-geometry G, we obtain an image where the effects of the aberrations from the imaging-reflector are reduced. The projection can be visualized in Figure 10.3 when the intensity of the photo-sensors is projected onto the axis of incident-directions. For details on projecting the light-field onto images see the Sections 9.2 and 9.4.

10.2 Example – spherical imaging-reflector

Spherical imaging-reflectors are one of the simplest to be fabricated. Spherical imaging-reflectors are often used to have large field-of-views [Fors et al., 2013, Cortina et al., 2016], but like other imaging-reflectors they suffer from aberrations. We simulate the imaging on a spherical imaging-reflector which has the same focal-length/diameter= 1.5 ratio as Portal's large imaging-reflector. One after the other, we simulate the exposures of a classic image-sensor and three different light-field-sensors. The image-sensor and the light-field-sensor have the same pixel-sizes of 0.067° . The light-field-sensors only differ in the number of paxels they use to segment the principal-aperture-plane. We have light-field-sensors with 3, 9, and 27 paxels on the diagonal of the aperture. This simulation is in two dimensions, and assumes that the light-field-sensors are perfect and only limited by their discrete number of paxels.

Before we reconstruct images from the responses of the different sensors, we estimate the light-field-geometry of each sensor, even the light-field-geometry $G_{\text{spherical imaging-reflector + image-sensor}}$ of the classic image-sensor. This makes the

comparison fair. Now both the image of the classic image-sensor and the images of the light-field-sensors are corrected for distortions caused by the spherical imaging-reflector. Distortions are when the absorption-position of a photon on the sensor-plane is not linear proportional to the incident-direction of the photon. Distortions can be, and usually are, corrected for when reconstructing images from image-sensors. The four Figures 10.4, 10.5, 10.6, and 10.7 show the images reconstructed by both the image-sensor and the light-field-sensors for various incident-directions. Finally, in Figure 10.8 we summarize our findings and show how good light-field-sensors can overcome aberrations of spherical imagingreflectors.

Description for the Figures 10.4, 10.5, 10.6, and 10.7

Each figure consists of six panels. The two panels at the top show the spherical imaging-reflector, the optical-axis, the sensor-plane, and the trajectories of the photons. In the left panel at the top, we find an overview of the setup, and in the right panel at the top we find a close-up on the sensor-plane. In the left panel at the top, the close-up is indicated with a black square. Below we have four panels showing the four one-dimensional images reconstructed by the four different sensors. The upper most one-dimensional image is from the image-sensor, the lower ones are from the light-field-sensor with different numbers of paxels. The four panels showing the one-dimensional images have a vertical, dashed line to indicate the true incident-direction of the photons.

Discussion

From the reconstructed, one-dimensional images shown in the Figures 10.4, 10.5, 10.6, and 10.7, we find: First, that the spread of the reconstructed incidentdirections of the photons is reduced when we use light-field-sensors instead of image-sensors. Second, that the spread of the reconstructed incident-directions of the photons becomes smaller the more paxels are used in the light-field-sensor. And third, we find that the asymmetry of the reconstructed incident-directions of the photons is reduced on the light-field-sensors. The binning-artifacts in the reconstructed images seen in Figure 10.7 do not significantly effect our findings presented here.

In Figure 10.8, we find that even light-field-sensors with low numbers of paxels provide a strong reduction of the effect of aberrations on imaging. From a geometric point-of-view it is only natural, that when the number of paxels is increased further, aberrations of imaging-optics are overcome completely. This might become more clear when we describe the light-field-geometry G with other words: In the case of the plenoscope composed from an light-field-sensor and an imaging-reflector, the light-field-geometry G describes the surface-normal of the aperture, see the small surface-normals indicated in Figure 10.1. So when we

Figure 10.4: 0.0° incident-direction.

Figure 10.5: 2.3° incident-direction.

Figure 10.6: 4.6° incident-direction.

Figure 10.7: 7.0° incident-direction.

Figure 10.8: The spread of the reconstructed incident-directions of photons versus the true incident-direction of the photons. The number of paxels here is the number of paxels on the diagonal of the aperture. For comparison, our Portal Cherenkov-plenoscope has 9 paxels across the diagonal of its large imagingreflector.

have more paxels in the light-field-sensor, we have a more dense sampling of the aperture's surface-normals, and so we can correct better for aberrations which originate from these surface-normals.

10.3 Enlarging the field-of-view

In Figure 10.8 we find that the spread of the reconstructed incident-directions is much reduced and becomes more constant over the range of true incidentdirections when we use light-field-sensors instead of image-sensors. Of course more detailed studies are needed, but Figure 10.8 suggests that a Cherenkovplenoscope could be build with an enormous 16° diagonal field-of-view. A 201 deg² field-of-view would be an improvement of more than one order-of-magnitude over the field-of-views on todays Cherenkov-telescopes with about 16 deg², see Figure 5.12. And it would still be an improvement by a factor of 4 over the planned Schwarzschild-Couder-Cherenkov-Telescopes which are dedicated for wide field-of-views [Acharya et al., 2013] and also reach angular resolutions in and below the 0.1° regime.

The bottom-line is that Cherenkov-plenoscopes become interesting independent of their benefits for observations of low energetic gamma-rays, but because they can enlarge the field-of-view which we currently can not achieve by other means.

10.4 Upgrading the Cherenkov-telescope

We suggest to equip the Cherenkov-telescope¹ with a light-field-sensor not to gain plenoptic perception, but to improve image-quality. With imaging-reflectors with diameters below $\approx 23 \,\mathrm{m}$, there is not much plenoptic perception-power for airshowers to be gained anyhow, compare Chapter 6. However, the size of the fieldof-view, the sharpness of the images, and especially the consistency of the images across the field-of-view would be improved dramatically. In case one fears the costs for additional read-out-channels in a light-field-sensors, we propose a way to mutilate the light-field-sensor in order to reduce the number of read-out-channels to the same number needed for image-sensors, while still profiting from corrections for imaging provided by plenoptic perception. We can hardwire the light-fieldgeometry G into the light-field-sensor to sum up the photo-sensors which belong to a reconstructed pixel before these photo-sensors are fed into individual readout-channels. Projecting the light-field onto an image is about summing up the correct photo-sensors as we show in the Sections 9.2, and 9.4. To be clear: The number of individual photo-sensors will increase to the number of lixels, but the number of read-out-channels for digitization will stay the lower number of pixels. A Cherenkov-telescope equipped with such a mutilated light-field-sensor would have the optics of a plenoscope, but the read-out of a telescope. The resulting Cherenkov-telescope would not record light-fields, but it could record images with much larger field-of-views, and much reduced aberrations.

10.5 Overcoming aberrations in Portal

The imaging-reflector of Portal is not free of aberrations. We can visualize this aberrations using the light-field-geometry of Portal. When we describe the projection of the light-field onto images as a matrix-multiplication, as we do in Section 9.2, we can visualize the columns of the imaging-matrix $U_{\text{imaging}}[n, k]$ just as we do in Figure 9.1. The aberrations should show up as asymmetric patterns in the visualizations of the columns of the imaging-matrix $U_{\text{imaging}}[n, k]$. Now in the Figures 9.1, 9.4, and 9.5, we hardly see any hint for this asymmetry because the

¹In general. This includes all existing and future Cherenkov-telescopes.

columns visualized in these figures correspond to the central pixel n = 4,221 in the field-of-view. For the central pixel, the aberrations induced by the imagingreflector of Portal are only minor. However, aberrations can be seen for the outer regions in the field-of-view. Here we visualize six of these matrix-columns for six pixels ranging from the center of the field-of-view at 0.0° to the outer perimeter of the filed-of-view at 3.0°. We compute the imaging-matrix $U_{\text{imaging}}[n, k]$ according to Equation 9.14. Table 10.1 shows the incident-directions of the six different pixels. Figure 10.9 shows the photo-sensors participating to the six pixels on the photo-sensor-plane of the light-field-sensor in Portal. The Figures 10.9, and 10.10 do not show the point-spread-function of the imaging-reflector, but they visualize which photo-sensors are summed to synthesize a pixel because their corresponding lixels have near-by incident-directions as the pixel. Based on the light-field-geometry for Portal, we can overcome a large part of the aberrations induced by the large imaging-reflector. In Chapter 11, reconstructed images of a phantom-source observed with the Portal plenoscope, and a telescope are shown side-by-side. The reduction of aberrations can be seen in the reconstructed images recorded by the plenoscope, in contrast to the images reconstructed from the image-sensor of the telescope.

Figure 10.9: Black photo-sensors are summed to synthesize the six pixels with incident-directions 0.0° , 0.6° , 1.2° , 1.8° , 2.4° , and 3.0° . The black boxes indicate the range of the close-ups shown in Figure 10.10.

Figure 10.10: Black photo-sensors are summed to synthesize pixels in the image because their corresponding lixels have incident-directions close to these pixels. Figure 10.9 shows the summation of all the six different pixels at once. Upper, left shows 0.0° , upper, right shows 0.6° , middle, left shows 1.2° , middle, right shows 1.8° , lower, left shows 2.4° , and lower, right shows 3.0° .
Chapter 11

Compensating misalignments between the light-field-sensor and the imaging-reflector

On telescopes, the alignment of the image-sensor with respect to the imagingoptics has a strong effect on image-quality. Building telescope-mounts and supportstructures which keep the optics aligned becomes an expensive challenge on larger telescopes. However, if a light-field-sensor is used instead of an image-sensor, and if the actual alignment of the light-field-sensor with respect to the imaging-optics is known, the quality of the images reconstructed from the light-field is little to none effected by misalignments.

Compensating the misalignments of the light-field-sensor is a key-feature of the Portal Cherenkov-plenoscope. It allows us to mechanically separate the light-field-sensor from the large imaging-reflector in order to defer the physical limit of the square-cube-law, and to build larger apertures, see Chapter 16. We show that the compensation of misalignments is already included in the light-field-geometry G which we introduce in Chapter 8, and is closely related to the overcoming of aberrations discussed in Chapter 10.

First, we organize the misalignments into four components and discuss their effects on imaging. Second, we show how the light-field-geometry G can be used to compensate such misalignments. And third, we simulate the imaging of the Portal Cherenkov-plenoscope and a same sized Cherenkov-telescope when both observe a three-dimensional phantom-source located up in the atmosphere while the sensor-planes of both the telescope and the plenoscope are misaligned in various ways.

11.1 Organizing components of misalignments

We organize the misalignments between the sensor-plane and the imaging-optics into four components listed below. We use the frame of the imaging-optics as a

Figure 11.1: Translations parallel to the optical-axis. The photons \overline{ea} , $\overline{ea'}$, and $\overline{ea''}$ only converge in a single point on the image-sensor when the sensor-plane-distance d is equal to the image-distance b. But when the image-sensor is translated away from its target-position, the absorption-positions i, i', and i'' do not converge and the image of e is blurred.

reference, and translate and rotate only the image-sensor.

$\stackrel{\text{\tiny (i)}}{\longrightarrow} Translations parallel to the optical-axis$

When we translate the sensor-plane parallel to the optical-axis of the imagingoptics, see Figure 11.1, we change the sensor-plane-distance d introduced with the thin-lens in Figure 6.2. A parallel translation corresponds to focusing the image to different object-distances. On Cherenkov-telescopes we have to choose one optimal object-distance to focus on [Hofmann, 2001, Trichard et al., 2015] before the image of the air-shower is recorded. On image-senors, we can not correct for parallel translations, not even when we know the actual parallel translation. Image-sensors do not measure the trajectories ia, i'a', and i''a'', but only the absorption-positions i, i', and i''. However, light-field-sensors on the other hand do measure the trajectories ia, i'a'' and thus can reconstruct the intersection-positions of such trajectories on a virtual sensor-plane to restore the image. We discuss the restoring of images focused to any object-distance in Section 9.4.

We estimate the acceptable tolerances for parallel translations before the effect shows up in the reconstructed images for a Cherenkov-telescope of the same size as the Portal Cherenkov-plenoscope. When we target to focus on an object-distance $g_{\text{target}} = 10.0 \text{ km}$, our target-sensor-plane-distance is $d_{\text{target}} = 107.64 \text{ m}$ according to the Thin-lens-equation 6.1. According to the Depth-of-field-equation 6.2 the depth-of-field spans from $g_{-} = 9.18 \text{ km}$ to $g_{+} = 10.8 \text{ km}$. The corresponding sensor-plane-distances to focus exactly on the start and end of the depth-of-field are $d_{-} = 107.75 \text{ m}$, and $d_{+} = 107.56 \text{ m}$ respectively. We identify the difference between our targeted sensor-plane-distance d_{target} and the sensor-plane-distances which would move our focus beyond our depth-of-field d_{\pm} as the acceptable tol-

Figure 11.2: Translations perpendicular to the optical-axis. The photons \overline{ea} , $\overline{ea'}$, and $\overline{ea''}$ will still converge in the absorption-points i = i' = i''. Although the photons enter different photo-sensors when the image-sensor is translated perpendicular to the optical-axis, they still can be assigned to the pixel corresponding to their incident-directions.

erance for parallel translations

$$\Delta_{\parallel}^{\text{trans}} = d_{\text{target}} - d_{\pm} \tag{11.1}$$

$$d_{\pm} = \frac{1}{\frac{1}{f} - \frac{1}{g_{\pm}}}.$$
(11.2)

The sensor-plane must not be translated further than +104 mm and -88 mm parallel to the optical-axis before the image differs recognizably. In units of the focal-length this tolerance is $8.5 \times 10^{-4} f$.

(\downarrow) Translations perpendicular to the optical-axis

When we translate the sensor-plane perpendicular to the optical-axis of the imaging-optics, see Figure 11.2, the image will simply show a different region of incident-directions. As long as the actual perpendicular translation is known, and the field-of-view is large enough so that our region-of-interest does not drop out of it, then translations perpendicular to the optical-axis do not effect the image-quality. On real imaging-optics unfortunately, distortions and aberrations dilute the angular resolution the larger the incident-direction of the photons becomes. So on real telescopes, we expect that translations perpendicular to the optical-axis have an effect on the image-quality which becomes larger, the larger the perpendicular translation becomes. However, with light-field-sensors on the other hand we can even compensate the increasing aberrations of the imaging-optics, see Chapter 10, so that the quality of the images reconstructed from light-field-sensors is not effected by perpendicular translations.

If we would not correct for perpendicular translations, a Cherenkov-telescope of the same size of Portal could tolerate perpendicular translations up to about the

Figure 11.3: Rotations parallel to the optical-axis. All photons coming from e still converge in one absorption-position i = i' = i''. Just as for perpendicular translations, shown in Figure 11.2, the photons might be absorbed by a different photo-sensor now, but they still can be assigned to the pixel corresponding to their incident-directions.

extend p of the projection of a pixel onto the sensor-plane

$$\Delta_{\perp}^{\text{trans}} = \pm \frac{p}{2}, \qquad (11.3)$$

which gives $\Delta_{\perp}^{\text{trans}} \approx \pm 63 \,\text{mm}$, and is related to $\Delta_{\parallel}^{\text{trans}}$ by a factor of f/D. In units of the focal-length, this tolerance is $5.8 \times 10^{-4} f$.

(\uparrow) Rotations parallel to the optical-axis

When we rotate the image-sensor parallel to the optical-axis of the imaging-optics, see Figure 11.3, we simply end up with an image rotated around its center. We can fully compensate rotations parallel to the optical-axis in post when we know the actual parallel rotation.

Again we can estimate the tolerance for a parallel rotation angle

$$\Delta_{\parallel}^{\rm rot} = \frac{\Delta_{\perp}^{\rm trans}}{f \tan(\theta_{\rm FoV}/2)}$$
(11.4)

when we would not correct for it in post. We use the acceptable tolerance for perpendicular translations $\Delta_{\perp}^{\text{trans}}$ and divide it by the radius of the sensor-plane. For the example of the Cherenkov-telescope of the same size as Portal we get $\Delta_{\parallel}^{\text{rot}} = 0.59^{\circ}$.

$\left(\begin{array}{c} \vdots \\ \vdots \end{array}\right)$ Rotations perpendicular to the optical-axis

When we rotate the sensor-plane perpendicular to the optical-axis of the imagingoptics, one region on the sensor-plane will be closer to the imaging-optics than the opposite region on the sensor-plane, see Figure 11.4. The two regions effectively have different sensor-plane-distances, what corresponds to the two regions being

Figure 11.4: Rotations perpendicular to the optical-axis. The absorptionpositions i, i', and i'' are effected in a similar way as shown in the component for parallel translations, see Figure 11.1.

focused to different object-distances. So we expect similar effects on the imagequality as for translations parallel to the optical-axis, but more complicated since the image is not evenly out-of-focus, but differently for different regions. Just as for the parallel translations, on image-sensors we can not compensate the effects of this perpendicular rotations in post, not even when we know the actual perpendicular rotation. Again, this is because an image-sensor does not measure the trajectories ia, i'a', and i''a'', but only the absorption-positions i, i', and i''. For the same argument we pointed out for parallel translations, a light-field-sensor can compensate perpendicular rotations when the rotation is known. We can estimate the tolerance for perpendicular rotation angles

$$\Delta_{\perp}^{\rm rot} = \frac{\Delta_{\parallel}^{\rm trans}}{f \tan(\theta_{\rm FoV}/2)} \tag{11.5}$$

based on the tolerance for parallel translations $\Delta_{\parallel}^{\text{trans}}$ and the radius of the sensorplane. This gives us a tolerance for perpendicular rotations of $\pm 0.83^{\circ}$ for a Cherenkov-telescope with the size of Portal before the image differs recognizably.

Summarizing misalignment-components

Based on the Figures 11.1, 11.2, 11.3, and 11.4, we summarize our findings in Table 11.1. However, Table 11.1 addresses perfect light-field-sensors. As we will see next, real light-field-sensors are limited in resolution or in the acceptance-angles for incoming photons.

misalignment-	acceptable tolerances	can be compensated on:	
component	mponent without compensation		light-field-sensor
	$\Delta_{\parallel}^{\text{trans}} = -88 \text{mm to } +104 \text{mm}$	No	Yes
ţ)	$\Delta_{\perp}^{\rm trans} = \pm 63\rm mm$	Yes, partly	Yes
	$\Delta_{\parallel}^{\rm rot} = \pm 0.59^{\circ}$	Yes	Yes
	$\Delta_{\perp}^{\rm rot} = \pm 0.83^{\circ}$	No	Yes

Table 11.1: Summary of the four misalignment-components. The acceptable tolerances are estimated for a Cherenkov-telescope with the size of Portal. The restriction 'partly' here refers to aberrations caused by real imaging-optics.

11.2 Using the light-field-geometry

Figure 11.5 shows a plenoscope observing the three photons A, B, and C while its light-field-sensor is misaligned with respect to the imaging-reflector. Despite the misalignment, the three photons are absorbed by the photo-sensors inside the light-field-sensor, see Figure 11.6. When we know the actual alignment \hat{T}_{actual} between the light-field-sensor and the imaging-reflector, we can estimate the specific light-field-geometry $G(\hat{T}_{actual})$ for the whole misaligned plenoscope, see Figure 11.7. Although the photons A, and C have the same incident-directions, they enter different small cameras in the light-field-sensor. But using the actual lightfield-geometry $G(\hat{T}_{actual})$, we can still reconstruct the actual incident-directions of A, and C. In the Figures 11.6, and 11.7 we also show the target-alignment \hat{T}_{target} of the light-field-sensor in light gray. We find that in Figure 11.7, the black Photons A, B, and C which are detected by the misaligned light-field-sensor are close to their light gray counterparts which are detected by the light-field-sensor in its target-alignment.

From our thoughts summarized in Table 11.1, we already concluded that the superior knowledge of the light-field-sensor about the trajectories of the photons will allow it to compensate misalignments. In Figure 11.7 we see how this superior knowledge shows up as a distortion of the light-field-geometry $G(\hat{T}_{actual})$. But from the plenoscope shown in the Figures 11.5, and 11.6 we also see that real light-field-sensors have limited resolutions. They have a limited number of small cameras, and a limited number of photo-sensors inside the small cameras. In the next Section 11.3 we take a look at the actual compensation-power for misalignments on the Portal Cherenkov-plenoscope which has such limited resolutions as it is meant to be fabricated in a cost-effective way.

Figure 11.5: The same three photons A, B, and C from Figure 2.2, but this time the light-field-sensor is misaligned in \hat{T}_{actual} with respect to the imaging-reflector. In bright gray we indicate the target-alignment \hat{T}_{target} of the light-field-sensor. Figure 11.6 shows a close-up of the light-field-sensor.

m - support-positions (x, y)

Figure 11.7: A visual representation of the light-field-geometry $G(\hat{T}_{\text{actual}})$ corresponding to the misalignment \hat{T}_{actual} shown in Figures 11.5, and 11.6.

11.3 Imaging a phantom-source with Portal

To get a qualitative feeling for the effects of misalignments on imaging, and to get a qualitative feeling for the compensation-power for misalignments of Portal's light-field-sensor, we reconstruct images of a phantom-source. The phantomsource has a well defined shape in the three-dimensional space, and is described in the Figures 11.8, and 11.9. The phantom-source extends from an object-distance of 2.5 km up to 20.0 km, and all its photons reach the principal-aperture-plane in a 1 ns time-window, similar to Cherenkov-photons produced in air-showers. There are no night-sky-background-photons, but only the photons from the phantomsource. In our simulation we set up the Portal Cherenkov-plenoscope and a Cherenkov-telescope of the same size as Portal. The plenoscope records a lightfield-sequence over a period of 50 ns, and the telescope records an image-sequence also over a period of 50 ns. Both instruments take 2×10^9 samples per second. However, for the static flash of photons from the phantom-source we just look at the integrated light-field and image respectively. Both instruments have their sensor-plane-distances set to $d_{\rm target} = 107.65\,{\rm m}$ to focus to an object-distance of $g_{\text{target}} = 10 \,\text{km}$. The images reconstructed from the telescope are corrected as much as possible for the given situation, e.g. they are corrected for perpendicular translations, parallel rotations, and distortions caused by the imaging-reflector. The images reconstructed from the light-field from the plenoscope are in addition also corrected for the remaining components of misalignments such as parallel translations and perpendicular rotations. One might argue that with a target object-distance of $g_{\text{target}} = 10 \text{ km}$, the Cherenkov-telescope can never produce a fully sharp image of any layer in the phantom-source, since there is no layer exactly at this object-distance, and thus a side-by-side comparison of the telescope and the plenoscope is not fair. Yes, it is not fair, but not because we designed the phantom-source this way, but because the plenoscope is the superior instrument. The purpose of these instruments is to record air-showers, and just as air-showers, our phantom-source spans a wide range of object-distances which simply exceeds the depth-of-field of a Cherenkov-telescope of the size of Portal, see Chapter 6. Focuses on different object-distances of the air-shower offer different advantages for the reconstruction of different properties of the air-shower [Hofmann, 2001], and thus any focus chosen on a Cherenkov-telescope of the size of Portal ends up to be an inferior compromise. Actually some of the misalignments will by chance even improve the imaging on the telescope.

What we expect to see in the images

- 1. We expect the images reconstructed from the light-field recorded by the plenoscope to always look the same regardless of the actual scenario of misalignment of the light-field-sensor.
- 2. We expect the plenoscope to be able to project its light-field onto images focused to different object-distances to e.g. find the sharpest response for the spiral, the sun-symbol, and the smiley in the phantom-source.
- 3. We expect the images from the telescope to be only one single image for each scenario of misalignment, and not multiple images taken with different focuses. This might be obvious, but we want to remind ourselves that like the plenoscope, the telescope has only one single chance to record the airshower. The telescope has to choose one focus which it can not optimize in advance for the individual air-shower.

Scenarios of misalignments

We set up four different scenarios of misalignments, see Table 11.2. First, we look at images of the phantom-source when the light-field-sensor is in its targetalignment for an object-distance of 10 km. Second, we look at images taken with three different perpendicular rotations of up to 8.31° . Third, we look at images taken with four different parallel translations from -877 mm to +1,035 mm. And fourth, we look at images taken when all components of misalignment come together.

Table 11.2: Overview of the simulated scenarios of misalignments. The magnitude of the misalignments is up to one order-of-magnitude above the acceptable tolerances listed in Table 11.1. We concentrate on the components of misalignment which can not be compensated by image-sensors.

Description for the Figures 11.10 to 11.20

The Figures 11.10 to 11.20 show images of the phantom-source. The top of the figure shows the type and magnitude of the misalignment, compare with Table 11.2. The figures are split into two columns. The left column named 'Telescope', shows the single image recorded by the Cherenkov-telescope. The right column named 'Plenoscope' shows three images projected from the light-field recorded by the Portal Cherenkov-plenoscope. The three reconstructed images are focused such that the spiral, the sun-symbol and the smiley are sharp in the image. The choice of three images here is arbitrary and could always be extended to a more detailed series of refocused images like the series shown in the Figures 11.11, and 11.12. Always keep in mind that the images $\mathcal{I}[c_x, c_y]$ we look at are only incomplete projections of the light-field $\mathcal{L}[c_x, c_y, x, y]$, and that the only reason for doing so is to allow our limited visual perception to get an impression.

Discussing the reconstructed images

When we look at the images in the right plenoscope-column of the Figures 11.10, to 11.20, we find that they all look remarkably similar despite the different scenarios of strong misalignments. Even misalignments which exceed the acceptable tolerances for image-sensors by one order-of-magnitude are apparently not an issue for the light-field-sensor in Portal. The spiral, the sun-symbol, and the smiley can in all scenarios be focused on sharply. Neither the sun-symbol nor the spiral show signs of asymmetries or aberrations, in contrast to the images of the telescope in the left columns. This is because the images reconstructed from the light-field are naturally also corrected for aberrations, see Chapter 10. In fact, the images look so alike that it is hard to belief they were reconstructed from the light-fields recorded in scenarios of different misalignments. But when we take

a close look on the scenario of strong perpendicular rotations of 8.31° along the y-axis in Figure 11.15, we find that the hexagonal pixels in the images have small gaps in between them for negative incident-directions in c_x , and are compressed for positive incident-directions in c_x . This irregular grid of the pixels is caused by the rotation of the sensor-plane. Also when we look at the composition of several misalignments in Figure 11.20, we see that the reconstructed images are from a light-field recorded during this specific misalignment as we see that the sun-symbol is not fully included anymore in the field-of-view. Also the grid of pixels is rotated in Figure 11.20 to compensate the parallel rotation. In all reconstructed images from the light-field we can see that it is possible to nail the focus on one particular part of the phantom-source. In all the refocused images focused on the smiley we can clearly see its mouth and eyes. In all the refocused images focused on the sun-symbol we can clearly see the flares of the sun-symbol and even see the gap between the flares and the ring. And in all the refocused images focused on the spiral, the spiral is evenly glowing, the parts of the spiral close to the center of the image are as sharp as the parts of the spiral in the outer realm of the image. There are no signs of aberrations.

Not so for the images of the telescope. All images of the telescope show asymmetries in sharpness across the field-of-view. Already in the target-alignment shown in Figure 11.10, the mouth and the eyes of the smiley are washed out and the spiral is almost gone. The flares of the sun-symbol are hardly recognizable. During the perpendicular rotation along the y-axis in the Figures 11.13, to 11.15, the sensor-plane happens to reach sensor-plane-distances which favor the imaging of the smiley and the sun-symbol.

The bottom-line here is that although the images from the telescope are not completely useless during misalignments, the images reconstructed from the lightfield of the plenoscope simply nail the focus in every scenario. However, the serious argument for the plenoscope is not that its images are sharper, but the fact that we can reconstruct the object-distances of the individual parts of the phantom-source. Equation 9.26 states, that for any sensor-plane-distance of a virtual sensor-plane there is a corresponding object-distance. The plenoscope can reconstruct the phantom-source in the third dimension, a dimension which is beyond the perception of the telescope. We discuss the full potential for threedimensional reconstructions in Chapter 15 about tomography.

Figure 11.8: The phantom-source in three dimensions consists of a triangle-wire, a spiral-wire, and a sun-symbol-wire. The wires emit photons. At the bottom is the principal-apertureplane of the imaging-reflector. The symbols scale with with the object-distance they are located in. This way, they appear with similar sizes in the images. Note, the axis of the object-distance is compressed, and not to scale.

Figure 11.9: The symbols are located in different objectdistances above the aperture: $g_{\text{triangle}} = 2.5 \text{ km}$ $g_{\text{spiral}} = 4.2 \text{ km}$ $g_{\text{sun-symbol}} = 7.1 \text{ km}$ $g_{\text{smiley}} = 11.9 \text{ km}$ $g_{\text{cross}} = 20.0 \text{ km}$

Target-alignment

Figure 11.10: See a detailed series of refocused images from the plenoscope in the Figures 11.11, and 11.12.

Figure 11.11: A series of images showing the phantom-source. The images are projections of the light-field recorded by the Portal Cherenkov-plenoscope. Each image is focused to a different object-distance g, shown in the lower, left corner of each image. The series continues in Figure 11.12.

Figure 11.12: Continuation of Figure 11.11.

Figure 11.13: By chance, the rotation helps the imaging of the smiley and the sun-symbol on the telescope.

Figure 11.14: Again, the rotation helps with the imaging of the smiley and the sun-symbol on the telescope, see Figure 11.13.

Figure 11.15: Note the tiny white gaps between the pixels on the left half of the images. The regular grid of pixels is distorted due to the strong rotation.

Figure 11.16: Sensor-plane-distance is $d = d_{\text{target}} - 877 \,\text{mm} = 106.77 \,\text{m}$, and corresponds to a focus on an object-distance of 42.2 km.

Figure 11.17: Sensor-plane-distance is $d = d_{\text{target}} - 240 \,\text{mm} = 107.41 \,\text{m}$, and corresponds to a focus on an object-distance of 12.6 km.

Figure 11.18: Sensor-plane-distance is $d = d_{\text{target}} + 398 \,\text{mm} = 108.04 \,\text{m}$, and corresponds to a focus on an object-distance of 7.5 km.

Figure 11.19: Sensor-plane-distance is $d = d_{\text{target}} + 1,035 \text{ mm} = 108.68 \text{ m}$, and corresponds to a focus on an object-distance of 5.3 km.

Figure 11.20: The misalignment moves and rotates the image in the space of incident-directions c_x , and c_y . For example, the sun-symbol is not any longer fully included in the image.

Chapter 12

Triggering the Cherenkov-plenoscope

The continuous stream of sensor-responses in a Cherenkov-telescope or plenoscope is too large to be analyzed in detail. Limited processing-resources force us to reject large parts of the observed sensor-responses, and only analyze a small fraction of it. The logic which decides what parts to reject, and what parts to analyze is called the trigger. At an expected trigger-rate of $\approx 59 \times 10^3 \,\mathrm{s}^{-1}$, and an exposure time of 50 ns for each event, the trigger on Portal rejects 99.705%of the continuously observed light-field-sequence, and copies only 0.295% of it to a more permanent-storage for further reconstructions of air-showers, compare Figure 2.9. A smart, yet simple trigger is crucial for the cost-effective detection of low energetic cosmic gamma-rays. With current technology we can read-out all the photo-sensors in real-time, but we can not store the resulting light-fieldsequence for further reconstructions. We can only buffer the light-field-sequence for a short duration of $\approx 100 \,\mathrm{ns}$ up to a few 1 us. This is possible because all the read-out-channels can write to their own, fast but small memory-buffer in parallel. On Cherenkov-telescopes, there exist digital, and analog implementations of this memory-buffer. Digital implementations can use flash-analog-todigital-converters [Weinstein et al., 2007, Bulian et al., 1998] followed by a digital memory-buffer. Analog implementations can use e.g. a sequence of sample-andhold-circuits¹ [Funk et al., 2004, Sitarek et al., 2013], or even a delay-line [Kildea et al., 2007. All these implementations permanently overwrite the oldest part of the recorded image-sequence with the latest one coming from the photo-sensors. Just as in the Cherenkov-telescope, the trigger in the Cherenkov-plenoscope has to decide whether the current light-field-sequence inside the memory-buffer contains Cherenkov-photons from an air-shower worthwhile to analyze.

In this Chapter: First, we discuss how established triggers in Cherenkov-telescopes make their decision based on the density of photons in image-sequences. Second, we propose to adopt triggers acting on image-sequences for the Cherenkov-

 $^{^1\}mathrm{Also}$ called domino-ring-sampler [Ritt, 2008], or switched-capacitor-array, or analog-ring-sampler.

plenoscope, but we propose to implement multiple of such image-sequences refocused to different object-distances. Third, we motivate the trigger-threshold chosen for the simulations of Portal, and show the performance of the simulated trigger.

12.1 Triggering Cherenkov-telescopes

Two methods are used to make the trigger in a Cherenkov-telescope more sensitive to air-showers, and less sensitive to fluctuations of the night-sky-backgroundphotons. First, triggers look for a high density of photons in time. The compact \approx 10 ns arrival of Cherenkov-photons on ground clearly separates these from the steady arrival of night-sky-background-photons. Second, triggers look for spatial patterns in the image-sequences. Cherenkov-photons are likely to populate nearby pixels in the image-sequences because their emission-positions in the air-shower populate a rather compact volume. Both methods are often used in parallel or in stages to make the final trigger-decision. However, since the atmospheric Cherenkov-method approaches the regime of single-photons, there is an additional aspect relevant for the trigger-decision. The observable fluctuations in the arrival of night-sky-background-photons can be large because the pixels sample only small solid-angles, and integrate only over short periods of ≈ 5 ns. This limitation is known as the Law of Large Numbers [Poisson, 1837]. Because of this, the threshold for the trigger has to be larger than the anticipated threshold deduced from the average flux of the night-sky-background-photons. Otherwise the trigger will store too many image-sequences only containing fluctuations of the night-sky-background. The larger the number of photons used for the trigger-decision becomes, the smaller becomes the relative statistical fluctuation of this number. Therefore, some Cherenkov-telescopes sum up multiple read-out-channels before comparing the result to a threshold [Delagnes et al., 2006, Vogler et al., 2011, Garcia et al., 2014]. This is called a sum-trigger. Other Cherenkov-telescopes do compare the density of photons on individual pixels, but then demand compact regions of triggered pixels in a second stage Bulian et al., 1998, Weinstein et al., 2007, Kildea et al., 2007] to counteract the fluctuation of the night-sky-background-photons. With these methods, air-showers induced by lower energetic particles are more likely to be recorded while fluctuations of the night-sky-background-photons are more likely to be rejected.

12.2 A light-field-trigger for Portal

For this study of the Portal Cherenkov-plenoscope, we adopt aspects of both trigger-implementations on Cherenkov-telescopes and create a trigger with two stages. In the first stage, we adopt the summation of the established sum-trigger to reduce the effect of statistical fluctuations as early as possible. We sum up

Figure 12.1: The differential flux of night-sky-background-photons. The solid line is used in the simulations of Portal. We assume that the flux of night-sky-background-photons at the observatory on Roque de los Muchachos on Canary island La Palma, Spain is representative for most sites where Portal might be build. Numerical values of solid line are taken from [Gaug et al., 2013], which is based on [Benn and Ellison, 1998]. For comparison, the dashed line is taken from [Preuss et al., 2002].

Figure 12.2: A possible trigger-pixel for the center of the field-of-view. Focus is set to infinity. A total of 427 black photo-sensors are summed up to form a trigger-pixel. Just like Figure 9.1, this is created using Equation 9.31 but with a wider pixel-radius of $1.1 \times 0.067^{\circ}$.

 ≈ 427 lixels each into large, and overlapping trigger-pixels. These trigger-pixels form a trigger-image-sequence. The intensity in these trigger-pixels is then integrated continuously over a period of 5 ns where the integral is compared with a predetermined trigger-threshold.

In a second stage, we adopt the search for coincident patterns and thus demand that at least two neighboring trigger-pixels must exceed their predetermined threshold in order to trigger the read-out.

For this, the light-field-sequence needs to be projected onto an trigger-imagesequence in real-time. This projection can be written as a matrix-multiplication, see Equation 9.24 in Sections 9.2, and 9.4. Each trigger-pixel in the resulting image-sequence is computed from the sum of corresponding lixels (read-outchannels) in the light-field-sequence. This means, that we can hardwire a realtime-projection of the light-field-sequence into the housing of the light-field-sensor itself using e.g. operational amplifiers to sum up the analog output-potentials of the corresponding photo-sensors. This is for the same reasons as discussed in Section 10.4. From the implementation point-of-view, the sum-trigger for the Cherenkov-plenoscope is the same as the sum-trigger for the Cherenkov-telescope. Both are summing up certain read-out-channels into trigger-pixels. In the simplest case, this summation into a trigger-pixel can look like e.g. the patterns shown in the Figure 12.2.

A single trigger-pixel thus contains on average $7 \times 61 = 427$ read-out-channels (lixels). As we discuss in Chapter 10, the (trigger-)image-sequence has much reduced aberrations and distortions. In contrast to Cherenkov-telescopes, the Portal Cherenkov-plenoscope profits from its plenoptic-perception here. To take

Duration of sliding integration	$5\mathrm{ns}$
Num. of refocused image-sequences	3
Object-distances of refocused image-sequences	$7.5, 15.0, and 22.5 \mathrm{km}$
Num. of trigger-pixels per trigger-image-sequence	8,443
Num. of lixels summed-up into one trigger-pixel	427
Avg. nsb-photons in time-integrated trigger-pixel	$53.5\mathrm{photons}$
Threshold for time-integrated trigger-pixel	$103\mathrm{photons}$
Min. num. of neighboring trigger-pixels above threshold	2
Expected trigger-rate due to air-showers	$59 \times 10^3 {\rm s}^{-1}$
Expected trigger-rate due to nsb-fluctuations	$\mathcal{O}(22\mathrm{s}^{-1})$
Avg. rate of nsb-photons in lixel	$25\times10^6{\rm s}^{-1}$

Table 12.1: The basic specifications of Portal's trigger. Here nsb is short for night-sky-background. We use the night-sky-background shown in Figure 12.1.

even more advantage of the plenoptic-perception, we actually implement three layers of summations, creating three (trigger-)image-sequences from one lightfield-sequence in parallel. The individual (trigger-)image-sequences are focused to object-distances of 7.5 km, 15 km, and 22.5 km each. Figure 12.3 shows the three different summations implemented for the central trigger-pixel (n = 4, 221) in the field-of-view. We create trigger-pixels which include all lixels within a radius of $110\% \times 0.067^{\circ}$ in incident-directions. Portal's trigger is able to differentiate between air-showers which reach their maximum Cherenkov-photon-production on different altitudes. It partly overcomes the depth-of-field-limit on the triggerlevel. Table 12.1 summarizes the basic specifications of Portal's trigger.

12.3 Portal's trigger-threshold

As the rate of air-showers with energies from 1 GeV to 10 GeV is very high, the expected trigger-rates of $\approx 59 \times 10^3 \,\mathrm{s}^{-1}$ on Portal will be higher than the trigger-rates of existing Cherenkov-telescopes, see Figures 2.7, and 2.9. A trigger-rate of $59 \times 10^3 \,\mathrm{s}^{-1}$ on Portal gets close to the limits of todays implementations on Cherenkov-telescopes [Delagnes et al., 2006] which are designed to reach $100 \times 10^3 \,\mathrm{s}^{-1}$. As a consequence, we apply a rather high trigger-threshold so that in addition to the trigger-rate induced by air-showers, the trigger-rate induced by fluctuations in the night-sky-background is low. We set the trigger-threshold such that there are no accidental triggers caused by the night-sky-background-photons in all of the $\approx 45 \,\mathrm{ms}$ of simulated observations in which the trigger is exposed. From this we conclude that the accidental trigger-rate will not drastically exceed $22 \,\mathrm{s}^{-1}$. During the dark night, there are 53.5 photons in a trigger-pixel integrated over 5 ns. In the simulations of Portal we use the night-sky-background-flux shown in Figure 12.1. The predetermined threshold for an integrated trigger-pixel is 103 photons, which is $\approx 6.7 \,\mathrm{standard}$ -deviations above the fluctuations of

Figure 12.3: Signals from black photo-sensors (lixels) will be summed up to form the central trigger-pixel in the field-of-view of Portal.

Figure 12.4: The trigger-probability for gamma-rays from a point-source versus the number of true and detected Cherenkov-photons.

the night-sky-background. Figure 12.10 shows Portal's trigger-rate depending on the trigger-threshold.

12.4 Performance of Portal's trigger

In the Figures 12.4, 12.6, and 12.8, we show Portal's trigger-probability depending on the number of true and detected Cherenkov-photons. Although both Figures 12.4 and 12.6 show the trigger-probability for electromagnetic air-showers, the gamma-rays in Figure 12.4 come from a point-source, while the electrons in Figure 12.6 come from a diffuse source. In Figure 12.4 we find that for gamma-rays coming from a point-source within Portal's field-of-view, the air-showers which have ≈ 100 of their Cherenkov-photons detected also have a 50% chance to trigger. We also find that the probability to trigger vanishes for air-showers with only 20 or less Cherenkov-photons. When comparing the trigger-probabilities for diffuse electrons in Figures 12.6 with the trigger-probability for diffuse protons in Figure 12.8, we find that protons need about twice as much Cherenkov-photons to be detected in order to trigger Portal. This is probably due to the wider spread of secondary particles in hadronic air-showers. This wider spread also widens the spread of the Cherenkov-photons, and this leads to a lower density of Cherenkovphotons in the trigger-pixels. Because of this, the correlation of the number of true and detected Cherenkov-photons with the true energy of the cosmic particle is more clear for gamma-rays in Figure 12.5, and electrons in Figure 12.7, then for protons in Figure 12.9.

Figure 12.5: Number of true and detected Cherenkov-photons versus the true energy of gamma-rays coming from a point-source. The histogram in the upper panel has the sum along its columns normalized to one. The lower panel shows the number of events populating the columns in the upper histogram.

Figure 12.6: The trigger-probability for electrons from a diffuse source versus the number of true and detected Cherenkov-photons.

Figure 12.7: Number of true and detected Cherenkov-photons versus the true energy of electrons coming from a diffuse source. The histogram in the upper panel has the sum along its columns normalized to one. The lower panel shows the number of events populating the columns in the upper histogram.

Figure 12.8: The trigger-probability for protons from a diffuse source versus the number of true and detected Cherenkov-photons.

Figure 12.9: Number of true and detected Cherenkov-photons versus the true energy of protons coming from a diffuse source. The histogram in the upper panel has the sum along its columns normalized to one. The lower panel shows the number of events populating the columns in the upper histogram.

Figure 12.10: The trigger-rate versus the trigger-threshold for the Portal Cherenkov-plenoscope. This is often called rate-scan. Based on our simulations. The solid black line is the sum of triggers caused by fluctuations of the night-sky-background-photons according the flux shown in Figure 12.1, and charged cosmic-rays (protons, electrons, and positrons) according to the fluxes shown in Figure 2.7. The dotted line is only the triggers caused by the night-sky-background. For low trigger-thresholds below ≈ 85 photon-equivalents, our simulation runs out of statistics which is why the trigger-rate seems to saturate at $2 \times 10^7 \, \text{s}^{-1}$. The vertical gray line marks the trigger-threshold of 103 photo-equivalents which we use for Portal's performance-estimate in Section 2.6. The instrument-response-functions in Figures , 2.4 and 2.5 correspond to a trigger-threshold of 103 photo-equivalents.

12.5 Conclusion

Our first trigger for the Portal Cherenkov-plenoscope can be implemented with established technology, and allows Portal to reach an energy-threshold for gammarays of 1 GeV. The sum-trigger for Portal effectively reduces accidental triggers caused by fluctuations in the night-sky-background. Portal's trigger makes its decision based on image-sequences just like the trigger in a Cherenkov-telescope, but Portal's trigger profits from reduced aberrations and distortions provided by the plenoptic-perception. By summing up the responses of individual readout-channels (lixels), it is possible to implement the projection of the light-fieldsequence onto image-sequences in real-time. The light-field-sequence can even be projected onto multiple refocused image-sequences in real-time. Choosing between multiple layers of refocused image-sequences might allow to correct for misalignments between the light-field-sensor and the large imaging-reflector in real-time on the trigger-level. We choose a high trigger-threshold to eliminate accidental triggers. The lower trigger-rate due to the high trigger-threshold will ease the trigger's implementation and also the further processing of the lightfield-sequences.

12.6 On Portal's target-object-distance

The patterns shown in Figure 12.3 can be improved. In Figure 12.3, the targetgeometry for Portal is such that the sensor-plane of the light-field-sensor is exactly in a distance of one focal-length to the principal-aperture-plane of the large imaging-reflector. Using Equation 9.12 without the refocusing used in Equation 9.25, this corresponds to a target-object-distance on infinity. However, to optimize the trigger for closer object-distances, the light-field-sensor's target-position can be adjusted to the corresponding sensor-plane-distance in the first place. This way, the summation-patterns shown in Figure 12.3 would be much more dense in the sensor-plane what probably will ease their implementation. In contrast, focusing to infinity would yield a much more spread summation-pattern than the one shown in Figure 12.2.
Classifying Cherenkov-photons

About 99.9% of the photons recorded by Portal, are night-sky-background-photons which do not carry information about the origins of the cosmic particles. It is important to tell apart Cherenkov-photons from the pool of night-sky-backgroundphotons. This can only be done based on the structure and density of the photons in the recorded light-field-sequence. In this first investigation, we fall back to established methods used on Cherenkov-telescopes where photons are classified based on their density in image-sequences. This is in the three-dimensional space of incident-directions c_x , c_y , and arrival-times t. So we project Portal's lightfield-sequence $\mathcal{L}[c_x, c_y, x, y, t]$ onto an image-sequence $\mathcal{I}[c_x, c_y, t]$ and then apply the exact same methods shown in Chapter 26 of Part II in this thesis. The projection of the light-field is done using Equations 9.24 and 9.31. The only difference with the Portal Cherenkov-plenoscope is, that we repeat the classification multiple times for a single light-field-sequence by each time refocusing the image-sequence to a different object-distance. In the end, we classify all the dense photons found in all refocused image-sequences to be the Cherenkov-photons using a logical AND-operation. Probably it will be worth to investigate novel methods in the future which take the light-field into account more naturally, but for this first investigation we are pleased with the classification-performance.

Estimating the angular resolution for gamma-rays at 1 GeV

A high angular resolution for cosmic gamma-rays is key for gamma-ray-astronomy. In this Chapter, we show how we estimate the angular resolution of Portal which we present in Figure 2.8. In this early estimate of the angular resolution, we focus on gamma-ray-energies close to the energy-threshold of Portal at 1 GeV, since those events will be most abundant in the observations. For higher energies, we argue that Portal will at least reach the angular resolutions reached by arrays of Cherenkov-telescopes, because the light-field-sequences recorded by Portal can always be interpreted as multiple image-sequences recorded by an array of Cherenkov-telescopes. Also in this early estimate, we choose to estimate the incident-direction of cosmic gamma-rays not using images, as it is usually done on Cherenkov-telescopes, but using the orientation of the Cherenkov-light-front in the recorded light-field-sequence, compare Figure 8.1. Our intent here is not to present the best method, but to present a method which makes most use of the Cherenkov-plenoscope's novel possibilities.

14.1 Cherenkov-light-front

When the read-out of Portal is triggered, see Chapter 12, Portal records a light-field-sequence. In this light-field-sequence, we classify Cherenkov-photons and night-sky-background-photons, see Chapter 13. Next we reconstruct the threedimensional movement of the Cherenkov-photons above the principal-apertureplane, see Figure 8.1. The position of a photon j on its trajectory, or more precisely the position of a photon on the ray $\vec{r_k}(\lambda = -c(t - t_{\text{pap}j}))$ describing the k-th lixel which contains the j-th photon, depends on the global time t. The rays $\vec{r_k}(\lambda)$ are defined by the light-field-geometry G, see Chapter 8. We choose t such that the point-cloud of Cherenkov-photons is centered around the principal-aperture-plane. Figure 14.1 shows the Cherenkov-light-front created by a gamma-ray and reconstructed by the Portal Cherenkov-plenoscope.

14.2 Limitations due to timing-resolution

We simulate Portal's timing-resolution (standard-deviation) for the arrival-time of single photons to be $\Delta_t \approx 1$ ns according to our findings for the timing-resolution of todays Cherenkov-telescopes, see Chapter 25 in Part II of this thesis. This finite timing-resolution sets a limit to the angular resolution for the reconstruction of a Cherenkov-light-front's surface-normal. The paxels with the furthest distance in the Portal Cherenkov-plenoscope have a baseline of $L \approx 65$ m. Within the duration of the timing-resolution, a photon travels a distance of $\Delta l = c\Delta_t \approx 0.3$ m along its trajectory. Here c is the speed-of-light. Thus the angular resolution will be limited to about $\arctan(\Delta l/L) = 0.26^{\circ}$. Although the statistics of many Cherenkov-photons in the light-front help to improve the angular-resolution, we find in Figure 14.2 an angular resolution of 0.31° which is already close to the limitations caused by a finite timing-resolution.

Figure 14.1: The Cherenkov-light-front reconstructed by the Portal Cherenkovplenoscope for a gamma-ray with energy 997 MeV, incident-direction $c_x = 1.87^{\circ}$, $c_y = -0.28^{\circ}$, and core-position x = 34 m, and x = -95 m. The same event in all three images, only the perspective is slightly rotated each time. Each blue point is a photon recorded by Portal and classified to be a Cherenkov-photon from within a pool of $\approx 0.5 \times 10^6$ night-sky-background-photons.

Figure 14.2: The residual incident-directions of cosmic particles inducing electromagnetic air-showers. The true energies of the cosmic particles here is restricted from 750 MeV to 1,500 MeV. The true incident-directions of the particles are diffusely distributed inside and beyond the field-of-view of Portal. A total of 68% of the reconstructed events are left of the vertical black line at 0.31°. This vertical black line marks the 1 σ -containment-radius which is shown in Figure 2.8.

Reconstructing air-showers using tomography

To reconstruct the type, energy, and direction of a cosmic particle from the lightfield-sequence we have multiple options. We might perform a feature-generation similar to the generation of Hillas-features for images [Hillas, 1985] but in higher dimensions for the light-field. We also might have a look-up-table¹ [Le Bohec et al., 1998] where a recorded light-field is compared to a collection of simulated light-fields for which the cosmic particle's properties are known. Both these methods work fine with imaging on Cherenkov-telescopes and are probably a good starting-point.

However, with the observation-power of the Cherenkov-plenoscope it might be possible to do particle-physics within the air-showers themselves as individual jets emerge. For particle-physics, we propose to use tomography to reconstruct the air-shower itself in three spatial dimensions. From the light-field-sequence, we already know the three-dimensional trajectories and the arrival-times of the Cherenkov-photons. But we still do not know the photon's production-positions. We try to estimate the Cherenkov-photon's production-positions using an assumption. We assume that a volume-cell in the atmosphere in which many trajectories of Cherenkov-photons come close to each other, has a high probability to also contain the production-positions of these Cherenkov-photons. The method to estimate this probability from a light-field is known as tomography² [Levoy et al., 2006].

Here we present our first steps into tomography with the Cherenkov-plenoscope.

15.1 Motivation

The reconstruction of three-dimensional densities from either a stack of refocused images [McNally et al., 1999], or from a light-field itself [Levoy et al., 2006] is

¹Also called 'template-matching', or 'log-likelihood-fitting'.

 $^{^2\}mathrm{Also}$ called 'focus-stack-deconvolution', or 'light-field-microscopy', or 'narrow-angle-tomography'.

a well established method in microscopy. In microscopy, the density of lightemitting structures of biological cells is studied. Biological cells are so small that their structures appear to be almost transparent when imaged with a microscope. Often the cells are not shine through with an external light-source, but are made to shine themselves by fluorescence. In a light-field-mindset, fluorescence-emission in biological-cells is very similar to Cherenkov-emission in air-showers. In both scenarios the vast majority of the observed medium is transparent with only small regions emitting photons. In both scenarios, we are interested in the productionpositions of the photons. In both scenarios, large apertures induce narrow depthof-fields. Here large does not mean the absolute size, but the size relative to the objects to be observed. Microscopy motivates us to investigate tomography for the Cherenkov-plenoscope. However, there are also differences between fluorescenceemission and Cherenkov-emission. Most of all, unlike the isotropic emission of fluorescence-photons, Cherenkov-photons are only emitted in a narrow cone. Also in Cherenkov-astronomy, we might profit from the measurement of the photons arrival-times.

15.2 Basic Method

Tomography starts with a light-field-sequence $\mathcal{L}[c_x, c_y, x, y, t]$ recorded by a plenoscope, or an array of telescopes³, and a three-dimensional structure inside a threedimensional volume which has emitted the photons recorded in \mathcal{L} . Now to reconstruct the three-dimensional structure which has emitted the photons, we have to relate the light-field-geometry G of our instrument with the volume it is observing. We divide the three-dimensional volume into densely packed volume-cells, and we approximate the light-field-cells in G using rays, see Equations 2.1, and 8.6. Figure 15.1 shows a simplified light-field-geometry G approximated with 9 rays facing a volume divided into 4 volume cells. We relate the rays with the volume-cells by calculating their overlap, and represent it in a matrix

$$S[v, k] = \begin{bmatrix} 0 & 0 & 1.1 & 0 & 0 & 0 & 0 & 1.0 & 0 \\ 0 & 0 & 0 & 0 & 1.0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0.6 & 0 & 1.0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0.4 & 0 & 0 & 0.5 & 0 & 1.0 & 0 \end{bmatrix},$$
(15.1)

which is often called system-matrix in tomography. Here S[v, k] has V = 4 rows for the volume-cells, and K = 9 columns for the rays. In our representation S[v, k] contains the Cartesian-distance a ray travels through a given volume-cell, with the edge of the volume-cell having length 1. From here on, we can follow different methods to reconstruct the volume-cell's intensities D[v] using the system-

³In tomography this is also called a line-integral, as it represents the intensity integrated along the light-field-cells which can be approximated by rays.

Figure 15.1: Basic tomography with rays and volume-cells. Equation 15.1 shows the corresponding system-matrix.

matrix S[v, k], and the recoded light-field $\mathcal{L}[k]$. Here D[v] is a one-dimensional vector containing the reconstructed photon-emission-intensity in each of the Vvolume-cells, and $\mathcal{L}[k]$ is the a one-dimensional vector containing the measured intensities in each of the K light-field-cells. For the reconstruction of D[v], we first explored filtered-back-projection, and then went on to iterative methods such as the (simultaneous)-algebraic-reconstruction-technique [Andersen and Kak, 1984]. Figure 15.4 shows reconstructions using our first implementation of filtered-backprojection.

For Cherenkov-astronomy it is important to note that, with the exception of recent advances in positron-emission-tomography [Conti, 2009], established tomography in microscopy, biology, and medicine does not take into account the photon's time-of-flight. Equation 15.1 does not contain the distance between a volume-cell and the support-position of a ray on the aperture-plane.

Also, Equation 15.1 is only approximative as the light-field-cells are only approximated using single rays. In the future this can be improved by approximating a light-field-cell with multiple rays contained in it.

15.3 Portal's reconstruction-power

Figure 15.2 shows Portal's three-dimensional reconstruction-power relative to the atmospheric volume. The atmospheric cube with a volume of $2 \times 2 \times 20 \text{ km}^3$ above Portal is divided into $200 \times 200 \times 200$ volume-cells. Each volume-cell is $10 \times 10 \times 100 \text{ m}^3$. The figure shows the number of stereo-baselines in each volume-

cell. The number of stereo-baselines in a volume-cell is

$$N_{\text{Baselines}} = \frac{1}{2} (N_{\text{Supports}}^2 - N_{\text{Supports}})$$
 (15.2)

where N_{Supports} is the number of unique support-positions that emit rays into this volume-cell. For Portal the maximum number of stereo-baselines in a volume-cell is 1,830 when all of Portal's 61 support-positions (paxels) emit at least one ray into this volume-cell. In Figure 15.2 we find that Portal's reconstruction-power vanishes towards larger object-distances. At the given binning of the atmosphericvolume, Portal's reconstruction-power is optimal up to object-distances of \approx $10 \,\mathrm{km}$. When pointing to zenith, this corresponds to an altitude of $15 \,\mathrm{km}$ a.s.l. when building Portal on 5,000 m a.s.l. We also find that there is no reconstructionpower in the first few 100 m above Portal's aperture as the bundles of rays originating in each support-position have not yet overlapped. Naturally we find that there is only reconstruction-power within Portal's view-cone. This very asymmetric population of rays inside volume-cells increases the chance for unresolvable artifacts, and is often discussed as 'narrow-angle-tomography'. From Figure 15.2 we can already see possible limitations to Portal's three-dimensional reconstruction-power. Air-showers which emit Cherenkov-photons in volume-cells with low numbers of stereo-baselines will be more difficult to be reconstructed. Further, even if an air-shower emits Cherenkov-photons within a volume-cell, this does not yet mean that those Cherenkov-photons will reach Portal's aperture as the emission of Cherenkov-photons is not isotropic.

15.4 Reconstructing air-showers in the refocusedimage-space

In Figure 15.2 we find that the volume-cells in the Cartesian-space above the atmosphere are populated very asymmetrically. Some have many, others have no rays passing through them. This asymmetry can be overcome when the tomography is done in the three dimensional space of a refocused stack of images [McNally et al., 1999]. Instead of the Cartesian-rays defined in Equation 2.1, we use the image-rays introduced in Section 9.4. Instead of subdividing the Cartesian-volume above the Cherenkov-plenoscope, we subdivide the three dimensional space of refocused images in incident-directions c_x , and c_y , as well as image-distances b, compare Equations 9.26, and 9.29. The advantage of this refocused-image-space is, that the density of rays in the cells is almost the same for all the cells. The plenoscope's vanishing reconstruction-power for larger object-distances is taken into account here naturally. In our first tests with iterative reconstructions, this reduces many artifacts when estimating the emission-density of Cherenkov-photons D[v]. Again, the overlap of image-rays and the pixels in the

Figure 15.2: Portal's three-dimensional reconstruction power. The number of stereo-baselines in the volume-cells above Portal's aperture-plane. Portal's aperture-plane goes along the bottom of the figure at object-distance = 0 km. Here we see only the few volume-cells in the x-object-distance-slice for y = 0. Each volume-cell is 10 m in x, 10 m in y, and 100 m in object-distance. The darkening here is proportional to the square-root of the number of stereo-baselines $N_{\text{Baselines}}$, which is proportional to the number of unique support-positions in a volume-cell N_{Supports} , see Equation 15.2.

refocused-image-space can be represented in a system-matrix as shown in Equation 15.1, and is often called three-dimensional-point-spread-function. Figure 15.3 illustrates the basic idea of the refocused-image-space.

15.5 Conclusion

We see great potential for tomographic reconstructions of air-showers using the Cherenkov-plenoscope, or a powerful array of Cherenkov-telescopes such as the Cherenkov-Telescope-Array (CTA). The big similarity with tomography in microscopy allows the atmospheric-Cherenkov-method to adopt many well established techniques. For the 150 m diameter Cherenkov-plenoscope investigated by Axel Arbet Engels, the reconstruction-power for air-showers using the a simple filtered-back-projection is extraordinary, see Figure 15.4. Tomography is the generalization of the stereo-technique and will potentially enable us to observe the inner structure of air-showers.

Figure 15.3: A light-source in object-distance g is observed by the plenoscope with focal-length f. The dashed line is the optical-axis and the horizontal line at the bottom is the principal-aperture-plane. When we refocus a stack of images from the light-field (right part of figure), the image of the light-source will be sharpest in the image for image-sensor-distance b which corresponds to a focus on object-distance g. Other images for image-sensor-distances $\neq b$ will show the blurring (Bokeh) induced by the narrow depth-of-field caused by the large imaging-reflector. In this figure, the lowest image in the refocused stack is for a image-sensor-distance of f, which corresponds to a focus on ∞ .

Figure 15.4: Figures taken from [Engels, 2017]. A tomographic reconstruction of an air-shower induced by a hadronic cosmic-ray. Upper figures show a x-y-slice of volume-cells at object-distance = 10.9 km, and lower figures show a x-y-slice of volume-cells at object-distance = 12.4 km. Compare the bright structures in both the simulation-truth on the left, and in the reconstruction on the right. The filtered-back-projection used in this figures is developed and implemented by the author of this thesis (S.A.M.). In his master-thesis, Axel Arbet Engels investigates the reconstruction of direct Cherenkov-photons using tomography on a perfect Cherenkov-plenoscope with an enormous 150 m aperture-diameter. The goal is to push the limits of chemical composition-measurements using direct Cherenkov-photons emitted by the cosmic nuclei itself.

Pointing the Cherenkov-plenoscope using the cable-robot-mount

We propose the cable-robot-mount to point the Cherenkov-plenoscope to different gamma-ray-sources in the sky. Although it might be possible to mount the 71 m diameter Portal on a conventional altitude-azimuth-mount, we decide to investigate the cable-robot-mount as it potentially offers a more cost-effective solution. The concept of the cable-robot-mount is proposed by the author of this thesis (S.A.M.), while the details are worked out in close collaboration with the department for civil, environmental and geomatic engineering at ETH-Zurich.

- 1. We motivate a dedicated cable-robot-mount to point the Cherenkov-plenoscope.
- 2. We list technical specifications, identify states of operation, and investigate environmental properties of possible sites.
- 3. We briefly describe how civil-engineer Spyridon Daglas together with the author of this thesis (S.A.M.) simulate the cable-robot-mount.
- 4. We briefly summarize the findings of Spyridon Daglas on the performance and feasibility of cable-robot-mounts ranging from 30 m to 100 m in diameter.

16.1 Motivation – A mount for the plenoscope

To reach an energy-threshold for gamma-rays of 1 GeV, the Portal Cherenkovplenoscope needs a large imaging-reflector of 71 m in diameter. Established Cherenkov-telescopes only have mounts for imaging-reflectors up to 28 m in diameter, see Section 19.6. Although the conventional altitude-azimuth-mount of the Cherenkov-telescope might be an applicable mount for the Portal Cherenkovplenoscope, we see the potential for a more cost-effective mount. On the Cherenkovplenoscope, the demand for a rigid alignment between the imaging-reflector and the light-field-sensor is much more relaxed in contrast to the demand for a rigid alignment between the imaging-reflector and the image-sensor on a Cherenkovtelescope, see Chapter 11. As long as the actual alignment is known, the Cherenkovplenoscope can compensate misalignments between its imaging-reflector and its light-field-sensor. While on the Cherenkov-telescope rigid support-structures between the imaging-reflector and the image-sensor are mandatory, on the Cherenkovplenoscope this rigid support-structures can be omitted. Rigid support-structures shadow the aperture, and add up weight to the moving parts. But the main problem that we identify with rigid support-structures is, that all the forces needed to hold the image-sensor are guided through the support-structure of the imaging-reflector, compare Figures 19.7, 19.10, 19.11, 19.16, 19.17, and 19.19. Since the forces holding the image-sensor change with the pointing-direction of the Cherenkov-telescope, also the shape of the imaging-reflector changes. And such deformations of the imaging-reflector must be minimized for high optical quality. On small Cherenkov-telescopes such deformations might be too small to effect optical quality, but on larger telescopes it becomes increasingly difficult to find cost-efficient solutions in order to keep the deformations below an acceptable limit, or to actively correct for them [Biland et al., 2007]. The physical limit of the square-cube-law [Galilei, 1638] makes the forces needed to hold a structure grow quicker than the areas which have to tolerate these forces. As a consequence, we can not simply scale up an existing mount.

Another drawback of the altitude-azimuth-mount is that it can not move fast near the zenith what conflicts the hunt for transient phenomena in the highly variable gamma-ray-sky. The inverse kinematics of the altitude-azimuth-mount has a near-zenith-singularity [Borkowski, 1987] which causes unacceptably large accelerations and forces when moving close to the zenith during a repositioning. Motivated by the Arecibo radio-telescope [Altschuler and Nieves, 2002], the NIST cable-robot-manipulator [Albus et al., 1993], and the cable-robot-simulator [Miermeister et al., 2016], see Figures 16.1, and 16.2, we decided to investigate a different design for the mount of Portal. We call it the cable-robot-mount. Our cable-robot-mount for Portal is separated into two independent mounts. One mount is only actuating the large imaging-reflector, and the second mount is only actuating the light-field-sensor. The two independent mounts always try to establish the desired target-alignment between the light-field-sensor and the large imaging-reflector, while we compensate possible misalignments due to e.g. wind-gusts later in software, see Chapter 11. The independent actuation of the two components reduces the forces running through the support-structure of the large imaging-reflector and thus allows us to build larger imaging-reflectors. The cable-robot-mount supports the imaging-reflector, and the light-field-sensor with many cables in parallel which are actuated by winches in order to minimize the mass of the moving structures. The cable-robot-mount extensively uses robotics, which is the study of controlling the actuated winches using a computer that is

Figure 16.1: Figure taken from [Miermeister et al., 2016]. The cable-robotsimulator by Max-Planck-Institute for Biological Cybernetics in cooperation with the Fraunhofer-Institute for Manufacturing, Engineering, and Automation. This impressive motion simulator can accelerate payloads of up to 500 kg with up to 14 ms^{-2} . The design-goal of the cable-robot-simulator is not to slowly move the large components of a Cherenkov-plenoscope, but to be a motion simulator for up to two passengers with an 'extraordinary' [Miermeister et al., 2016] power to weight ratio for maximum acceleration. See also Figure 16.2. For the Cherenkovplenoscope, we adopt the icosahedron-shape of the moving platform to mount the light-field-sensor. Compare Figure 5.8.

Figure 16.2: Figure taken from [Miermeister et al., 2016]. A prototype of the cable-robot-mount is implemented in a so called 'crossed over' configuration and has eight powerful actuated winches in each corner of a large room. See also Figure 16.1. Compare this configuration with the cable-robot-mount for the light-field-sensor shown in Figure 2.1.

Figure 16.3: A possible parking position for the Portal Cherenkov-plenoscope and its cable-robot-mount.

aware of the parallel, elastic, and inverse kinematics of the entire mount. The cable-robot-mount is meant to trade large and costly support-structures, as well as large and expensive mechanical joints in change for computer-control and parallel actuation. We suspect, that in contrast to the costs for support-structures and mechanical joints, the costs for computer-control and parallel actuation scale less rapidly with the size of the mount. The cable-robot-mount only has one moving support-structure which is the dish holding the mirror-facets of the imagingreflector. The remaining support-structures in the cable-robot-mount are fixed towers where the cables and winches are attached to. Such large towers are common in e.g. overhead-power-lines what reduces the costs for their engineering and production. Figures 16.3, and 16.4 show conceptual drawings of Portal and its cable-robot-mount. In summary, we expect the cable-robot-mount to reduce the forces running through the support-structure of the imaging-reflector which shall allow the construction of larger imaging-reflectors. We expect the cable-robotmount to reposition the Cherenkov-plenoscope faster during its hunt for transient phenomena because its inverse kinematic is free of singularities. And further, we expect the cable-robot-mount to be very cost-effective because all its fixed towers and actuated winches are mass produced components which are commonly used in e.g. overhead-power-lines, wind-turbines, and harbor-cranes.

16.2 Technical specifications

To find a cost-effective design and to communicate our needs, we formulate the technical specifications for the Cherenkov-Plenoscope's mount. With these specifications in mind, Figure 16.5 illustrates what components of the cable-robot-mount have potential to be investigated. Because a light-weight design for the imaging-reflector is crucial, we investigate the dimensions and masses of existing mirror-facets in Table 16.1. We want to reach zenith-distances of up to 45° .

Figure 16.4: Portal and its cable-robot-mount pointing to different zenith-distances of 0.0° , 22.5° , and 45.0° .

well established

worth investigating

Figure 16.5: This is based on the author's interpretation of the potential for civilengineering after discussions and studies with the experts. The tall masts are considered to be standard components used in overhead-land-lines. The cage for the light-field-sensor is also considered to be fairly standard. The steel-cables are considered higher standard, but still well within range of commercial products for e.g. harbor-cranes. The concrete-pillars are considered to be simple from a load-point-of-view, but are worth to investigate cost-effective, and wind-shielding designs. Clearly, the civil-engineers consider the large imaging-reflector's supportstructure holding the mirror-facets to be most worthy to investigate in order to find cost-effective designs.

States of operation

We identify three states of operation for the Portal Cherenkov-plenoscope.

- 1. Parking. During the day, the large imaging-reflector and the light-fieldsensor are both lowered to their own pedestals for parking, see Figure 16.3. When the large imaging-reflector rests on its pedestal pointing to zenith, the intense¹ $7.4 \,\mathrm{MW}\,\mathrm{m}^{-2}$ image of the Sun can not be projected onto objects on ground.
- 2. Fast pointing. The Cherenkov-plenoscope points fast from one source in the sky to another source. Both the large imaging-reflector and the light-field-sensor are moved independent of each other. Since there are no near-zenith-singularities, the cable-robot-mount always rotates the Cherenkov-plenoscope along one single axis only. For fast pointing, we desire angular velocities of 90°min⁻¹. In this state, the Cherenkov-plenoscope does not have to reach its target-geometry, as it will not record air-showers during fast pointing.
- 3. Slow tracking. Only here the Cherenkov-plenoscope tries to reach its targetgeometry. Only during slow tracking, the Cherenkov-plenoscope records

 $^{^1} Solar-constant~1.3\,\rm kW\,m^{-2}~\times$ aperture-area of imaging-reflector 3,684 m² \div area of projected image of the Sun $0.68\,\rm m^2$

Figure 16.6: Figure taken from [Radford et al., 2008]. Atacama-desert in Chile near the summit of Cerro Chajnantor on 5,612 m a.s.l.

air-showers. To counteract the rotation of the earth, an angular velocity of 0.25° min⁻¹ is mandatory. To continuously spread the signal-, and background-regions across different regions inside the field-of-view [Finnegan et al., 2011]², we desire an angular velocity of 0.75° min⁻¹. Together, we conclude that low angular velocities during slow tracking can be approximated using static load-scenarios.

Site and environment – Atacama-desert, Chile

We choose to adopt the environmental properties of Atacama-desert in Chile on $\approx 5,000 \text{ m}$ a.s.l.. The environmental properties of this site are well documented by e.g. the European-Southern-Observatory's ALMA-telescope, and the Cherenkov-Telescope-Array. Further, the Atacama-desert fulfills our demands for exceptional dark, and clear skies, and it is high in altitude. Although the geomagnetic cutoff-rigidity of $\approx 10 \text{ GV}$ is not the highest, compare Figure 2.6, it is representative for our estimate of Portal's performance. Figure 16.6 shows the landscape of Atacama-desert. And the Figures 16.7, and 16.8, show typical temperatures and wind-speeds for this site. Temperature, and changes in temperature effect the choice of materials. Wind speeds are used to formulate a worst-case load-scenario during observations. Occasional wind-gusts are used to formulate a survival-load-scenario. We want observations to be possible up to wind-speeds of 15 ms⁻¹ (54 kmh⁻¹), and we want the mount to survive wind-speeds of up to 55 ms⁻¹ (200 kmh⁻¹).

 $^{^{2}}$ E.g. so called orbit-mode implemented in the VERITAS Cherenkov-telescopes.

Table 16.1: Mirror-facets on Cherenkov-telescopes. Here the spacing is the flatto-flat-, or inner-diameter of the facets. We assume that the weight of a two-axisactuator for the orientational fine-alignment is $\approx 5 \text{ kg/facet}$, regardless of the area of the facet. The MAGIC, and FACT facets we measured ourselves. The geometry of VERITAS is taken from [Perkins et al., 2007], while we assume that the density of the glass is $\approx 2,800 \text{ kg m}^{-3}$. Cherenkov-Telescope-Array (CTA) specifications are taken from [Pareschi et al., 2013a]. Mass of the CTA-LST facet is taken from [Teshima et al., 2011]. Here LST is short for Large-Size-Telescope, MST is short for Medium-Size-Telescope, and INAF is short for Instituto-Nazionale-di-AstroFisica.

16.3 Designing a support-structure for the imagingreflector

As indicated in Figure 16.5, we focus on investigating the imaging-reflector's support structure. Spyridon proposes to use a space-truss to support the mirror-facets. He proposes to use a rectangular space-truss-lattice to ease the mounting of the hexagonal mirror-facets as it is shown in Figure 16.9. In this configuration, the corners of the mirror-facets line up with the nodes of the space-truss. He disfavors a ribbed-dome space-truss, as it makes the mounting of the mirror-facets more complicated, and deforms in potentially worse shapes harming the optical quality. After initial simulations, he identified that stiffening the outer realm of the imaging-reflector could prevent tensions from running into the inner parts. A tension-ring in the outer realm will potentially lower the overall weight and deformations. Such a tension-ring-design can be implemented by e.g. using stiffer bars in between the outer nodes of the space-truss.

Therefore, our focus is on a space-truss with an outer tension-ring. But for example another proposal by Prof. Mario Fontana suggests to use large inflatable air-bags between the bars of the space-truss-lattice to increase the stiffness of the overall imaging-reflector.

16.4 Simulating the cable-robot-mount

We implement a simulation to investigate the deformations of Portal's large imaging-reflector under various load-scenarios, as well as the impact of these deformations on the optical quality. The simulation is implemented in equal parts by Spyridon Daglas, and the author of this thesis (S.A.M.). We quantify the optical quality using the standard-deviation of the imaging-reflector's pointspread-function for incoming photons running parallel to the optical-axis.

The imaging-reflector is simulated in a fully parametrized way. This allows us to investigate the optics when we change parameters such as the diameter, the focal-length, or the type of curvature. But it also allows us to investigate the mechanics when we change parameters such as mirror-facet-size, space-truss-designs, and material-properties.

We also define load-scenarios. We simulate pointing the cable-robot-mount to various zenith-distances. We simulate constant wind, wind-gusts, and even earthquakes.

For each tuple of load-scenario, and imaging-reflector:

- 1. We simulate the deformation of the imaging-reflector under gravity when pointing to zenith. This is the default-load-scenario.
- 2. We estimate the optimal orientational fine-alignment for each mirror-facet under the default-load-scenario. This is the default-alignment.
- 3. We point the imaging-reflector to its target zenith-distance, and simulate its deformation under this load-scenario.
- 4. We estimate the point-spread-function of the imaging-reflector while it is under the actual load-scenario, and while its mirror-facets have the defaultalignment.

With this procedure, and the point-spread-function as a feedback, Spyridon explores the parameter-space for different imaging-reflectors using a particle-swarm-optimization [Daglas, 2017]. He uses the estimated point-spread-function as a feedback for the next iteration of the imaging-reflector's parameters. Figure 16.10 shows the parameter-search done by Spyridon for imaging-reflectors with a space-truss and tension-ring design. The figure shows a search for an imaging-reflector with 71 m diameter of reflective surface. However, the tension-ring-design made the space-truss-lattice more like 80 m in diameter, with an outer region of ≈ 5 m not covered by mirror-facets. This solution was easy for us to implement in our first investigation, but is not recommended for the actual implementation. For the time being, we consider it to be an additional safety-margin.

16.5 Conclusion

The cable-robot-mount for the 71 m Portal Cherenkov-plenoscope can be build today. Spyridon estimates that somewhere between aperture-diameters of 50 m to 70 m is the point where the cable-robot-mount takes over the altitude-azimuthmount in cost-effectiveness. Spyridon further estimates that a 100 m diameter Cherenkov-plenoscope is potentially in reach with the cable-robot-mount.

From Spyridon's point-of-view, the support-structure for the imaging-reflector is most worthy to investigate further. The remaining components of the cablerobot-mount can be adopted from existing solutions in industry.

Spyridon finds that the space-truss-lattice is unnecessary dense when coupling it to 'small' 2 m^2 mirror-facets. He proposes to use larger mirror-facets, or to have space-truss-layers of different densities. A dense layer to mount the mirror-facets, and more coarse layers below.

Spyridon further finds confirmation for his tension-ring-design. The outer realm of the space-truss shall be made stiffer than the light-weight inner part.

Spyridon also finds that the deformations in the imaging-reflector scale rapidly for the zenith-distance above 30° . He estimates that a mount pointing to maximum zenith-distances of 30° can be implemented with much simpler solutions.

For the materials, Spyridon finds that, except for the imaging-reflector, concrete and steel are the best choices. Only for the support-structure of the imagingreflector, carbon-fiber-reinforced-polymers are the better choice because of their stiffness.

To be clear, we only explore the cable-robot-mount for static load-scenarios. Although we consider all states of operation slow enough to be static, further discussions with experts [Miermeister et al., 2016] in robotics are needed.

Figure 16.9: Figure taken from [Daglas, 2017]. The hexagonal perimeter of the mirror-facets favors a rectangular type of space-truss-lattice. Spyridon organizes the individual space-truss-layers in a so called square-on-offset-square pattern.

Figure 16.10: Figure taken from [Daglas, 2017]. The estimated point-spreadfunction of the imaging-reflector during the 45°-zenith-distance-load-scenario versus the mass of the support-structure. Each dot corresponds to a specific set of parameters for the imaging-reflector. Here all imaging-reflectors are 71 m in diameter and 106.5 m in focal-length. The '3L' here means 3 layers of nodes in the space-truss, as can be seen in Figure 5.4. Imaging-reflectors left of the vertical red line are considered to be sufficient to observe without actuating their mirror-facets to correct for deformations. The yellow star marks the lightest imaging-reflector which does not need to actuate its mirror-facets yet.

Estimating Portal's cost

Naturally, the 71 m Portal Cherenkov-plenoscope has its costs. We estimate that Portal will cost about 218.5×10^6 CHF.

We split the cost-estimate into three parts: First, the costs for the cable-robotmount, which is mainly worked out by civil-engineer Spyridon Daglas [Daglas, 2017]. Second, the costs for the optics and electronics. And third, the costs for organization and execution.

17.1 Cable-robot-mount

Spyridon estimates that the material needed for Portal's cable-robot-mount will cost about $34.0 \times 10^6 \text{ CHF}^1$. This costs include the cable-robot-mount for the large imaging-reflector, its concrete-pillars, the actuated winches, the cables and the space-frame where the mirror-facets (not included) will be mounted on. It also includes the cable-robot-mount for the light-field-sensor, its four high steel-frame-towers, the actuated winches, the cables, and the light-field-sensor's housing where the electronics (not included) will be mounted.

17.2 Optics and electronics

We estimate that Portal's light-field-sensor will cost about 99.6×10^6 CHF. Portal's mirror-facets and actuators will cost about 13.0×10^6 CHF. Table 17.1 lists our estimated costs for the individual components. Photo-sensors: Private communication with sales-engineer Marius Metzger from Hamamatsu-photonics. Read-out-electronics: The CTA Schwarzschild-Couder-telescope reports a cost of 80 CHF channel⁻¹ [Williams et al., 2015]. The developers of the Domino-Ring-Sampler-4 read-out-electronics even claim a cost of 10 - 15 CHF channel⁻¹ [Ritt, 2011]. However, this does not include the integration-costs necessary for

¹In his master-thesis [Daglas, 2017], Spyridon reports the total costs for the 71 m Cherenkovplenoscope to be 170×10^6 CHF, where he assigns 34×10^6 CHF (20%) to the costs of the structure's materials. In his master-thesis, Spyridon reports only 170×10^6 CHF based on early cost-estimates provided by us for the electronics and optics.

component	unit-costs	demand	$total/10^6 {\rm CHF}$
Photo-sensors	$5 \times 10^5 \mathrm{CHF m^{-2}}$	$115\mathrm{m}^2$	57.5
Read-out-electronics	$80{\rm CHFchannel^{-1}}$	$515,023\mathrm{channels}$	41.2
Lenses	$100{\rm CHFlens^{-1}}$	$8,443 \mathrm{lenses}$	0.9
Mirror-facets	$3 \times 10^3 \mathrm{CHF m^{-2}}$	$3,\!684\mathrm{m}^2$	11.1
Mirror-facet-actuators	$1 \times 10^3 {\rm CHF} {\rm facet}^{-1}$	$1,842\mathrm{facets}$	1.9
Sum			112.6

Table 17.1: Unit-costs for optics and electronics.

	fraction/%	$total/10^6 CHF$
Cable-robot-mount	16	34.0
Optics and electronics	51	112.6
Central control-system	5	10.9
Project-engineering	5	10.9
Project-management	13	28.3
Site-infrastructure	10	21.8
Sum	100	218.5

Table 17.2: Portal's costs-distribution. We contribute the estimate for the costs of the cable-robot-mount, the optics, and the electronics. The remaining matters of expenses are added according to ESO's cost estimates for OWL [Aglae et al., 2004], [Brunetto et al., 2004]. Here our sum of the 'cable-robot-mount', and the 'Optics and electronics' give 67% and corresponds to ESO's sum for 'opto-mechanical subsystems' (42%), 'instrumentation' (5%), and 'telescope structure' (20%) which gives also 67%.

Cherenkov-astronomy such as amplifiers and analog-to-digital-converters which is why we better assume 80 CHF channel⁻¹ instead. Lenses: Fortunately, UVtransparent silica-glass-optics are wide spread for lasers in industry. We found offers for lenses with similar dimensions as shown in Figure 7.2 for about 50 CHF. Mirror-facets and actuators: Private communication with Adrian Biland expert for optics in MAGIC, and also involved in CTA.

17.3 Organization and execution

As a guidance for the total costs of such a large project, we follow the costestimates for the OverWhelmingly-Large-telescope (OWL) proposed by the European-Southern-Observatory (ESO) [Aglae et al., 2004], [Brunetto et al., 2004]. After all, we want to estimate Portal's costs when erected in the harsh environment of Atacama-desert in Chile. Table 17.2 shows how we distribute the costs.

Simulating Portal's observations

We investigate the Cherenkov-plenoscope with a computer-simulation of the observations on the event to event level. An event starts with the entrance of a cosmic particle into earth's atmosphere, and ends with a response of the Cherenkovplenoscope. We simulate the observation of gamma-rays, electrons or protons. For the majority of the events, the response of the Cherenkov-plenoscope is to not even trigger. But for those few events which pass the trigger, the response of the Cherenkov-plenoscope is further investigated. For example we reconstruct the incident-direction of the cosmic particle. In our simulations, events are independent of each other. We use established [Bernlöhr et al., 2013] tools such as CORSIKA [Heck et al., 1998] to simulate extensive air-showers created by cosmic particles in the earth's atmosphere and the IACT/ATMO-package [Bernlöhr, 2008] to simulate the emission and interaction of Cherenkov-photons in the atmosphere. When the Cherenkov-photons reach the Cherenkov-plenoscope on ground, our own simulation takes over. Our photon-propagator merlict simulates the interactions of Cherenkov-photons with the scenery of the Cherenkov-plenoscope. Together with the Cherenkov-photons, we inject night-sky-background-photons, see Section 18.3. We simulate the photo-sensors, and the analog-to-digital-conversion. For the analog-to-digital-conversion we simulate the shortcomings of the read-outelectronics in the First Geiger-mode Avalanche photo-diode Cherenkov Telescope (FACT) which we are familiar with, see Part II of this thesis. Depending on the size of the Cherenkov-plenoscope, a single event involves from 10^0 to 10^6 Cherenkov-Photons, several 10^6 night-sky-background-photons, 10^4 to 10^6 pieces of geometric primitives describing the Cherenkov-plenoscope, and 10^4 to 10^6 readout-channels for the light-field-sensor. Table 18.1 lists the different programs used to simulate Portal.

Table 18.1: The programs to simulate Portal Cherenkov-plenoscope. merlict and plenopy are both written by the author of this thesis (S.A.M.).

18.1 Simulating air-showers – CORSIKA

We use the COsmic Ray SImulations for KAscade (CORSIKA) to simulate extensive air-showers. CORSIKA is developed at Karlsruhe Institute of Technology (KIT). Listing 18.1 identifies our specific flavor of CORSIKA used to simulate Portal. For thread-safety during parallel deployment, we wrap CORSIKA with a program that gives each CORSIKA-instance its own 'run'-directory with its own local buffer-files. Our wrapper also allows CORSIKA to be called system-wide, and grants writeaccess to the eventio-output-files.

18.2 Propagating photons - merlict

We simulate the interaction of photons with the Chrenkov-plenoscope using a computer-simulation based on ray-tracing called merlict. The merlict was written by the author of this thesis (S.A.M.) and can efficiently propagate photons in complex sceneries. The merlict is not specifically written for the Cherenkov-plenoscope, but for arbitrary sceneries, and arbitrary optical instruments. To propagate photons efficiently in complex sceneries with millions of surfaces, the merlict is a so called 'non-sequential' ray-tracer which represents its scenery using a bounding-volume-hierarchy to avoid unnecessary intersection-tests. Currently, merlict can simulate specular reflections, absorptions in volumetric ob-

jects, refraction, as well as Fresnel-reflections and Fresnel-transmissions. The merlict can read in sceneries represented using triangle-meshes in the Stereolithography (STL) format [Roscoe et al., 1988] which is commonly used in Computer-Aided-Design (CAD). Also the merlict can read in photons in various formats, including the eventio-format used in the IACT/ATMO-package [Bernlöhr, 2008] for CORSIKA. To render a scenery fast for live previews, the merlict uses a second propagator for simple, reverse ray-tracing of so called 'camera-rays'. Camera-rays do not behave like photons, but are often sufficient to render images of a scenery for a visual inspection of the geometry before the actual scientific propagation of photons. For example, the Figures 5.2 to 5.10 are rendered images created by the merlict. The merlict has a moderate test-coverage of ≈ 450 unit-tests and integration-tests. These tests range from simple checks of the internal bookkeeping and linear algebra to complex tests where e.g. photons are guided through lenses and certain point-spread-functions are expected.

18.3 Simulating night-sky-background

For Portal we simulate the night-sky-background-photons of a dark night at a clear site adequate for optical astronomy. We choose the Observatory on Roque de los Muchachos on Canary island La Palma, Spain to be representative for the flux of night-sky-background-photons. Figure 12.1 shows the flux of nightsky-background-photons used in the simulations of Portal. To reduce computations, we do not propagate each night-sky-background photon through the scenery of the Portal Cherenkov-plenoscope every time we simulate the observation of an air-shower. Instead we inject night-sky-background-photons directly into the photo-sensors with the appropriate rate and wavelength-distribution. Not every photo-sensor in the light-field-sensor in Portal has the same collection-efficiency $\overline{\eta}$, compare Figures 8.6, and 8.7. We take this into account by using $\overline{\eta}$ from the light-field-geometry G to inject the correct rate of collected photons into the individual photo-sensors. This is possible because we know the area and the solid-angle which is exposed in the estimation of the light-field-geometry G, and because the collection-efficiency $\overline{\eta}$ is defined with respect to this exposure. On Cherenkov-telescopes it is not common to take collection-efficiencies of individual photo-sensors into account, because fortunately on telescopes the variations in collection-efficiency between different photo-sensors is only minor.

18.4 Ensuring large enough scatter-radii and scatterangles

To estimate Portal's instrument-response-function, all possible events of cosmic particles creating air-showers have to be simulated. For each particles-type, the energy, the scatter-angle, and the scatter-radius have to be drawn randomly. The scatter-angle here is the angle between the cosmic particle's trajectory and the optical-axis of Portal. The scatter-radius here is the distance between the center of Portal's principal-aperture-plane and the scatter-position of the cosmic particle. While the scatter-position is where the elongated trajectory of the cosmic particle intersects the principal-aperture-plane.

However, since computing-resources are limited, we can not simulate every possible event. We have to compromise and avoid the simulation of events which are both rare to occur in nature, and unlikely to trigger the read-out of Portal. In this section: First, we show the compromises used in the current simulations of Portal. And second, we discuss what might be improved in future simulations.

Compromises in Portal's simulations

To reduce the amount of simulations needed for this first estimate of Portal's performance, we apply three compromises:

- We only simulate gamma-rays, electrons, positrons and protons.
- For the diffuse electrons, and protons we only draw scatter-angles within a maximum scatter-angle which is twice the radius of Portal's field-of-view.
- Depending on the particle-type we only draw scatter-radii within a maximum scatter-radius which we make to depend on the energy of the particle, see Figure 18.2.

The Figures 18.3, and 18.4 show the distributions of the squared scatter-angles for diffuse electrons, and diffuse protons respectively. Since the scatter-angles are drawn uniformly in the solid-angle of the opening-cone defined by the maximum scatter-angle, the distributions of the square of the thrown scatter-angles are flat in the Figures 18.3, and 18.4. We find the ratio of triggered over thrown events versus the squared scatter-angles to approach zero for larger scatter-angles. The Figures 18.5, 18.6, and 18.4 show the distributions of the squared scatterradii. We find that unlike in the distributions for the scatter-angle, the ratio of triggered over thrown events does not peak at zero a scatter-radius of zero. This is probably because of the extended area on the principal-aperture-plane which is illuminated by Cherenkov-photons produced by each air-shower. We also find that all the ratios of triggered over thrown events approach zero for larger scatterradii. In the Figures 18.6, and 18.7 we find that for electrons the ratio of triggered over thrown events decreases faster for larger scatter-radii than for protons. The non uniform absolute distributions of the scatter-radii for thrown events is the result of our energy depended choice of the maximum scatter-radius shown in Figure 18.2.

Figure 18.2: The maximum scatter-radius of a particle versus its energy. Gammarays with parallel incident-directions coming from a point-source and electrons with scattered incident-directions coming from a diffuse pool. Protons also have scattered incident-directions coming from a diffuse pool. Since the detectionefficiency for small scatter-radii in the order of Portal's aperture-radius of 35.5 m is not yet explored, we better be safe and do not reduce the maximum scatterradius below 150 m. The resulting instrument-response-functions for Portal are shown in the Figures 2.4, and 2.5.

Figure 18.3: Absolute (upper), and relative (lower) distributions of squared scatter-angles of diffuse electrons, and positrons. Gray, vertical line indicates radius of Portal's field-of-view $(6.5^{\circ}/2)^2$. Integrated over all energies, and all scatter-radii.

Figure 18.4: Absolute (upper), and relative (lower) distributions of squared scatter-angles for diffuse protons. Gray, vertical line indicates radius of Portal's field-of-view $(6.5^{\circ}/2)^2$. Integrated over all energies, and all scatter-radii.

Conclusion and improvements for future simulations

We identify the distributions for the ratios of triggered over thrown events as a benchmark for our choices of maximum scatter-angles, and maximum scatterradii. Ideally we want to see these distributions to vanish towards zero for larger scatter-angles, and scatter-radii. In the current simulations, the vanishing for the ratio of triggered over thrown events is least well estimated for the scatter-radius of protons in Figure 18.7. But still, for all distributions the vanishing itself is clearly visible.

From this figures alone we do not see a method yet which allows us to conclude that the compromises made on the maximum scatter-angles and maximum scatter-radii do not spoil the instrument-response-functions too much. In the end, it is also important how often the corresponding events occur in nature, what can not be concluded from the figures here. The conclusion here is, that a more quantitative procedure based on the instrument-response-functions themselves is needed in the future to estimate this in more detail.

Chapter 19

Comparing the plenoscope with other methods

We compare how the Cherenkov-plenoscope samples the light-field in contrast to how existing methods, like the Cherenkov-telescopes, sample the light-field. First, we introduce the light-field-sampling-graph to illustrate how each particular method samples the light-field. And second, we list existing and future planned methods together with the Cherenkov-plenoscope to point out differences and similarities.

The light-field-sampling-graph

The light-field-sampling-graph is a two-dimensional graph which shows the space of support-positions x, y on the horizontal axis, and the space of incident-directions c_x, c_y on the vertical axis, see Figure 19.1. We only show one observation-method at a time in the light-field-sampling-graph. Our light-field-sampling-graph is not to scale, and is only meant as a guidance.

Figure 19.1: The light-field-sampling-graph. Black boxes correspond to readout-channels. The vertical extension of the read-out-channel in c_x, c_y represents the coverage of incident-directions. This is often called the picture-cell, or *pixel*. The horizontal extension of the read-out-channel in x, y represents the coverage of support-positions. We call this the principal-aperture-cell, or *paxel*. The hatched area in the read-out-channel represents the coverage of the light-field. We call this area the light-field-cell, or *lixel*. We put a red curve which illustrates the space enveloped and thus instantaneously accessible to the trigger. The further a *single* trigger-envelope is spread along the axis of support-positions, the larger is the collection-area for Cherenkov-photons, and thus the lower is the energy-threshold. In yellow we show parallel star-light. Star-light shows up as a horizontal line because it has only a single incident-direction in c_x , and c_y , but it shines on the entire aperture-plane in x, and y. In blue we show a typical pool of Cherenkov-photons. Cherenkov-photons from an air-shower are tilted in this graph to illustrate that their incident-directions correlate with their supportpositions. This is why stereo-observations with multiple telescopes see different images of the same air-shower.

19.1 Areal-sampling (sparse)

Figure 19.2: Tunka-133 [Lubsandorzhiev et al., 2008], compare Figure 19.3.

Sparse arrays of photo-sensors on ground are used to reconstruct the incoming Cherenkov-light-front based on the different arrival-times of the photons at different support-positions. There is no imaging-optics. The whole wide field-of-view is just one pixel. See in Figure 19.2 the read-out-channels being wide extended in c_x , c_y , but being narrow and sparse in x, y. The lack of sampling in incident-directions c_x, c_y limits the power to tell apart gamma-rays from cosmic-rays. Because of the wide spacing of support-positions, the trigger has only access the collection-area of single photo-sensors. This raises the energy-threshold up to $\approx 10^5$ GeV. Yet the sparse design allows for large collection-areas at energies close to the 'knee' at 3×10^6 GeV. Implementations are Tunka-133 [Lubsandorzhiev et al., 2008] in Figure 19.3, and AIROBICC [Karle et al., 1995].

Figure 19.3: Figures taken from [Lubsandorzhiev et al., 2008]. The Tunka-133 array for sparse areal-sampling in Tunka-valley. A total of 133 large photo-sensors (1) with light-guides (4) (lower figure) are arranged in a hexagonal grid in the Tunka-valley (upper figure).

19.2 Areal-sampling (dense)

Figure 19.4: STACEE-48 [Chantell et al., 1998, Covault et al., 2001], compare 19.5.

A dense array of tiltable mirrors on ground reflects the light from a narrow region of incident-directions onto an array of photo-sensors mounted on a nearby tower. Each mirror reflects its light to a different photo-sensor. This allows to densely sample the support-positions. Often [Chantell et al., 1998] the mirrorfacets are slightly canted so that each mirror reflects light from a slightly different incident-direction. This is done to focus onto a certain object-distance ≈ 10 km above ground where Cherenkov-photons are most likely to be produced. Pointing dependend time-delays between the read-out-channels allow the trigger to access all mirrors which lowers the energy-threshold. Figure 19.4 shows the read-outchannels for dense areal-sampling. Note the canting which makes the read-outchannels follow the shape of the Cherenkov-photon-pool. Figure 19.5 shows the STACEE solar-concentrator. Similar implementations are CELESTE [Paré et al., 2002], and CACTUS [Lizarazo et al., 2006].

Figure 19.5: Figures taken from [Covault et al., 2001, Chantell et al., 1998]. The STACEE solar-concentrator for dense areal-sampling. The upper drawing shows the canting of the mirror-facets. Cherenkov-light reaches different mirrors (heliostats) on ground but was produced in the same point.

19.3 Telescope

The telescope collects light only from a small region of support-positions. An imaging-system maps the photons based on their incident-directions to different positions on an array of photo-sensors which is called image-sensor. Telescopes have fields-of-views large enough to comfortably contain the photons produced in one air-shower. A high resolution in incident-directions allows the telescope to tell apart gamma-rays from cosmic-rays based on the structure of the Cherenkov-photons in the space of incident-directions (in the image) [Hillas, 1985]. Figure 19.6 shows how the telescope samples the light-field. The Whipple-telescope in Figure 19.7 pioneered the method, and many successors improved it ever since. Figure 19.8 shows the optics of Cherenkov-telescopes using the same three photons are CAT-France [Barrau et al., 1998], FACT [Anderhub et al., 2013a], and all the Cherenkov-telescopes used in telescope-arrays, see Section 19.4.

Figure 19.7: Figure taken from [Kildea et al., 2007]. The pioneer of the imagingatmospheric-Cherenkov-method. The Whipple Cherenkov-telescope on Mount Hopkins had 10 m effective aperture-diameter.

Figure 19.8: A telescope observing the thee photons A,B, and C. Compare the telescope with the plenoscope in the Figures 2.2, and 2.3.

19.4 Telescope-array (sparse)

number	≈ 250	≈ 4
coverage	$\approx 49 \times 10^{-3} \rm deg^2$	$10\mathrm{m}^2$
spacing	dense, $0.25 \deg$	$70\mathrm{m}$

Figure 19.9: HEGRA [Bulian et al., 1998], Roque de los Muchachos 2,200 m a.s.l, Canary island La Palma, Spain.

About four Cherenkov-telescopes are sparsely positioned on ground such that they can collect photons from the same air-shower. The array of telescopes can sample the incident-directions like a usual telescope. But at the same time it can sparsely sample the support-positions. The array of telescopes is very powerful and cost-effective to observe gamma-rays with energies above 100 GeV. Unfortunately, the energy-threshold for the trigger in an array of telescopes does not go below the energy-threshold for the trigger of the individual telescope. Figure 19.9 shows how a sparse array of Cherenkov-telescopes samples the light-field. Implementations are H.E.S.S. [Funk et al., 2004], MAGIC [Garcia et al., 2014], VERITAS [Weinstein et al., 2007], and the upcoming CTA [Acharya et al., 2013] and TAIGA [Budnev et al., 2017].

Figure 19.10: Figure taken from [Puehlhofer et al., 2003]. One of the four Cherenkov-telescopes in the HEGRA telescope-array. Each telescope has $3.4 \,\mathrm{m}$ effective aperture-diameter.

Figure 19.11: Figure taken from [H.E.S.S. collaboration, 2018]. Two of the four telescopes in H.E.S.S., Namibia. The telescopes have 12 m effective aperturediameter and are positioned on a square with 120 m long edges.

19.5 Meridian-telescope

The meridian-telescope is intended to observe a large part $(60 \text{ deg} \times 5 \text{ deg})$ of the sky. Facing zenith all the time, the meridian-telescope waits for the sources in the sky to pass by its field-of-view while the earth is rotating. The meridian-telescope samples the light-field in a similar way to the telescope. But in the meridian-telescope different incident-direction-bins (pixels) are exposed to different parts of the aperture. This creates a slight skew in the light-field-sampling-graph in Figure 19.12. The slight skew in the light-field-sampling-graph does not reduce the performance of the meridian-telescope, but it is a unique quirk which put the meridian-telescope into this list for comparison. The Figures 19.13, and 19.14 show the MACHETE meridian-telescope. MACHETE is not yet build.

Figure 19.13: Figure taken from [Cortina et al., 2016]. The meridian-telescope MACHETE is optimized to nightly monitor a large fraction of the gamma-ray-sky at energies below 1 TeV down to 150 GeV.

Figure 19.14: Figure taken from [Cortina et al., 2016]. MACHETE uses a spherical imaging-reflector and an image-sensor which only accepts photons in a limited range of incident-directions relative to its surface-normal. This is why different photo-sensors in the image-sensor collect photons from different parts of the imaging-reflector which leads to the slight skew in the light-field-sampling-graph in Figure 19.12.

19.6 Large telescope

Large telescopes are like telescopes but with a wider sampling of support-positions. Since there is only one bin to sample the support-positions in x, y, the supportposition of the individual photon-trajectory is not well known. In Figure 19.15 we see that different read-out-channels sample light from different parts of the large telescope's aperture. The slope of the Cherenkov-pool in Figure 19.15 indicates that different parts of the wide aperture in x, and y create different images. This is the reason for the narrow depth-of-field on large telescopes. Large telescopes investigate focusing [Trichard et al., 2015] to minimize the blurring caused by their narrow depth-of-field. The energy-threshold of the trigger can go below 50 GeV for large telescopes, what makes them today the best choice for observations of low energetic gamma-rays on ground. Similar proposals are ECO-1000 [Baixeras et al., 2004], Large-Size-Telescopes in the Cherenkov-Telescope-Array [Acharya et al., 2013], and MACE [Borwankar et al., 2016].

Figure 19.17: Figure taken from [Borwankar et al., 2016]. The MACE telescope has 21.3 m effective aperture-diameter. Here it is at its production site in Hyderabad before it is moved to Hanle at 4,270 m a.s.l..

Telescope-array with topological trigger 19.7

 $70\,\mathrm{m}$

spacing

The topological trigger tries to make the decision to read-out or not to readout the array of telescopes as early as possible by combining as much information from multiple telescopes as technology allows. The information about the arrival of photons is reduced by lowering the resolution of incident-directions and time. Further, time-delays are applied depending of the pointing of the individual telescopes. Even with these reductions, current topological triggers can still not handle the flood of information to be the first stage of the trigger in a telescopearray. There is still a first layer of the trigger which only acts on the individual telescope. In simulations, the topological trigger for telescope-arrays shows to lower the energy-threshold for gamma-rays. Although current implementations of topological triggers are held back by technology, the red curve of the triggerenvelope in the light-field-sampling-graph indicates the intended goal which is spreading the aperture-area of the trigger onto multiple telescopes. Similar work is done in VERITAS [Schroedter et al., 2009].

Figure 19.19: The MAGIC Cherenkov-telescopes. Photograph by Thomas Kraehenbuehl.

Figure 19.20: Figure taken from [López-Coto et al., 2016]. Schematics of the topological trigger in the MAGIC telescope-array. Based on the pointing of the incident-direction of the gamma-ray and the location of the telescopes, the topological trigger expects certain regions in the images of both telescopes to be correlated to the air-shower. Current implementation act on coarse regions composed from small pixels to reduce the demands for processing.

Figure 19.21: The STAR [Jung et al., 2005] proposal, see also Figure 19.22.

A dense array of telescopes can sample the light-field densely in both incidentdirections c_x , c_y and support-positions x, y. It can sample the light-field in a very similar way as the plenoscope, [Wilburn et al., 2005]. The STAR-proposal [Jung et al., 2005] pointed out the need for a trigger which can act instantaneously on all the apertures of the individual telescopes. In STAT, possible solutions like timedelays which depend on the pointing of the telescopes were investigated. The trigger-envelope intended by the STAR-proposal is shown by the dashed, red line in the light-field-sampling-graph in Figure 19.21. However, we added the many but much smaller trigger-envelopes of each individual telescope which we think are possible to implement today. For a low energy-threshold of the trigger, it is best to have the read-out-channels, which belong to similar incident-directions, physically close together. But in a telescope-array this is not the case which confronts proposals like STAR with huge technological challenges. Somewhat related are the Durham telescopes Mrk III and IV in Narrabri [Brazier et al., 1990].

Figure 19.22: Figure taken from [Jung et al., 2005]. A schematics of the STARproposal illustrating the important flow of signals coming from near-by pixels in different telescopes. On the left are two telescopes of the array. Further to the right are hexagonal grids which illustrate the two images recorded by the two telescopes. Now the signal-flow of the trigger is shown as it tries to make the trigger-decision based on the sum of pixels which are near to each other in the space of incident-directions, but come from different telescopes. The signal-flow here is only shown for one incident-direction, see the red pixels. The signals from the different telescopes need to be delayed depending of the pointing of the array before the sum of near-by pixels is created. The problem illustrated by this simple but brilliant figure turned out to be a huge technological challenge.

Figure 19.23: The Portal Cherenkov-plenoscope.

The plenoscope can sample the light-field densely in both incident-directions c_x , c_y and support-positions x, y, see Figure 19.23. It can sample the light-field in the same way as the dense telescope-array. However, in the plenoscope all the photosensors which belong to similar incident-directions are physically close together, and do not need variable time-delays to compensate different pointing-directions. This allows the plenoscope to have a trigger which acts on its full aperture to reach the lowest possible energy-threshold for gamma-rays. The plenoscope is able to sample the entire (plenum) state of Cherenkov-photons relevant for the reconstruction of air-showers (support-positions, incident-directions, and arrival-times). The sampling of the light-field provided by the plenoscope shown in Figure 19.23 is the best possible result which can be reached in the light-field-sampling-graph.

Part II

Every single photon counts

Pushing Gamma-Ray-Astronomy on Cherenkov-Telescopes by sensing Light in the Quantum-Regime

Chapter 20

Introduction

We identify Cherenkov-telescopes to have unused potential. First, we find that established Cherenkov-telescopes are limited by the way they represent their recorded air-shower-events. And second, we find that the image-sensors of future Cherenkov-telescopes can be build more cost-effectively by going to a true digital read-out and leaving all analog processing behind.

Established Cherenkov-telescopes represent air-shower-events not by describing observables of photons, but by describing electric-pulses which are the responses of specific photo-sensors to these photons. Established Cherenkov-telescopes have photo-sensors which respond with analog pulses to incoming photons where the shape and the arrival-time of the pulse need to be interpreted. Such a representation of air-shower-events based on analog pulses limits the classification of Cherenkov-photons and night-sky-background-photons which prevents the detection of air-showers induced by cosmic particles with lower energies. Detecting air-showers induced by cosmic particles with lower energies is of great interest. It means either, that the costly aperture-area for Cherenkov-photons of future telescopes can be reduced while recording particles with the same energies, or that future telescopes will have more statistics of gamma-rays when recording the more abundant gamma-rays with lower energies.

Here we propose a more natural representation of air-shower-events to overcome present limitations. We propose to break with describing the largest electric pulses but to describe the recorded air-shower-event as what it naturally is: The arrival-times of individual photons in the pixels of an image-sensor. In this part of the thesis:

- We discuss the established procedure to detect gamma-rays with Cherenkovtelescopes on the example of the FACT Cherenkov-telescope.
- We discuss the established representation of air-shower-events which is based on the largest pulses found on analog time-series.
- We propose a natural representation for air-shower-events which is based on observables and not on the specific responses of specific sensors.

- We implement our natural representation for air-shower-events on FACT and call it photon-stream.
- We quantify the gain in performance for the classification of Cherenkovphotons when using the natural representation with the photon-stream over the established representation of largest-pulses.
- We estimate the performance and limitations of our photon-stream on both simulations and observations of FACT.
- Finally, we propose a digital read-out for Cherenkov-telescopes that does not need costly processing and routing of analog signals, and that records the natural photon-stream directly.

Chapter 21

FACT – A demonstration

The First Geiger-mode-Avalanche-photo-diode Cherenkov-Telescope (FACT) is a small Cherenkov-telescope on Canary island La Palma, Spain, see Figures 21.1, and 21.2. FACT demonstrates the usage of novel photo-sensors based on silicon outside the lab, but in the field. FACT monitors bright sources of cosmic gammarays such as Markarian 421 and Markarian 501. FACT also monitors the steady Crab nebula to validate that its own sensitivity does not degrade over time. Sensing photons with Silicon-Photo-Multipliers (SiPMs)¹ instead of Photo-Multiplier-Tubes (PMTs) is a novelty [Anderhub et al., 2013b] for Cherenkov-telescopes. FACT has a 9.5m² aperture for Cherenkov-photons provided by a segmented imaging-reflector with 4.889 m focal-length. The image-sensor of FACT has 4.5° field-of-view, and has 1440 hexagonal pixels with $\approx 0.1°$ field-of-view each, see Figure 21.3. As established Cherenkov-telescopes, FACT reconstructs the direction, the energy and the type of individual cosmic particles from air-shower-events to do gamma-ray-astronomy.

We take a close look at FACT and the imaging-atmospheric-Cherenkov-technique in general in two approaches. First, we will tell the story of the observation of one single air-shower-event and we will follow the information as it flows through the telescope. Second we will describe the general response-behavior of FACT in a quantitative way using not the statistics of one, but of many air-shower-events.

21.1 Story of a single event

It begins with a cosmic particle entering earth's atmosphere. The cosmic particle has the three properties: Direction, energy and type. The first interaction of the cosmic particle in the atmosphere at 25 ± 15 km above sea-level starts an air-shower. From now on, the properties of the cosmic particle can not be measured directly anymore. All following steps have the sole goal to reconstruct the three properties again from the observation of the air-shower.

¹Originally called Geiger-mode-Avalanche-Photo-Diode (GAPD). Nowadays often called Silicon-Photo-Multiplier (SiPM), or Single-Photon-Avalanche-Diode (SPAD).

Figure 21.1: FACT during the night on Rouque de los Muchachos 2,200 m above sea-level. The two large Cherenkov-telescopes MAGICI (left) and MAGICII (right) can be seen in the background. Image by Thomas Kraehenbuehl.

In the atmosphere the air-shower grows towards ground and emits, among others, bluish Cherenkov-photons. These Cherenkov-photons rush down the atmosphere and move with the local speed-of-light head-to-head with the other highly relativistic interaction-products of the air-shower. In a narrow front of $\approx 2 \text{ m}$ height, the interaction-products of the air-shower reach ground, and illuminate an area with the shape of a disc with about $\approx 200 \text{ m}$ diameter. A small fraction of the Cherenkov-photons fall into the 3.5 m diameter imaging-reflector of FACT which is looking up into the night-sky, approximately anti-parallel to the trajectory of the cosmic particle.

The Cherenkov-photons, together with the night-sky-background-photons fall into the imaging-reflector, see Figure 21.2. The imaging-reflector bins the photons, depending on their incident-directions c_x and c_y , into the pixels of the image-sensor with 0.1° resolution, see Figure 21.3. The Cherenkov-photons reach the image-sensor within a narrow time-window of ≈ 5 ns.

The SiPM-photo-sensors in the pixels produce electric pulses corresponding to the arriving Cherenkov-photons and night-sky-background-photons.

The coincident arrival-times of the pulses related to the air-shower, together with the directional-coincidence of near-by pixels, creates a pattern in the recorded video that sets itself apart from the pattern of the night-sky-background-pulses alone in the video. When the pattern of an air-shower is found in the video from the ensemble of pixels, the recording of the video is triggered. Today, the time-series of electric amplitudes of the pixels can not be recorded continuously to permanent-storage². FACT records the time-series of all pixels simultaneously for a time-window of 150 ns with a sampling-rate of 2 GHz. The trigger-threshold is continuously adjusted such that FACT records \approx 70 air-shower related videos per second.

On each time-series of a pixel, the charge-integral C and the arrival-time t of the largest pulse is extracted. As the charge-integral C is correlated to the number of photons arriving in the time-window of the integration, it is called photon-equivalent. The resulting representation of the air-shower-event with large pulses has two values C and t for each pixel and can be visualized in two images, see Figure 21.4. The identification of large pulses is already the first of multiple stages to classify Cherenkov-photons in the pool of night-sky-background-photons. A largest-pulse corresponds to the highest density of photon-arrivals in a pixel. In further stages, a set of pixels with a high density of photon-equivalents is searched in the image and associated with the air-shower³. About ≈ 10 geometric features are generated from the image of photon-equivalents. Figure 21.5 shows the basics of the popular ellipse-model for air-showers proposed by Micheal Hillas [Hillas, 1985] which is also used in FACT. Such so called *Hillas*-features describe the

 $^{^{2}1440\,\}mathrm{pixel} \times 12\,\mathrm{bit}$ resolution $\times 2 \times 10^{9}$ samples/s gives $4.32\,\mathrm{TByte/s.}$ Today 500 GByte/night is the most FACT can tolerate for permanent-storage.

³This is often called image-cleaning.

Figure 21.2: The FACT Telescope. See also Figure 21.1.

Figure 21.3: The inner components of the image-sensor of FACT. Cut open to see the inner workings. The actual image-sensor has much more cabling going on.

Figure 21.4: An air-shower-event recorded with FACT in the night of the 13th of November in 2015 (Run: 109, Event: 1506). Note that largest-pulses with small photon-equivalents (p.e.) have random arrival-times t. The hexagonal arrangement of the pixels here is because of FACT's image-sensor-plane, see Figure 21.3.

Figure 21.5: A simple ellipse-model for the intensity of the photon-equivalents in the image. The most common features are the length, and the width of the ellipse. Those are often computed using the covariance-matrix of the intensitydistribution in the image. Different Cherenkov-telescopes use different additional features to describe both the photon-intensity and the arrival-time-distribution of the largest-pulses in more detail. This is the same air-shower-event as shown in Figure 21.4.
air-shower in the image using an ellipse model.

For each recorded air-shower-event where Hillas-features could be generated, these Hillas-features⁴ are compared with the Hillas-features of simulated airshower-events of which the properties of the cosmic particle are known. From this comparison, the type, the direction, and the energy of the observed cosmic particle is estimated.

By comparing the incident-directions of gamma-rays with known directions of cosmic sources in the sky, FACT estimates the flux of gamma-rays from these sources. Finally, FACT publishes the estimated flux of gamma-rays of cosmic sources on its *Quick-Look-Analysis*-webpage [Dorner et al., 2017] about 10 min after the cosmic gamma-ray entered the atmosphere. FACT also emits alerts for increased fluxes of gamma-rays to its subscribers such as other telescopes on ground or in space.

21.2 Statistics of responses to cosmic particles

The statistics of the responses of FACT to different cosmic particles are a quantitative description of the performance of FACT. For Cherenkov-telescopes, such statistics of responses⁵ are estimated in simulations. Calibrations in the lab with artificial sources of gamma-rays and charged particles are not feasible today at energies in the 1 TeV regime. For FACT, we simulate the observation of individual air-shower-events while specific properties of the cosmic particle are drawn randomly for each simulated event⁶ The incident-direction and position of the trajectory ⁷ of the cosmic particle relative to the telescope is drawn randomly as well as the energy of the cosmic particle is drawn randomly. We estimate the statistics of the responses of FACT by counting the number of thrown events and counting the number of events that lead to a response in the telescope. In this case, the response we are looking for is the activation of the trigger for the read-out in the image-sensor of FACT. Figure 21.6 shows the effective collection-areas for both cosmic gamma-rays and cosmic protons which triggered the readout of FACT. These effective collection-areas of the trigger give an upper-limit on the largest possible area for the collection of gamma-rays that can be obtained from the recorded air-shower-events. For the detection of gamma-rays, hadronic cosmicrays need to be rejected which reduces the effective collection-area for gamma-rays by about one order-of-magnitude [Noethe et al., 2017]. When we convolve the

⁴Also called Hillas-parameters. FACT uses a flavor Hillas-features which are independent of the position of a hypothetical source of gamma-rays. Other Cherenkov-telescopes might use different definitions.

 $^{^5\}mathrm{Also}$ called response-function, instrument-response-function, or depending on the context also called effective area

⁶We use CORSIKA [Heck et al., 1998] to simulate air-showers and the emission of Cherenkovphotons [Bernlöhr, 2008].

⁷The trajectory is a ray with a support-vector (position) and a direction-vector (direction) in the three-dimensional frame of the telescope.

Figure 21.6: Based on simulations. The effective collection-area of the trigger of FACT.

effective collection-area of the trigger of FACT with the fluxes for cosmic gammarays [Hillas et al., 1998] and cosmic protons [Olive et al., 2014], we obtain the expected rate of the trigger of FACT, see Figure 21.7. The integrated expected rates of the trigger over the range of simulated energies of cosmic particles are $5.7 \,\mathrm{s}^{-1}$ for cosmic protons and only $0.045 \,\mathrm{s}^{-1}$ for cosmic gamma-rays. The flux of gammarays here is the flux of the Crab nebula, which is one of the brightest source in the gamma-ray-sky. In our simulations we use the flux of night-sky-backgroundphotons shown in Figure 22.3, which is the dark night on Canary island La Palma. This flux for night-sky-background-photons gives $\approx 30 \times 10^6 \,\mathrm{s}^{-1}$ photons in each pixel of FACT's image-sensor. FACT's trigger is discussed in [Vogler et al., 2011]. Figure 21.8 illustrates a mayor advantage of Cherenkov-telescopes over direct detectors for gamma-rays in space. Although the aperture for Cherenkov-photons of FACT is only $\approx 3.5 \,\mathrm{m}$ in diameter, FACT is well able to record air-showers where the trajectory of the cosmic gamma-ray intersects the ground $\approx 100 \,\mathrm{m}$ off the telescope. This is because Cherenkov-telescopes rely on the air-showers illuminating large areas on ground with $\approx 100 \,\mathrm{m}$ radius. The trigger of FACT has an effective collection-area of $> 10^4 \,\mathrm{m}^2$ for gamma-rays which exceeds its aperture-area for Cherenkov-photons by ≈ 3 orders-of-magnitude. This makes Cherenkov-telescopes cost efficient to investigate cosmic-rays and gamma-rays.

Figure 21.7: The differential rate of the trigger of FACT. Based on the effective collection-area of the trigger of FACT, see Figure 21.6.

Figure 21.8: Areal-density of the support-position of the trajectory of gammarays on ground. Left is the density of all thrown gamma-rays. Right is the density of the gamma-rays which triggered the readout of FACT. Based on the same simulations as Figure 21.6. The radial truncation for the thrown events is only to reduce the need for computation.

Chapter 22

The image-sensor of FACT

The photo-sensors, trigger, and read-out-electronics in the image-sensors of Cherenkovtelescopes are the most complex component of a Cherenkov-telescope. The imagesensor of a Cherenkov-telescope records videos with $\approx 10^9$ images per second at a resolution of $\approx 10^3$ pixel. The photo-sensors in the image-sensor respond already to single-photons within nano-seconds¹. The trigger of the image-sensor identifies the pattern of air-showers in the video within nano-seconds to allow the read-out of the video to permanent storage. Image-sensors for Cherenkov-telescopes have to work in the field where weather and light-conditions might change unexpectedly. Image-sensors are expensive and very demanding to develop. They use custom-build, high-bandwidth electronics for the processing of analog signals. It is difficult to find the best compromise of power-consumption, heat-removal, signal-to-noise-ratio, event-throughput, weight, part-availability, and cost. The design of the image-sensor also effects the rest of the telescope which for example must be built more rigid when the weight of the image-sensor increases. From the experience with FACT, we learned that routing of analog signals with highbandwidth in cables or on circuit-boards is possible, but very demanding and costly. Because FACT is small, it can tolerate a relatively heavy but compact image-sensor with all its read-out within one housing. But the large MAGIC Cherenkov-telescopes for example are forced to put their read-out-electronics off the moving telescope what creates additional challenges [Bartko et al., 2005] and costs for cabling and the transmission of analog signals.

22.1 SiPMs in FACT

FACT senses photons using Silicon-Photo-Multipliers (SiPMs) of the type Hamamatsu MPPC S10362-33-50C. SiPMs are two-dimensional arrays of Geiger-modeavalanche-photo-diodes (GAPDs) which are typically [Golovin, 1998, Sadygov, 1998] all connected in parallel and operated with reverse bias. SiPMs respond to incoming photons with an electric pulse on their analog signal-output. Figure

 $^{^{1}}$ On some Cherenkov-telescopes the number of photons needed to resolve the response of a photo-sensor might be higher, but is usually below 10.

Figure 22.1: A single-photon arriving in an SiPM-pixel of FACT. The average pulse observed in the image-sensor of FACT is blue. The example time-series of an SiPM-pixel of FACT with its electronic-noise is gray.

22.2 shows a pixel of the image-sensor of FACT with its SiPM, and Figure 22.9 shows the circuit diagram of the SiPMs used in FACT. In reverse bias, all GAPDs act like capacitors, each storing the same amount of charge. The SiPMs used in FACT operate at ≈ 70 V of bias-potential. When a GAPD is hit by a photon it might discharge thus creating a well defined, and easy to sense electric-pulse on the time-series of the terminal of the SiPM. When multiple GAPDs are hit in short time, their pulses add up on the time-series. Figure 22.1 shows an electric-pulse on the time-series of a SiPM-pixel used in FACT when a single-photon arrives. The gain² of the SiPMs used in FACT is $\approx 1.1 \times 10^7$.

22.2 PMTs in established Cherenkov-telescopes

Established Cherenkov-telescopes use Photo-Multiplier-Tubes³ (PMTs) to sense photons. PMTs are photo-sensors which respond to photons with electric pulses on their analog signal-output. PMTs are vacuum-tubes with a transparent entrance window. The inner surface of the entrance window is coated with a material where incoming photons can release electrons into the vacuum of the tube. A static electric-field inside the vacuum-tube accelerates the electron which falls into a plate of metal where additional electrons are released from the impact on the metal-plate. This way the number of released electrons is multiplied. In a cascade of metal-plates and electric-fields, the process of acceleration and release is repeated until the number of released electrons is large enough to be processed and read out. As we will show in the following, dedicated PMTs are optimized to

²This is comparing the power falling into the sensor in form of visible photons (100 × 10^6 photons s⁻¹ × 3 eV photon⁻¹) to the power from the bias supply which is released by the GAPDs in form of current (7.5 uA × 70 V). The values are taken from the upcoming Figures 25.16 and 25.17.

³Also called photo-multiplier without the tube.

Figure 22.2: A pixel of the image-sensor of FACT, compare Figure 21.3. A transparent light-guide concentrates the hexagonal aperture of the pixel down to a square output-window glued to the silicon-chip of the SiPM. The light-guide is made out of poly-methyl-methacrylate (PMMA), and was mass produced using injection-molding. The SiPM part designation is Hamamatsu MPPC S10362-33-50C. The GAPD-array has $60 \times 60 = 3600$ GAPDs. All GAPDs are connected in parallel to the terminals of the SiPM.

offer a well suited, and high photon-detection-efficiency for blueish photons what makes them a great choice for Cherenkov-telescopes. However, we will also see that PMTs lack single-photon-resolution which is due to the statistical process of the multiplication of the released electrons.

22.3 Alternative photo-sensors

Two alternative photo-sensors relevant for Cherenkov-Telescopes must be acknowledged as well. First, there are Hybrid-Photo-Detectors (HPDs) which are a hybrid of the entrance-window from a photo-multiplier-tube and a single avalanche-photo-diode within the same vacuum-tube [Tridon et al., 2010]. HPDs have great potential for Cherenkov-telescopes as they have similar, or even higher, photon-detection-efficiencies as PMTs, but also have a high singlephoton-resolution like SiPMs. According to private communication with Adrian Biland (MAGIC-collaboration), HPDs were not deployed on MAGIC due to extensive aging of at least the first production-batch during typical observationconditions. Second, there are photo-sensors using electric discharges in gas filled multi-wire-proportional-chambers. The CLUE-experiment [Alexandreas et al., 1995] successfully recorded images of air-showers using such chambers. The gas-chambers are most sensitive to photons with wavelength in the range between 150 nm and 350 nm which naturally results in strong rejection of reddish night-sky-background-photons. We are not sure why, but apparently no other Cherenkov-telescope used gas filled multi-wire-proportional-chambers after CLUE.

Figure 22.3: Initial amount of photons before reaching the telescope. Reconstructed from a simulated air-shower-event of FACT with 50 ns exposure-time. Night-sky-brightness is $\approx 21 \text{ mag arcsec}^{-2}$ and $\approx 12 \times 10^3$ photons total in the shown interval of wavelengths. The spectrum of the night-sky-brightness is taken from [Benn and Ellison, 1998]. About 1.1×10^3 Cherenkov-photons produced by a 3 TeV gamma-ray from direction zenith.

22.4 Photon-detection-efficiency

Exploiting the different spectra of the wavelengths of blueish Cherenkov-photons and of reddish night-sky-background-photons can be a first step to achieve a classification of Cherenkov-photons, see Figure 22.3. Although Cherenkov-telescopes do not have photo-sensors which can measure the wavelength of the incoming photons, Cherenkov-telescopes use photo-sensors which are optimized to sense blue photons and to reject red photons. Here, the photon-detection-efficiency of the first generation of mass-produced SiPMs used in FACT falls behind the photon-detection-efficiency of state-of-the-art PMTs, see Figure 22.4. Table 22.1 estimates how much the ratio of Cherenkov-photons and night-sky-background-photons changes if FACT had sensors with the photon-detection-efficiency of state-of-the-art PMTs.

22.5 Single-photon-resolution

SiPMs have a good single-photon-resolution. For photo-sensors which output analog signals, a good single-photon-resolution means that a certain number of simultaneously arriving photons, will create a charge-integral C of a certain amplitude which can be told apart from the amplitudes of other charge-integrals created by different numbers of photons. We call the number of photons arriving

Figure 22.4: Photon-detection-efficiency for a state-of-the-art PMT [Toyama et al., 2013] and the SiPM used in FACT. Photon-detection-efficiency of the SiPM is based on claims of the manufacturer on the spectral-distribution [Hamamatsu, 2009] and our own experiences [Anderhub et al., 2013b] with the peak-efficiency.

	Night-sky-background/1	Air-shower/1	ratio/%
before image-sensor	11856	1132	9.5
SiPM	2500	200	8.0
PMT	1414	313	22.1

Table 22.1: Ratio of Cherenkov-photons to night-sky-background-photons and absolute amounts during 50 ns of exposure-time. Observing an air-shower induced by a 3 TeV gamma-ray from direction zenith. Based on Figures 22.4, and 22.3. Note: This estimate is limited to the range of wavelengths of current simulation-tools [Heck et al., 1998, Bernlöhr, 2008].

9	0.000	0.001	0.009	2.427
10	—	—	0.007	1.975

Table 22.2: The rate of different photon-multiplicities for a time-window of 1 ns. The ratio indicates that 18.520% of all Cherenkov-photons arrive alone as single-photons, 16.437% of all Cherenkov-photons arrive in a tuple of two simultaneous photons, and so on. The majority of photons detected by FACT arrive alone as single-photons. Only 20% of all Cherenkov-photons arrive in tuples with multiplicities > 10. Compare and see uncertainties in Figure 22.8. The decay of the rate of the multiplicity of night-sky-background-photons is dominated by an artifact called optical-cross-talk which we describe later in Section 22.7.

within a small, simultaneous time-window the multiplicity of the arriving photons. The Figures 22.5 and 22.7 show the histogram of the charge-integrals of the SiPMs used in FACT and a state-of-the-art PMT. Because of the individual, but identical GAPDs in the SiPM, we find several distinct peaks of distinct photonmultiplicities in the histogram of charge-integrals in Figure 22.5.

The Figure 22.8 and Table 22.2 show how often different photon-multiplicities occur⁴during the observations of FACT. We find that the SiPMs used in FACT can tell apart the number of the arriving photons. In the measurement for the histogram in Figure 22.5, the probability for larger multiplicities drops exponentially which might create the impression that the single-photon-resolution of the SiPM vanishes for multiplicities larger than eight. But the measurement is just running out of statistics for larger multiplicities. Figure 22.6 shows an different measurement [Kraehenbuehl, 2017] which shows that the single-photon-resolution does not vanish beyond a multiplicity of eight.

We conclude that FACT does not need to represent photons vaguely by describing the continuous charge-integral C of its sensor. We conclude that FACT can describe the photons directly in a quantized way.

⁴The Figure 22.8 and Table 22.2 show the rates of photon-multiplicities separately for both night-sky-background-photons and Cherenkov-photons. The multiplicities of Cherenkovphotons are estimated by subtracting the multiplicities found in events which were randomly triggered from the multiplicities found in events which were triggered because the pattern of an air-shower was found in the video. Randomly triggered events are very unlikely to contain Cherenkov-photons. The multiplicities of the night-sky-background-photons are estimated from the randomly triggered events only.

Figure 22.5: Based on [Biland et al., 2014]. Single-photon-resolution of the SiPM used in FACT. Internally triggered on incoming electric pulses, hence no '0' peak, compare Figure 22.7. Across all 1440 SiPMs of the image-sensor of FACT, across all temperatures during operation, across several month of operation.

22.6 Wear and aging

While Cherenkov-telescopes with PMTs have to use additional filters [Archambault et al., 2017] for observations during bright moonlight in order to not degrade the sensitivity of their PMTs over several years [Gazda et al., 2016] of observations, the regular FACT Cherenkov-telescope with its SiPMs can observe Cherenkov-photons while the full-moon is in same field-of-view [Knoetig et al., 2013] without degrading the sensitivity of its SiPMs. After more than five years of observations with the SiPMs used in FACT, a charge of over 370 C was released in each SiPM-pixel [Neise et al., 2017] and we do not see any hint for a change in the performance to detect photons yet.

22.7 Artifacts

The SiPMs used in FACT have two artifacts which are relevant for Cherenkovtelescopes. First, the SiPMs used in FACT discharge their GAPDs accidentally even when it is dark and no photons arrive. This dark-noise increases with temperature, and is $\approx 4 \times 10^6 \,\mathrm{s^{-1}}\,\mathrm{pixel^{-1}}$ during room-temperature. On FACT, this accidental rate of discharges of GAPDs is only a minor issue because the rate of night-sky-background-photons in a pixel is about one order-of-magnitude larger at

Figure 22.6: Figure taken from [Kraehenbuehl, 2017]. In contrast to Figure 22.5 where only the rare accidental discharges of the SiPMs are used, here for each event a light-source deposited about 5 photons in the SiPM. Here 'cell' is the Geiger-mode-avalanche-diode. The left most pedestal-bump indicates that this Figure was created with a very different procedure than Figure 22.5. Here a method was used similar to the one shown in Figure 22.7 where one does not wait for sensor-responses to show up randomly, but reads out the sensor unconditionally after photons have been emitted by a controlled light-source which in rare cases might not emit any photon. Anyhow, for our purposes here it is only relevant that many distinct peaks can be found what indicates a high single-photon-resolution.

Figure 22.7: Based on [Masuda et al., 2015]. Single-photon-resolution of a stateof-the-art PMT. Externally triggered by a source of photons, hence the '0' peak when no electric pulse was released in the PMT. One specific PMT only.

 $\approx 30 \times 10^6 \,\mathrm{s^{-1}\, pixel^{-1}}$. For example, the sensor-responses used in Figure 22.5 are only caused by accidental discharges of GAPDs at a rate of $\approx 4 \times 10^6 \,\mathrm{s^{-1}\, pixel^{-1}}$. Second, the discharge of a GAPD can cause the discharge of other GAPDs on the same SiPM [Otte, 2009]. This so called optical-cross-talk of GAPDs causes false responses by the SiPMs which appear to be incoming photons but actually are not. For large rates of arriving photons, the optical-cross-talk results simply in an increase in gain of the sensor-response, but for the low rates of photons on FACT, where we are approaching the quantized regime of single-photons, optical-cross-talk becomes a noise [Buss et al., 2015] which is worked on to be minimized [Buzhan et al., 2009]. For FACT, the probability for a GAPD to optically cross-talk into another GAPD is 9.5% [Biland et al., 2014].

22.8 Read-out

In the image-sensor of FACT, the analog signals of all pixels are continuously written into a ring-buffer with a depth of 512 ns. When the trigger of the imagesensor detects the pattern of an air-shower in the video, the trigger stops the continuous writing into the ring-buffer and copies the recorded time-series from the ring-buffers to the slow permanent-storage. The ring-buffer of a pixel in FACT is an array of 1024 capacitors which are connected to the output of the pixel one after another for a time of 500 ps each. During these 500 ps when the capacitor is

Figure 22.8: The rate of different photon-multiplicities for a time-window of 1 ns. Recorded in the night of 11th November 2013 in run 160. Multiplicities of Cherenkov-photons in blue. Multiplicities of night-sky-background photons in orange. The exposure-time-equivalent for a single pixel is 1,440 pixels × 17,302 events × 50 ns/event = 1.2 s for the Cherenkov-photons and 1,440 pixels × 294 events × 50 ns/event = 21 ms for night-sky-background-photons. Total integrated photon-rate is $43.6 \times 10^6 \text{ s}^{-1} \text{ pixel}^{-1}$. Compare with Table 22.2. The gray, dotted line indicates the decay of the peaks in Figure 22.5 which are dominated by an artifact of the SiPM called optical-cross-talk which we describe later in Section 22.7.

Figure 22.9: A photon falling into the SiPM-pixel can discharge a GAPD. The electric-pulse of the discharge is stored in the array of capacitors in the dominoring-sampler. When the trigger detects the pattern of an air-shower in the pixels, the charge in the capacitors is converted to digital values which are stored permanently. This configuration is called quasi-digital-counter. Compare SiPM with Figures 22.2 and 21.3 and compare the time-series with Figure 22.1. Inspired by schematics by Stefan Ritt of the domino-ring-sampler.

connected to the output of a pixel, the potential of the capacitor floats towards the average potential of the analog signal of the pixel. When the next capacitor in the array is connected to the pixel, the first capacitor holds its potential until it is overwritten again 512 ns later when all 1024 capacitors have been connected to the pixel once. When the trigger decides to read out the ring-buffer, each capacitor is connected to an analog-to-digital-converter for a time of $\approx 1 \,\mu$ s. The output of the analog-to-digital-converter is then written to a permanent storage. Figure 22.9 shows the simplified schematics of the read-out-electronics used in FACT. The array of sample-and-hold-capacitors is called 'switched-capacitor-array', or 'domino-ring-sampler' [Ritt, 2008].

Chapter 23

Representing air-shower-events

Cherenkov-telescopes record a pool of night-sky-background-photons with a few Cherenkov-photons in it. Cherenkov-telescopes record three observables for each of these photons:

- The incident-direction c_x ,
- the incident-direction c_y ,
- and the arrival-time t.

The different pixels in the image-sensor measure the incident-directions c_x , and c_y , and the time-slices on the time-series of a pixel measure the arrival-time t. Current Cherenkov-telescopes do not record additional observables. As a consequence, the only way to classify Cherenkov-photons and night-sky-background-photons is to investigate the spatial structure of the photons in the three-dimensional space of observables. A limited description of these observables limits the performance to classify Cherenkov-photons and night-sky-background-photons, and thus prevents us from observing low energetic gamma-rays.

23.1 Largest-pulses

We name the group of established representations for air-shower-events the representation of largest-pulses. The representation of largest-pulses describes not the observables of the incoming photons, but the electric-pulses created by these photons in photo-sensors such as PMTs or SiPMs. Usually Cherenkov-telescopes describe the largest-pulse with two attributes. First a charge-integral, called photon-equivalent C, and second an arrival-time t. The representation of largestpulses can be visualized in two images as shown in Figures 21.4. As the largestpulse on a time-series of a pixel in a Cherenkov-telescope is associated with the Cherenkov-photons, the representation of largest-pulses is already the result of a first classification of Cherenkov-photons along the arrival-times of the photons. All past [Kildea et al., 2007, Barrau et al., 1998, Puehlhofer et al., 2003], current [Holder et al., 2006, Sitarek et al., 2013, Holler et al., 2013, Albert et al., 2008b], and future [Catalano et al., 2013, Yashin, 2015] Cherenkov-telescopes represent air-shower-events using the charge-integrals of analog photo-sensors in their pixels. Some Cherenkov-telescopes [Kildea et al., 2007, Barrau et al., 1998, Puehlhofer et al., 2003, Yashin, 2015] do not have additional arrival-time informations, but only the charge-integral. All the listed references focus on describing the air-shower-event using the response of their individual sensors and read-out. None of the listed references interprets their sensor-responses in order to restore all the observables of the individual photons. All references listed here stuff single-photons into one large pulse.

23.2 Photon-stream

When we describe all the observables of the incoming photons as they stream through the image-sensor-plane of a Cherenkov-telescope, we end up with a list of photon-arrival-times for each pixel. We call this representation the photonstream. The photon-stream is the most natural representation for air-showerevents possible for a Cherenkov-telescope. With the photon-stream it is not longer the question whether the representation of the air-shower-event itself is limited but whether we are able to create a Cherenkov-telescope which can record the natural representation of the photon-stream with sufficient accuracy to take advantage over the established representation of largest-pulses. As we will show later on, we believe that FACT with its SiPM-pixels, its low electronics-noise, and fast read-out is about to provide this accuracy. Figure 23.1 shows an airshower-event recorded on FACT and represented in the photon-stream.

The photon-stream is not dedicated to a specific photo-sensor or read-outelectronic. The photon-stream is decoupled from the hardware and only describes the observables of the incoming photons. We introduce here the photon-stream on the example of FACT with its SiPM photo-sensors, but the photon-stream is not limited to SiPM sensors. Although not practical at the moment, the quantized photon-stream could also be recorded with PMTs [Catalano et al., 2008] when the number of pixels is increased to lower the rate of photons in the individual pixels.

Figure 23.1: An air-shower-event recorded by FACT and represented as a stream of photons in the three-dimensional space of observables. Each blue dot represents one photon. All blue photon-dots have the same semi-transparent color, so that dense regions of photons look darker. The black ring on the bottom represents the field-of-view. This is the same air-shower-event as shown in Figures 21.4, 26.1, and 26.2.

Chapter 24

Single-Photon-Extractor

To create the photon-stream for FACT, we have to extract the arrival-time of each single-photon from the recorded time-series of a pixel. Our first implementation of a single-photon-extractor for the SiPMs in FACT is based on two assumptions:

- First, we assume that the amplitude on the time-series of a pixel is only the sum of discharge-pulses of individual GAPDs.
- And second, we assume that discharge-pulses of all GAPDs are the same for all pixels, and time-epochs.

24.1 Algorithm

We run an iterative detection and subtraction of single-pulses on the time-series of a pixel. In each iteration we append the extracted arrival-time of a single-pulse to the resulting list of arrival-times and subtract the pulse we just found from the time-series. We stop the iteration when the time-series of the pixel is flat and does not contain anymore single-pulses.

Preparation

Before the extraction, we prepare two templates of discharge-pulses of our GAPDs. The first, called full-template-pulse $A_{\text{full}}[t]^{-1}$, contains the full, and uncut singlepulse. The second, called rising-edge-template-pulse $A_{\text{edge}}[t]$ contains a truncated single-pulse which only contains the rising-edge and the apex of the pulse. Find both pulses in Figure 24.1. The rising-edge-template-pulse will be used to detect candidates of single-pulses. The full-template-pulse on the other hand will be used to subtract a detected single-pulse from the time-series of the pixel.

¹We use brackets in A[t] instead of parentheses to stress the discrete array-character with 2 GHz sampling-rate and 500 ps sample-duration respectively of our implementation.

Figure 24.1: The full-template-pulse $A_{\text{full}}[t]$. The gray box from 0 ns to 10 ns marks the range of the rising-edge-template-pulse $A_{\text{edge}}[t]$. Compare Figure 22.1 to see the electronic-noise again.

Further, we create an empty list where the arrival-times of the single-pulses will be appended during the extraction.

Input

The input is the time-series of an individual pixel $A_{\text{pixel}}^0[t]$. We expect the calibration and the removal of artifacts of the read-out to be done already. However, we know and accept that rare artifacts, which we do not address yet, can still be present on the time-series. The most common of the not addressed artifacts is a sinusoidal resonance, see 'ringing' in [Vogler, 2017].

Detecting a single-pulse

We detect the *i*-th single-pulse by correlating the current (i - 1)-th input-timeseries of a pixel $A_{\text{pixel}}^{i-1}[t]$ with the rising-edge-template-pulse

$$R^{i}[t] = A^{i-1}_{\text{pixel}}[t] * A_{\text{edge}}[t].$$
(24.1)

In the correlation with the rising-edge-template-pulse, frequencies on the timeseries contained in the rising-edge-template-pulse are likely to pass on into $R^{i}[t]$. But other frequencies as e.g. the frequencies of the electronic-white-noise of our read-out are likely to be suppressed in $R^{i}[t]$. On the correlation-response, we identify the time-slice of the maximum

$$t_i = \operatorname{argmax}(R^i[t]) \tag{24.2}$$

and define its associated time t_i to be the arrival-time of the *i*-th single-pulse. We append this arrival-time t_i to the list of arrival-times for this pixel. Correlating the

input-time-series with a template-pulse [Puehlhofer et al., 2003] or simply with a rectangular-box [Sitarek et al., 2013] is already done on Cherenkov-telescopes to identify and restore the largest-pulse on a time-series.

Subtracting a single-pulse

After the detection of the *i*-th single-pulse, we subtract the full-template-pulse $A_{\text{full}}[t]$ from the current *i*-th iteration of the pixel-time-series

$$A^{i}_{\text{pixel}}[t] = A^{i-1}_{\text{pixel}}[t] - A_{\text{full}}[t - t_{i}]$$
(24.3)

at the corresponding arrival-time t_i .

Stopping-criteria

On the remaining time-series of the pixel $A^i_{\text{pixel}}[t]$ we further detect and subtract single-pulses until a stopping-criteria is fulfilled. The stopping-criteria is fulfilled when the maximum of the response $R^i[t]$ drops below 1/2 of the maximum of the response to a single-pulse. When the stopping-criteria was reached, the final time-series of the pixel is flat.

24.2 Example

We run our extractor on simulated time-series where the arrival-times of the photons are known. Figure 24.2 demonstrates the iterative procedure of our singlephoton-extractor. The simulated amplitude of electronic-white-noise is typical for FACT. The simulated rate of photons is $\approx 50 \times 10^6 \,\mathrm{s^{-1}}\,\mathrm{pixel^{-1}}$, which is $\approx 30\%$ higher than the rate of photons during a very dark night at $\approx 21 \,\mathrm{Mag}\,\mathrm{arcsec}^{-2}$.

24.3 Benefits of iterative subtraction

During our investigations, the iterative subtraction of single-pulses was the only method to identify the arrival of single-photons right after the arrival of a bunch of multiple, simultaneous photons. In technical terms: Only the iterative subtraction is able to identify single-pulses on the steeply falling edge of large, piledup pulses. Investigations with non iterative methods, in which only a single convolution-response is calculated, are not able to identify such photons, as the convolution-response is dominated by the steeply falling edge of the piled-up pulses. Th such scenarios, the rising edge of a single pulse is not enough to raise the convolution-response above the detection-threshold. However, with an iterative subtraction, the large, piled-up pulse is flattened out one pulse after another until a trailing single-pulse on its falling edge can raise the convolution-response above the detection-threshold.

Figure 24.2: The time-series after each iteration of the single-photon-extractor. Starting on the top, going down to the bottom. The extracted arrival-times are in red, and the true arrival-times are in green. Extracted and true arrival-times are expected to be close to each other. In the end of the extraction, the time-series is flat.

Chapter 25

Performance of extraction

We estimate the performance and limitations of our single-photon-extractor in three different ways. First, we evaluate the precision of our extracted arrivaltimes using simulated time-series. Second, we crosscheck if the photon-stream for FACT created by our single-photon-extractor still contains the information that is relevant for our established reconstruction of cosmic particles from largest-pulses. Third, we look for a saturation of the rate of extracted photons under different brightnesses of the night-sky.

25.1 Validation on Simulations

We perform two tests on simulated time-series. First, we investigate the reconstruction of the arrival-time for one isolated single-photon with different amplitudes of electronic-white-noise. Second, we investigate the reconstruction of the arrival-times of multiple photons during typical fluxes of night-sky-backgroundphotons on FACT.

Arrival-time of a single, isolated photon

We put one isolated pulse $A_{\text{full}}[t]$ on a time-series and add electronic-white-noise with different amplitudes. The true arrival-time of the pulse is drawn uniformly. Figure 25.1 shows the distribution of the

residual-arrival-time = true-arrival-time - extracted-arrival-time
$$(25.1)$$

for four different amplitudes of electronic-white-noise. For each amplitude of electronic-white-noise we simulate 10^5 trials. Table 25.1 shows the standard-deviation of the distribution of the residual arrival-times depicted in Figure 25.1. We express the amplitudes of electronic-white-noise using the standard-deviation of the electronic-white-noise in units of the maximum amplitude A of our single-pulse-template $A_{\text{full}}[t]$. FACT has a measured amplitude of electronic-white-noise of $\approx 0.1 A$.

$\begin{array}{c} \text{Electronic-white-noise} \\ \text{amlitude}/A \end{array}$	Arrival-time resolution/ps	number of trials	number of detections
0.0	144	100,000	100,000
0.05	260	100,000	100,000
0.1	416	100,000	100,000
0.2	718	100,000	100,000
0.4		1,000	1,021
0.6		1,000	1,483
0.8		1,000	5,477

Table 25.1: Resolution of the arrival-time of an isolated photon for four different amplitudes of electronic-white-noise. The resolution of the reconstruction of the arrival-times is the standard-deviation of the distribution of the residual arrival-times presented in Figure 25.1. The corresponding amplitude of electronic-white-noise for FACT is shown in black. For zero noise, we find the standard-deviation of a uniform distribution within the 500 ps sampling-duration which is $500 \text{ ps}/\sqrt{12} \approx 144 \text{ ps}.$

We find that our single-photon-extractor reaches 416 ps resolution for arrivaltimes of isolated single-photons on time-series with amplitudes of electronicwhite-noise that are typical for FACT. We also find that our single-photonextractor's intrinsic limitation of a fix sample-time-duration of 500 ps becomes the dominant limitation for the reconstruction of arrival-times when there is zero electronic-white-noise. Finally, we find that the performance of the reconstruction of arrival-times of our single-photon-extractor scales inverse to the amplitude of the electronic-white-noise as can be seen in the gray colored findings in Figure 25.1 and Table 25.1. For an amplitude of electronic-white-noise $\leq 0.2 A$, our single-photon-extractor detects exactly one photon in each trial. Only if the electronic-white-noise increases beyond 0.4 A, our single-photon-extractor starts to detect false photons, as can be seen in the lower part of Table 25.1. We notice that the residual arrival-time of our single-photon-extractor has a small systematic offset of about 125 ps, see Figure 25.1. For the reconstruction of the air-shower, such absolute resolution of the arrival-times is not relevant for FACT. We suspect this systematic to show up because of the asymmetric shape of the pulse and the limited sample-duration of 500 ps.

Arrival-times of multiple photons

We expect the resolution of the arrival-times for single-photons to drop when the rate of photons increases. For example, when the rate of photons approaches the sampling-frequency of the time-series, the time-series will be full of photons, but also it will be rather flat. In such a case, large photon-multiplicities will still be recognized, but the arrival-times of the photons which form the base of the time-series will not be recognizable anymore with our single-pulse-extractor.

Figure 25.1: Performance of the reconstruction of the arrival-time of singlephotons for four different amplitudes of electronic-white-noise. The corresponding amplitude of electronic-white-noise for FACT is shown in black. Table 25.1 shows the standard-deviation of the distribution of the residual arrival-times.

Here we simulate time-series with photons which represent the flux of night-skybackground-photons in FACT, such as shown and described in Section 24.2, and Figure 24.2. On simulated time-series, we know the true arrival-times of the photons. To quantify the performance, we define true-positive-, false-negative-, and *false-positive*-matches between a true and an extracted arrival-time. When counting the occurrences of these matches, we quantify the true-positive-rate 1 of our single-photon-extractor. After we ran our single-photon-extractor on a simulated time-series, we have both the list of true arrival-times and the list of extracted arrival-times. We loop over the list of true arrival-times and will remove matching extracted arrival-times from the list of extracted arrival-times in the process. In case the list of extracted arrival-times is already empty, we say it is a false-negative-match. Else, we calculate the residual arrival-time between the true arrival-time and its nearest match among the extracted arrival-times. When this residual arrival-time is smaller than, or equal to a certain coincidence-timeradius, we call this match a *true-positive*. On the other hand, when the residual arrival-time is bigger than our coincidence-time-radius, we call this match a *falsenegative*. Finally, when we have looped over the list of true arrival-times, we call each remaining extracted arrival-time a *false-positive*-match.

Figure 25.2 shows the true-positive-rate of our single-photon-extractor. We find 75% probability to extract the arrival-time of a single-photon within 1 ns of its true arrival-time. We can not stress enough that this is about individual photons expected while staring into the night-sky-brightness on Canary island La Palma. This is not about intense bunches of coincident photons from a calibration-source found in a lab.

25.2 Crosscheck with classic analysis

The list of arrival-times of single-photons can be converted back to an emulation of the original time-series. We add the full-template-pulse $A_{\text{full}}[t]$ to a time-series at each arrival-time where a single-photon was extracted. This back-converted time-series can be analyzed for air-shower-features by our classic extractor which uses largest-pulses on time-series. When feeding back-converted time-series into our classic extractor for air-shower-features, we can compare the features from the back-converted time-series to the features extracted from the original time-series. This way we can estimate if the photon-stream still contains the information that is relevant for our classic extractor for air-shower-features. This crosscheck of course does not use any of the additional information in the photon-stream which is not accessible with largest-pulses.

So we perform a crosscheck with a sample of observations of FACT with 18 h exposure-time and 4,233,265 recorded air-shower-events. This sample was simultaneously [Ahnen, 2017a] recorded with the MAGIC telescopes, see Figure

¹Also known as sensitivity.

Figure 25.2: In blue is the true-positive-rate of our single-photon-extractor during typical observations on FACT at a rate of nigh-sky-background-photons of $50 \times 10^6 \,\mathrm{s^{-1}}\,\mathrm{pixel^{-1}}$. In orange is the estimated true-positive-rate of our single-photon-extractor for isolated single-photons based on Figure 25.1. The dark night at 21 mag argsec⁻² has only $37 \times 10^6 \,\mathrm{s^{-1}}\,\mathrm{pixel^{-1}}$, see Figures 25.15, and 25.17. For each coincidence-time-radius we simulate $216\mu\mathrm{s}$ exposure-time.

21.1. This means, that both MAGIC telescopes and FACT observed the same air-showers induced by the same cosmic-particles. The records of this sample are sparsely scattered between November 2013 and December 2014. MAGIC observes air-showers with two telescopes for a stereo-view. Each MAGIC telescope has 230 m^2 aperture-area for Cherenkov-photons. MAGIC's lower energy-threshold for gamma-rays is below 100 GeV which is about one-order-of-magnitude below the lower energy-threshold of FACT. Because of this, the properties of the cosmic particle (direction, energy, and type) reconstructed by the two MAGIC telescopes are of excellent quality for cosmic particles with energies close to the energy-threshold of FACT at $\approx 1 \text{ TeV}$. Therefore, we assume that the properties of the cosmic particle reconstructed by MAGIC are the *true* properties and thus can serve as a benchmark for FACT. Further, we will not only look at the high-level benchmark of the properties of the cosmic particle, but we will also take a brief look at the air-shower-features extracted and used in between.

Air-shower features

The intermediate representation of the air-shower is done with Hillas-features, see Figure 21.5. The Figures 25.3, 25.4, 25.5, 25.6 and 25.7 show the Hillas-features which model the photon-distribution in the image using a simple ellipse. The onedimensional histogram on the left side of the figures shows the distributions of the features, and the two-dimensional histogram on the right side of the figures shows the confusion between the two time-series. The figures show that the distributions of the Hillas-features are similar for the original and the back-converted timeseries. Also the figures show that the confusion is low between the features reconstructed from the original and from the back-converted time-series. The spill-over in the confusion of Hillas-Alpha in Figure 25.6 at $\pm 90^{\circ}$ is because of the 180° rotation-invariance of the ellipse-model. The small deviation for long air-showers in Hillas-Length, see Figures 25.3, is not understood. Since there is not such a large deviation for air-showers with many photons in Hillas-Size, see Figures 25.7, the deviations in *Hillas*-Length do not seem to be a saturationeffect of the single-pulse-extractor. In *Hillas*-Size we find more air-showers with low numbers of photons reconstructed from the back-converted time-series. This might be because the generation of the air-shower-ellipse is sensitive to electronicwhite-noise, which is not present on the back-converted time-series. The Figures 25.8, 25.9 show the air-shower-features related to time. The mean arrival-time of the largest-pulses associated with the air-shower have similar distributions with even similar substructures for both the original and back-converted timeseries. The spread of the arrival-times of the largest-pulses associated with the air-shower, see Figure 25.9, is a bit wider for the back-converted time-series. This might be either a hint for a loss in precision of the arrival-time from the backconverted time-series, see Section 25.1, or a hint for different, probably more pixels

Figure 25.3: *Hillas*-Length, the long radius of the ellipse of the air-shower. The deviation for *Hillas*-Length> $0.8 \deg$ is not understood yet.

Figure 25.4: Hillas-Width, the short radius of the ellipse of the air-shower.

Figure 25.5: *Hillas*-Distance between the center of the air-shower-ellipse and the center of the image.

Figure 25.6: Hillas-Alpha, orientation of air-shower-ellipse in the image.

Figure 25.7: Hillas-Size, number of photons reconstructed from the air-shower.

Figure 25.8: Arrival-time-mean of the largest-pulses associated with the air-shower.

Figure 25.9: Arrival-time-spread of the largest-pulses associated with the air-shower.

in the air-shower-ellipses which have a wider time-spread. Overall the similarities between the air-shower-features extracted from both time-series are very high, and we conclude that our classic reconstruction of the cosmic particle should be able to use the back-converted time-series.

Reconstructed properties of the cosmic particle

The gamma-prediction is the outcome of a machine-learner which uses the ensemble of extracted air-shower-features to estimate the properties of the cosmic particle, in this case the type of the particle. Figure 25.10 shows the gamma-prediction to have a similar distribution and confusion for the original and back-converted time-series. The machine-learner here was only trained on features extracted from the original-time-series but is found to be able to assign features from the back-converted time-series appropriately. Since this sample consists vastly out of

Figure 25.10: Gamma-prediction ranging from not a gamma-ray 0 to gamma-ray 1.

protons and not out of gamma-rays, the distribution and confusion in Figure 25.10 show a great excess for low gamma-predictions. Based on the gamma-prediction estimated from the extracted air-shower-features, FACT classifies the cosmic particle to be of type gamma-ray or not. The standard [Noethe et al., 2017] cut for the gamma-prediction is > 0.85 to be classified as a gamma-ray. Based on the claims on the detection of gamma-rays in both MAGIC and FACT, we define matching-scenarios, see Table 25.2. When counting the matching-scenarios, we can estimate the true-positive-rate and the false-positive-rate for both the events in the original time-series and the events in the back-converted time-series. Figure 25.11 shows the ratio of the true-positive-rate and the false-positive-rate for both the original and the back-converted time-series. The gamma-prediction cut parameter is varied from 0.7 to 1. For a gamma-prediction threshold of 0.85, the true-positive-rate of the original time-series is 0.515 and 0.509 for the backconverted time-series. However, the back-converted time-series reaches 0.0388 false-positive-rate while the original time-series only reaches 0.0478. This means that when we use the back-converted time-series from the photon-stream, the signal-rate of gamma-rays drops by 1%, but at the same time the background-rate of cosmic-rays drops by 23% which will be beneficial for gamma-ray-astronomy. Finally, we take a look at the reconstruction of the incident-direction of the cosmic particle. Together with the gamma-ray-prediction, the incident-direction of a cosmic particle are important to detect cosmic sources of gamma-rays. Here we follow the standard [Noethe et al., 2017] procedure to detect a cosmic source of gamma-rays with FACT. Table 25.3 and Figure 25.14 show the significance of a detection of a cosmic source of gamma-rays for both the events processed from the original time-series and the events processed from the back-converted time-series.

Number of events original back-converted overlap	trigger image-cleaning ellipse-requirements gamma-prediction ≥ 0.85 gamma-prediction < 0.85 is gamma is not gamma	scenario

Table 25.2: The four possible matching-scenarios for each simultaneously observed air-shower-event of MAGIC and FACT. Here the number of events is shown for a gamma-prediction ≥ 0.85 , see dot in Figure 25.11. 'trigger' means that these events have activated the trigger in the image-sensor of FACT. 'imagecleaning' means that after the night-sky-background was removed, these events still contained the minimal structures necessary to apply the *Hillas*-ellipse-model. 'ellipse-requirements' means that these events have air-shower-ellipses which do not leak too far out of the image and have not too many sub-structures beside the ellipse.

Figure 25.11: Receiver-Operating-Characteristic (ROC) curves for original and back-converted time-series. Here the gamma-prediction cut, see Figure 25.10 is varied from 0.7 to 1.0. The dots mark the standard gamma-prediction-cut of 0.85.

	Significance Li&Ma [Li and Ma, 1983]	$N_{\rm on}$	$N_{\rm off}$	$t_{\rm on}/t_{\rm off}$
original	14.41	750	2046	0.2
back-converted	15.58	696	1755	0.2

Table 25.3: Significance of a detection of a cosmic source of gamma-rays for both original and back-converted time-series. Higher significance is better. Intermediate results $N_{\rm on}$, $N_{\rm off}$ are treated according to the standard [Noethe et al., 2017] procedure for detection of cosmic sources of gamma-rays with FACT. Figure 25.14 shows the reconstructed directions of the cosmic particle which are the basis for the significance of the detection of a source.

Figure 25.12: Gamma-ray-energy reconstructed by MAGIC for *truepositive* events in Table 25.2.

Figure 25.13: Gamma-ray-energy reconstructed by MAGIC for *falsenegative* events in Table 25.2.

Summary on back-conversion

We conclude that the back-converted time-series from the photon-stream contain the information for gamma-ray-astronomy that is relevant to our established extraction of air-shower-features from largest-pulses. The drop in false-positive-rate with the back-converted time-series in contrast to the original time-series makes the back-converted time-series from the photon-stream even preferable as the observations are dominated by cosmic-rays by ≈ 3 orders-of-magnitude. Figure 25.11 shows a gain in 'area under the ROC curve' for the back-converted timeseries across the whole relevant space of gamma-prediction cuts. As a result we find that the significance to detect a cosmic source of gamma-rays increases when using the back-converted time-series from the photon-stream, see Table 25.3. The Figures 25.12 and 25.13 show that the reconstruction-performance from both the original and the back-converted time-series follow a similar dependency of the energy. For true-positive gamma-rays in Figure 25.12, the back-converted timeseries offer slightly better performance for energies below 1 TeV. Such a good reproduction of air-shower-features, yet even an indication for a gain in the power to detect gamma-rays are not anticipated when keeping in mind that the backconverted time-series from the photon-stream is just an emulation of the original time-series.

However, the single-photon-extractor is first of all a filter. We suspect that the filtering of the single-photon-extractor, which only passes on signals which can be represented by adding up single-pulses, is beneficial for the established classification of Cherenkov-photons on largest-pulses. During the development we found a strong rejection-power of our single-photon-extractor to artifacts as e.g a sinusoidal resonances which occurs occasionally on the original time-series of FACT (See 'ringing', [Vogler, 2017]). Further, our established classification of

Figure 25.14: Great-circle-distance θ between the reconstructed position of the cosmic source and the true position of the source 'on'. As well as distance θ between the reconstructed and a false position of the source 'off'. When counting the events in both 'on' and 'off' regions, the significance of the detection can be estimated [Noethe et al., 2017]. Upper graph shows θ for the original time-series, and the lower graph shows θ for the back-converted time-series. Vertical and dashed line at $\theta^2 = 0.03 \text{ deg}^2$ marks the border of on- and off-regions.

Figure 25.15: The flux $F_{\text{night-sky-background}}$ of night-sky-background-photons observed with the sky-quality-meter [Birriel and Adkins, 2010] of FACT. Even though FACT observes during strong moon-light, the majority of the observations is done during dark nights.

Cherenkov-photons on largest-pulses uses statistical estimators which are biased like a search for the maximum. These biased estimators profit from the lack of electronic-noise on the back-converted time-series in contrast to the original timeseries which has electronic-noise.

Finally, we want to stress again that this crosscheck does not show the full potential of the photon-stream. This crosscheck only shows that the photon-stream contains at least the information for gamma-ray-astronomy which is relevant to our established methods based on the representation of air-shower-events using largest-pulses.

25.3 Saturation

As mentioned in Section 25.1, we expect our single-photon-extractor to miss photons when the rate of photons becomes too high. For the first implementation of the single-photon-extractor we focused on a good arrival-time resolution for single-photons during low fluxes of night-sky-background-photons. Figure 25.15 shows how often FACT observes during different fluxes of night-sky-backgroundphotons. The typical flux of night-sky-background-photons is $F_{\text{dark-night}}$ and corresponds to a surface-brightness of $\approx 21 \,\mathrm{mag/arcsec^2}$. Figure 25.16 shows how much current is flowing through the GAPDs in an SiPM-pixel for different fluxes of photons. Figure 25.16 shows that the current through the SiPMs does not saturate in the relevant range of fluxes of night-sky-background-photons. The current flowing through the SiPMs in FACT is rather proportional to the flux of night-sky-background-photons. Figure 25.17 shows that the rate of extracted photons correlates with the flux of night-sky-background-photons and is rather proportional in the range of fluxes of night-sky-background-photons which are most common on FACT. All Figures 25.15, 25.16, and 25.17 are based on the

Figure 25.16: The current released in the GAPDs of the SiPMs used in FACT is proportional to the flux of night-sky-background-photons observed by the skyquality-meter of FACT.

Figure 25.17: The rate of extracted photons from a time-series of a pixel in FACT correlates with the flux of night-sky-background-photons, but is not exactly proportional. The higher the flux of photons, the more photons are missed by our single-photon-extractor.

same sample which spans the time from July 2014 to September 2016. Each entry for the rate of extracted photons is estimated for a time-window of 5 min and is without the Cherenkov-photons.

We find that our single-photon-extractor misses more and more photons when the flux of photons increases. We find the saturation takes place in our singlephoton-extractor since the current released by the SiPMs does not show such a saturation. However, our first implementation of the single-photon-extractor extracts photons sufficiently proportional to the flux of photons. Especially in the range of fluxes of night-sky-background-photons from 1 to $3 \times F_{dark-night}$, where FACT observes most, our single-photon-extractor responses proportional to the flux of photons. Up to fluxes of $8 \times F_{dark-night}$, we do not see a hard limit of saturation of our single-photon-extractor yet.

Classifying Cherenkov-photons

Cherenkov-photons from one specific air-shower are likely to have similar incidentdirections and arrival-times as they are produced in a limited volume in the atmosphere and as they reach the ground almost at the same time. Nightsky-background-photons on the other hand are present all the time. And, with the exception of starlight, night-sky-background-photons have random incidentdirections. Here we try to take advantage of the photon-stream-representation to classify Cherenkov-photons. In this first attempt, we use solely the density of photons in the three-dimensional space of observables in the photon-stream.

We will first propose how to express the density of photons in the photon-stream, and second we will discuss an established algorithm which we find to be well suited for finding dense clusters of Cherenkov-photons within the pool of nightsky-background-photons.

26.1 Density in the photon-stream

The three-dimensional space of the photon-stream mixes incident-directions c_x , c_y , and arrival-time t. Therefore it is not obvious how to express a distance $d_{i,j}$ in the photon-stream between two photons i and j. To express the density of photons in the photon-stream, we have to introduce a metric which e.g. scales the time-axis to mediate between incident-directions and arrival-time. In our implementation for FACT, we define

$$c_t = \alpha t \tag{26.1}$$

and choose the scaling of the time-axis

$$\alpha = 0.35 \times 10^9 \frac{\text{Deg}}{\text{s}} \tag{26.2}$$

such that the one-dimensional density of photons in the scaled space of c_x, c_y , and c_t is the same along all three axes for a typical rate of photons arriving during a dark night. Depending whether one wants to prefer or penalize the coincidence

among incident-directions over the coincidence among arrival-times, one can alter the scaling α accordingly. With the scaling we define

$$d_{i,j} = \sqrt{(c_x^i - c_x^j)^2 + (c_y^i - c_y^j)^2 + (c_t^i - c_t^j)^2}$$
(26.3)

to be the distance between two photons i, and j. Figure 26.1 shows an example air-shower-event with the axes c_x , c_y , and c_t to scale.

26.2 DBSCAN Algorithm

We find that the 'density based algorithm for discovering clusters with noise' (DBSCAN [Ester et al., 1996]) is well suited to identify dense clusters of photons in the three-dimensional space of observables in the photon-stream ¹. Here we briefly describe DBSCAN from the photon-stream and Cherenkov-telescope point-of-view.

DBSCAN assigns each photon in the stream either to a cluster of dense Cherenkovphotons, or to the night-sky-background-photons. DBSCAN can identify multiple dense clusters of Cherenkov-photons at once, and makes no assumptions on the shape of the clusters. DBSCAN has only two parameters. First, there is the minimal number of photons m a dense cluster of Cherenkov-photons must have. On FACT we found m = 20 to be a decent first choice. Second, there is the maximum distance ϵ between each two photons which must not be exceeded for each two photons to be considered to be dense. On FACT, where we decided to express the time t using the scaled c_t , we found $\epsilon = 0.45^\circ$ to be a decent choice. The algorithm is split into two repeating processes. First, there is cluster-discovery which loops over the photons until it finds a photon which has at least m photons in its neighborhood of radius ϵ . Then second, there is cluster-expansion which adds photons to the newly discovered cluster when these photons are either directly density-reachable with respect to m and ϵ , or when these photons can be reached via a chain of photons in the cluster which are directly density-reachable. When all directly reachable, and iteratively reachable photons have been added to the cluster, the cluster-discovery starts again on the photons which are not yet assigned to a cluster. When all photons where looped, the photons which do not belong to a dense cluster are defined to be night-sky-background-photons. See Figure 26.2 to see two dense clusters of photons discovered by DBSCAN in an example event in the representation of the photon-stream.

 $^{^{1}\}mathrm{In}$ FACT we use the DBSCAN implementation of the scientific-python-kit [Pedregosa et al., 2011].

Figure 26.1: Two-dimensional projection of the photon-stream onto c_x and c_t on the left, and c_y and c_t on the right. The c_t -axis is scaled accordingly to Equation 26.1. Here, the distances in c_x , and c_y have the same importance as the distances in c_t . This is the same air-shower-event as shown in Figures 21.4, 23.1 and 26.2.

Figure 26.2: The air-shower-classification based on density identified two clusters in the photon-stream. The larger cluster is blue, and the smaller cluster is red. In the established classification of Cherenkov-photons using the representation of largest-pulses and image-cleaning, such separate clusters were often called 'islands'. This is the same air-shower-event as shown in Figures 21.4, and 23.1.

26.3 Summary

We propose to classify Cherenkov-photons in the photon-stream with the DB-SCAN algorithm. DBSCAN has a concept of background, and can discover multiple dense clusters. The classification of Cherenkov-photons in the photon-stream with DBSCAN depends only on three parameters. First, the scaling α between the axes in the photon-stream. Second, the minimum number m of photons in a cluster. And third, the maximum distance ϵ between two photons to be considered to be dense.

Performance of classification

We evaluate simulated air-shower-events of FACT to compare the performance of the classification of Cherenkov-photons. We compare the classification of Cherenkov-photons in the photon-stream based on density with the established classification of Cherenkov-photons based on image-cleaning on largest-pulses. Both methods use the density of photons in the space of observables c_x , c_y , and tto classify Cherenkov-photons. However, the established classification on largestpulses with image-cleaning has multiple and consecutive stages where in each stage only a sub-set of the observables is taken into account. Typically first a stage in time t, second a stage in incident directions c_x , and c_y , and third again a stage in time t. Our novel classification in the photon-stream on the other hand has only one single stage where all observables are taken into account at once. Here we will first introduce a measure of performance to discuss the performance

of the two methods in a quantitative way. Second, we will outline the procedure of the simulation of the air-shower-events. Third, we will briefly describe our implementations of the two methods. And fourth, we will show the resulting classification of Cherenkov-photons in example events, and discuss the results based on a sample of simulated air-shower-events which is representative for the observations of FACT.

27.1 Measure of performance on images

We estimate the performance of the classification of Cherenkov-photons by comparing the set of photons which was classified to be Cherenkov-photons with the set of true Cherenkov-photons. For simplicity, we compare images of photonintensities. An image of photon-intensities is a vector I of photon-intensities for all pixels. An image of photon-intensities has as many dimensions as there are pixels, which is dim $(I_{\text{FACT}}) = 1440$ in the case of FACT. Images of photonintensities are easy to visualize, see Figures 21.4, and are currently the basis of the generation of air-shower-features like the Hillas-features. However, images of photon-intensities alone neglect the time-structure of the air-shower. For each event we create three images. First, we create an image of the true Cherenkovphotons. Second, we create an image of the Cherenkov-photons classified in the photon-stream using clustering based on density. And third, we create an image of the Cherenkov-photons classified on largest-pulses using image-cleaning. We quantify the performance of the reconstruction of the Cherenkov-photons using two performance-measures. First we use the angle

$$\delta_{1,2} = \arccos\left(\frac{I_1 \cdot I_2}{\|I_1\| \|I_2\|}\right)$$
 (27.1)

between the images I_1 and I_2 to compare the structure in the images independently of the intensity. Second, we use the euclidean distance

$$D_{1,2} = ||I_1 - I_2|| \tag{27.2}$$

between the images I_1 and I_2 to compare the overall similarity. The smaller the angle $\delta_{\text{reconstructed, true}}$ and the smaller the distance $D_{\text{reconstructed, true}}$ are between a true image of the air-shower I_{true} and a reconstructed image of the air-shower $I_{\text{reconstructed}}$, the higher is the performance of the reconstruction.

27.2 Procedure of the simulation

We simulate the observation of air-showers on the FACT telescope. For airshowers which are bright enough to trigger the telescope, we take the true arrivaltimes of photons detected in the image-sensor. In the simulation, we know whether a photon originated from the air-shower or from the night-sky-background. The arrival-times of the these photons can be represented in two three-dimensional point-clouds, see Figure 27.1. From the arrival times of the photons, we emulate the electric response of the image-sensor. For each pixel we emulate the timeseries of the response of the photo-sensor, compare section 25.2. From these emulated representation of the air-shower-event using time-series, we proceed in two branches. First, we run the established [Noethe et al., 2017] reconstruction for air-showers of FACT which describes the photons using largest-pulses and classifies Cherenkov-photons in multiple, separate stages of density clustering along different dimensions of observables. And second we run the novel reconstruction for air-showers based on the photon-stream which reconstructs the arrival-times of single-photons with our single-photon-extractor, and classifies Cherenkov-photons in a single stage based on the density in the photon-stream.

27.3 Classification on the largest-pulses

We use the standard [Noethe et al., 2017] classification for Cherenkov-photons in FACT. In the implementation of FACT, the classification of Cherenkov-photons

Figure 27.1: Simulated telescope response. The true arrival-times t of both nightsky-background-photons (red), and Cherenkov-photons (blue) across the imageplane in c_x and c_y . Black ring illustrates the telescope's field-of-view.

on largest-pulses is split into three stages. In the first stage, largest-pulses are identified on the time-series of each pixel individually, which corresponds to a search of high photon-density along the dimension of time t. In the second stage, the photon-equivalents of the largest-pulses are compared with the photonequivalents of the largest-pulses found in neighboring pixels to identify regions of high photon-density in the dimensions of the incident-directions c_x , and c_y . In the implementation for FACT, pixels with photon-equivalents above a threshold of 5.5 p.e., and neighboring pixels with photon-equivalents above a threshold of 3 p.e. are declared to be candidates for pixels containing the Cherenkov-photons. Other implementations might set the thresholds for the pixels dynamically based on the variance of the occurrence of night-sky-background-photons [Krawczynski et al., 2006]. In the third stage, the arrival-times of the largest-pulses are taken into account to reject candidate-pixels which have largest-pulses arriving more than 10 ns off the median arrival-time of the largest-pulses of all the candidatepixels [Aliu et al., 2009]. The combination of the second and the third stage are often called image-cleaning. Figure 21.4 shows the full input of information to the image-cleaning on largest-pulses used in FACT. Finally, we create an image of photon-intensities only from those largest-pulses which are considered to contain Cherenkov-photons as they passed the cleaning of the image.

27.4 Classification in the photon-stream

From the time-series of each pixel, we extract single-pulses, as shown in Chapter 24. On the resulting photon-stream we run the clustering based on density, see Chapter 26, to classify Cherenkov-photons and night-sky-background-photons. Finally, we project the cluster of Cherenkov-photons into the plane of incident-directions to have an image of the photon-intensities associated with the air-shower.

Table 27.1: Performance of the classification of Cherenkov-photons. Comparing air-shower-classification on largest-pulses and in the photon-stream. Compare Figures 27.2, 27.3, 27.4, and 27.5.

27.5 Results

For FACT, the performance of the classification of Cherenkov-photons in the photon-stream turns out to be clearly superior to the classification of Cherenkovphotons on largest-pulses. This can be found in two ways. First, the clustering based on density in the photon-stream finds much more air-showers for the same measures of performance δ and D, see Table 27.1 and the Figures 27.2, and 27.3. Second, for the air-showers which are both found on largest-pulses and in the photon-stream, the air-showers of the photon-stream have much better measures of performance, as shown in Table 27.1 and the Figures 27.4, and 27.5. The Figures 27.6, 27.7, 27.8, 27.9, and 27.10 show examples of air-shower-events used in the comparison. Each row in the figures shows the three images of the same air-shower-event simulated on FACT. The middle image shows the true Cherenkov-photons. The image on the right shows the reconstructed Cherenkovphotons using largest-pulses, and the image on the left shows the reconstructed Cherenkov-photons using the photon-stream. Below each image of reconstructed Cherenkov-photons, the measures of performance δ and D are written. For airshower-events with a high intensities of Cherenkov-photons, the performance of the classification on largest-pulses comes close to the performance of the classification in the photon-stream, see Figures 27.6, and 27.7. However, when the intensity of the Cherenkov-photons is low, the classification in the photon-stream is superior, see Figures 27.8, 27.9, and 27.10. Since gamma-rays create higher

Figure 27.2: Gamma-rays. Density-clustering in the photon-stream finds 63% more air-showers with same or even better distributions of performance-measures δ and D. See Table 27.1.

Figure 27.3: Protons. Density-clustering in the photon-stream finds 126% more air-showers with same or even better distributions of performance-measures δ and D. See Table 27.1.

Figure 27.4: Overlap, air-showers found by both methods Gamma-rays. See Table 27.1.

Figure 27.5: Overlap, air-showers found by both methods. Protons. See Table 27.1.

densities of Cherenkov-photons in the images than protons [Badran and Weekes, 1997], the classification in the photon-stream finds 126% more proton-events, but only 63% more gamma-ray-events than the classification on largest-pulses with image-cleaning, see Table 27.1. To take advantage of the improvement in classifying Cherenkov-photons, the reconstruction of the properties of the cosmic particle (direction, energy, and type) will most likely have to be adjusted. Therefore, although the benefits of the photon-stream for the reconstruction of Cherenkov-photons is undeniable, the gain in performance for gamma-ray-astronomy can not be estimated from this investigation alone.

Figure 27.6: Middle is simulation truth, left is density-clustering in photonstream, right is two-level-time-neighbor-cleaning on largest-pulses. Rare but intense (> 100 air-shower photons) gamma-rays on FACT.

Figure 27.9: Additional typical gamma-rays, same as Figure 27.8.

Figure 27.10: Typical cosmic protons close to the trigger threshold.

A first test on muons

Relativistic muons which come close to the telescope can produce a ring like distribution of photons in the images. We find about 10 k events/night in the observations of FACT which show structures with the shape of a ring or the segment of a ring. Events induced by muons on a small telescope like FACT are a tough test for any classification of Cherenkov-photons. The directional density of photons from the muon is only a low ≈ 2.3 photons/pixel, and thus makes muons difficult to find in the presence of night-sky-background-photons. Muons allow us to test the limits of the photon-stream on observations of FACT. We will first discuss the origin of the rings in the air-shower-events and why we call such events 'muon-events'. Second, we will present our algorithm to find muon-events in the photon-stream of FACT. Third, we will show and discuss examples of muon-events, and we will show side-by-side the Cherenkov-photons found in the photon-stream with clustering, and the photons found on largest-pulses with image-cleaning.

28.1 Origin of muon-events

When faster than the local speed of light, any charged particle in the air-shower emits Cherenkov-photons. These Cherenkov-photons are emitted in a cone with a radial symmetry relative to the trajectory of the charged particle. The openingangle of this cone depends on the speed of the charged particle and the refractiveindex of the air the particle is traversing. Opening-angles observed on FACT range from $\approx 0.45^{\circ}$ up to 1.6° . To see a large part of the ring, the charged particle must be close to the telescope. At the typical opening-angle of 1.1° , the charged particle must be closer than ≈ 105 m to FACT to create full ring structures in the image. When the imaging-reflector maps the directions of the photons onto the image-sensor, a sharp ring structure emerges. Since muons are the most likely charged particles to come close to the telescope, we assume that all events with a ring-structure are caused by muons. Therefore we call such events 'muon-events' although every isolated, charged particle will induce the same ring-structures.

Max. trails of RANSAC	15
Max. stddev. of arrival-times of the photons	$5\mathrm{ns}$
Min. radius of ring	0.45°
Max. radius of ring	1.6°
Min. part of photons to agree with the ring	60%
Min. areal overlap of ring and the field-of-view	20%
Min. circumference of ring in the field-of-view	1.5°

Table 28.1: Criteria for muon-events.

28.2 Algorithm

We start with the observed air-shower-event represented in the photon-stream. First, we classify Cherenkov-photons and night-sky-background-photons based on the density in the photon-stream as shown in Chapter 26. We drop all nightsky-background-photons and continue only with the dense Cherenkov-photons. When multiple dense clusters of Cherenkov-photons were found, we combine these clusters into one cluster for simplicity¹. Second, we fit the model of a ring to the distribution of Cherenkov-photons in the three-dimensional space of the photonstream. For resistance against outliers, we use the Random-Sample-Consensus (RANSAC) [Pedregosa et al., 2011] algorithm to fit the model of the ring. Third, we assert that the model of the ring fulfills the criteria listed in Table 28.1.

28.3 Results

The Figures 28.1, 28.2, 28.3, 28.4, and 28.5 show the examples of muon-events which were found in the photon-stream of FACT. Each figure has five panels. The two panels on the top show the event represented in largest-pulses. The central panel shows the event represented in the photon-stream, and the photons are colored based on the density-clustering. Gray photons are classified to the nightsky-background, and blue photons are classified to the muon. The two panels at the bottom show the photons which were classified to the muon. First, in the left panel at the bottom is the projection of the photons in the c_x - c_y -plane of the photon-stream. The red ring was found with our RANSAC ring-model. Second, in the right panel at the bottom is the result of our standard [Noethe et al., 2017] image-cleaning algorithm on the largest-pulses.

We find that muons can be detected very well in the photon-stream of FACT with a classification of Cherenkov-photons based on density. We find that the ring of the muons is reconstructed better in the photon-stream, and conclude that this is a hint for the photon-stream to perform better in the classification of Cherenkov-photons.

 $^{^{1}}$ This is not optimal, and we loose muon-events where the air-shower itself is within the photon-stream as a dense, central and late cluster.

For FACT, the search for muons is important. On a Cherenkov-telescope which observes mono without other Cherenkov-telescopes which could rise a veto, muonevents have to be identified and rejected in the search for gamma-rays. Also muon-events can serve as a powerful calibration-device. With the photon-stream we have produced the largest sample of muon-events which was ever found on FACT. The muon-sample in the photon-stream has over 18×10^6 muons. It is the first sample of muon-events which spans all epochs of FACT.

Outlook

Future Cherenkov-telescopes might be build more cost effective and may output the photon-stream directly. For FACT, we process the photon-stream on a multi purpose computer after the analog time-series of the pixels have been recorded. But for future Cherenkov-telescopes we see the potential to lower the cost of read-out-electronics dramatically. Instead of recording analog time-series of SiPMs, we propose to not record analog time-series at all. We propose to drop all analog amplifiers, analog ring-buffers, and analog-to-digital-converters which are currently used in the image-sensors of Cherenkov-telescopes. We propose to start over directly at the GAPDs where the initial electric responses to the photons are produced. We propose to use a surface-array of N GAPDs, as classic SiPMs do, to receive photons. But this time we do not connect the GAPDs in parallel. Instead we connect each GAPD to a Schmitt-trigger. We adjust the Schmitt-trigger so that it creates digital pulses of a defined amplitude when its GAPD discharges. Then we clock all N outputs of the Schmitt-triggers into the (N,M) parallel-counter [Swartzlander, 2004]. Each GAPD-discharge causes input of the parallel-counter to be only high for a single clock. The M outputs of the parallel-counter represent the M digits of a binary number counting the number of GAPDs which have released a pulse. We copy the binary number at the output of the parallel-counter at a fixed, and clocked rate of e.g. $10^9 \,\mathrm{s}^{-1}$ into a digital memory-buffer such as a shift-register. We do this for each pixel in the image-sensor. Now we have the photon-stream in a digital memory-buffer in our image-sensor. There will be no need for costly high bandwidth electronics to process analog signals. Figure 29.1 shows a draft of our proposed SiPM Previous studies [Catalano et al., 2008] already pointed out the benedesign. fits of a digital representation of the air-shower-events with single-photons and proposed to shrink the size of the pixels while increasing their number to reach the necessary single-photon-resolution. Our proposal takes this previous study to the extremes by reading out each GAPD in the SiPM-pixel individually, but in contrast to this previous study we do not propose to increase the number of pixels and read-out-electronics but to condense the arrivals of single-photons in the parallel-counter of each SiPM-pixel to reduce the costs. In computer science,

Figure 29.1: Draft of our proposed SiPM design to output the photon-stream directly. On the left is the GAPD-array, compare Figure 22.2. All GAPDs have individual bias-supplies as implemented here [Frach et al., 2009]. Right of the GAPDs are the Schmitt-triggers which serve as amplifiers to reach bias-levels for digital processing. The logic for clocking the individual GAPDs into the parallel-counter is omitted here. When individual GAPDs are faulty and have high rates of accidental discharges, adjustments of the Schmitt-trigger thresholds can exclude these SiPMs, similar as demonstrated here [Frach et al., 2009]. Right of the array of GAPDs is the parallel-counter. The parallel-counter here is constructed from a tree of 11 full-adders (FA). Figure of parallel-counter is taken from [Swartzlander, 1973]. This particular SiPM has only N = 15 GAPDs and M = 4 bit outputwidth for simplicity. Actual SiPMs for Cherenkov-telescopes will have N > 1 k GAPDs. Also, actual parallel-counters might need buffers after each stage in order to be clocked at speed of $\approx 10^9 \text{s}^{-1}$. Such buffers are omitted in this figure.

Figure 29.2: The prototype schematics for a digital SiPM with integrated parallelcounter, by Jean-Francois Pratte and Fabrice Retiere [Jean-Francois and Retiere, 2017]. Here Single-Photon-Avalanche-Diode (SPAD) is the same what we use to call GAPD. It is reported, that prototype SiPMs were already build and are under evaluation. An arrival-time resolution < 1 ns is reported for the prototype SiPMs. This SiPM has 1 cm^2 photon-aperture, and was developed for the nEXO experiment which will cover a surface of 4 m^2 with these SiPMs. See the great similarity with our proposal in Figure 29.1.

our current implementation of recording time-series and later using analog to digital converters is known to be a possible implementation of a parallel-counter called the 'quasi-digital-counter' (See section 2.5, [Swartzlander, 2004]). Other users of SiPMs have also realized that the true potential of SiPMs goes way beyond PMTs when they are combined with dedicated electronics on the chip of the SiPM directly [Frach et al., 2009]. Our colleagues in particle-physics have a similar need for digital SiPM with $\approx 10^9$ Hz bandwidth and started developing first prototypes [Jean-Francois and Retiere, 2017] which are very similar to our proposal in Figure 29.1. Their advanced prototype of a digital SiPM is reported to cost $\approx 2 \times 10^6$ USD m⁻² which results in $\approx 26 \times 10^3$ USD for the sensitive area used in the image-sensor of FACT. The cost of the image-sensor including the read-out for the FACT prototype was $\approx 0.5 \times 10^6$ USD. Given the omission of the costly routing and processing of analog signals, there is valid hope to reduce the cost of the FACT's image-sensor by one order-of-magnitude when using digital SiPMs with integrated parallel-counters.

We propose to team up with the SiPM-experts [Jean-Francois and Retiere, 2017] and create a dedicated SiPM for Cherenkov-telescopes to build inexpensive and powerful Cherenkov-telescopes which output the photon-stream directly.

29.1 Outlook for FACT

We provide access to all simulated events of FACT in photon-stream-representation to the general public. We provide access to a sample of observations of FACT of the Crab-Nebula from November 2013 in photon-stream-representation to the general public. To the members of the FACT-collaboration we provide access to all¹ observed events of FACT in photon-stream-representation. We automatically add the latest observed events in photon-stream-representation. We allow the members of FACT to access our events without the need for accounts on specific computing-sites, which is a novelty. Go and visit

http://fact-project.org/photon-stream

to access the photon-stream of FACT. We implemented a format for storage and exchange of the photon-stream and implemented readers and writers in different programming languages. See the appendix in Chapter 31 for details on the implementation and a brief discussion on 'Known Limitations and Outlook'. Because of the accessibility, the photon-stream already contributes to projects

within the FACT-collaboration beside the activities of the author of this thesis. For the very immediate outlook on the photon-stream in FACT, here are a few projects which investigate the photon-stream and its possible benefits for gamma-ray-astronomy:

- Kevin Sedlaczek investigates the advantages of the additional timing information in the photon-stream for gamma-ray-astronomy. In his masterthesis, Kevin uses both simulations and observations of FACT in the photonstream-representation to improve the sensitivity to gamma-rays of the Crab-Nebula.
- Jan Moritz Behnken submitted a bachelor-thesis on the prospects of using machine-learning with deep neural-networks to reconstruct the particle-type from air-shower-events. He used the observations and simulations of FACT represented with the photon-stream.
- Dorothee Hildebrand, and Adrian Biland investigate muon-events to crosscheck novel methods for monitoring the production-efficiency of Cherenkovphotons in the atmosphere [Hildebrand et al., 2017] and a possible aging of the SiPMs in FACT. The muon-events were found in the photon-stream for FACT using the methods presented in Chapter 28.
- Kai Bruegge investigates the performance of observing gamma-rays with the novel photon-stream by implementing the generation of novel features from the photon-stream in his doctoral-thesis.

 $^{^1\}mathrm{About}~80\%$ of the time spent on this thesis was spent here. The computation of the fourth and final production-pass itself took 8 month.
- Jacob Bieker investigates to improve the reconstruction of the direction of the cosmic particles using machine-learning and the photon-stream for FACT in his bachelor-thesis.
- Amandeep Singh uses the photon-stream to investigate the rates of different photon-multiplicities to search for correlations with properties of the atmosphere, compare Figure 22.8.
- Laurits Tani uses the muon-sample in the photon-stream representation. In his master-thesis, he investigates how FACT's optical point-spread-function changes over time based on the sharpness of muon-rings.

Chapter 30

Conclusion

We have proposed to lower the energy-threshold of Cherenkov-telescopes for gamma-rays by improving the classification of Cherenkov-photons due to the use of a natural representation of air-shower-events which describes general observables of photons instead of describing special responses of special sensors. We have implemented such a natural representation for air-shower-events for FACT and called it the photon-stream. Based on simulations of FACT, we have shown that a density-based classification of Cherenkov-photons in the photon-stream is superior to the established classification of Cherenkov-photons in multiple stages on the largest-pulses. We have shown that no information relevant for gammaray-astronomy is lost when we use the photon-stream instead of the largest-pulses to represent the air-shower-events of FACT. We have proposed a design of an SiPM which allows to implement image-sensors for Cherenkov-telescopes without costly analog electronics, but with wide spread digital components which output the photon-stream directly.

We conclude that the photon-stream representation for air-shower-events has only benefits over the established representation of largest-pulses. The photon-stream contains more information and is easier to explain¹. The photon-stream is the most natural representation to store, exchange, and process air-shower-events within and among Cherenkov-telescopes.

30.1 Conclusion for FACT

Before the photon-stream was implemented, air-shower-events of FACT were only accessible in a representation of the raw time-series of all pixels. The raw representation using the time-series of all pixels is great to investigate the novel SiPMs in combination with the read-out of the image-sensor. Possible aging of the image-sensor, and artifacts can be investigated in great detail this way.

¹Largest-pulses need two concepts to be explained. First arrival-time, and second photonequivalent. The photon-stream has only one concept, which is arrival-time. Also largest-pulses can not be explained without explaining the specific photo-sensor and read-out-electronics which is used.

However, the raw representation of air-shower-events with time-series is very inefficient in storage-size and thus inefficient to do gamma-ray-astronomy. Since easy gamma-ray-astronomy was not the goal of FACT, no format was implemented to store the representation of largest-pulses permanently for easy and compact access. Some private studies in FACT do gamma-ray-astronomy by permanently storing the air-shower-events represented by their Hillas-features, but these private storages are difficult to access.

The photon-stream for FACT is two orders-of-magnitude more compact in storagesize than the raw representation of air-shower-events with time-series even when we apply our own dedicated compression [Ahnen et al., 2015] to the time-series. Instead of ≈ 800 TBytes of raw events, which are scattered over several physical storage units on several remote computing-sites, the photon-stream is only ≈ 8 TBytes in storage size for all simulations and observations ever done with FACT. The entire photon-stream for FACT can be stored on a single consumer storage unit in a single computer while it contains at least all the information for gamma-ray-astronomy that is relevant to our established analysis-chain based on largest-pulses and Hillas-features, see Section 25.2. The photon-stream for FACT is accessible on a web-server to all members of FACT and partly the photon-stream is even accessible to the general public. Now that the initial phase of demonstration is over for FACT, and the novel SiPMs are well understood, the photon-stream pushes the capability of FACT and its members to focus on gamma-ray-astronomy.

Chapter 31

Implementing the photon-stream

This is the read-me of our photon-stream repository. FACT specific aspects and key implementation aspects are outlined here.

thrown_events = pd.DataFrame(sim_reader.thrown_events())

Rationale

As a technology demonstrator, the FACT telescope records its observations in a format which is close to the read out hardware. This was a great choice to explore the novel SiPM and DRS4 readout chain, but turns out to be tedious to do astronomy as the raw events are rather bulky, full of artifacts and not calibrated. The raw events are 1440 pixels X 300 time slices X 16 bit dynamic range = 864kB in size. The raw events can not be analyzed independent of each other (readout artifacts) and further need additional calibration files, which are not straight forward to identify. Although effort was spent to compress the raw events with our dedicated zfits format, the events from 2011 to 2017 still need >500TB of disk storage. The years passed by and FACT is not longer a demonstrator, but a part of high energy gamma-ray astronomy. It is time to access and analyze our observations in an easier way. It is time for a physics format.

The photon-stream can compress FACT events down to a size of 2.7kB for dark nights. Based on this, the idea was born to create a no compromise, physics only file format with the potential to fit all events of FACT onto a single hard disk drive of 10TB. The photon-stream format is already calibrated and thus does not need additional files to be interpreted. Known instrument artifacts have been removed from the photon-stream and the events are now independent of each other.

The photon-stream format is intended to do **astronomy**. We believe that astronomy can only proceed when access to the observations is easy. We want to enable a Bachelor student to analyze years of FACT observations on her notebook! We want to enable students to transfer 5 min of FACT observations via email. We want to give students something that they are familiar with, i.e. the concept of single photons. Everybody knows single photons. But only established IACT experts know the concept of 'main-pulses' which carry 'photon equivalents', know readout calibration and artifact mayhem. We want to keep the air-shower physics and even gain additional timing knowledge which was not accessible with the established 'main-pulse' representation which is still a heritage of our PMT based ancestors. Finally, we want to reveal for the first time the true potential of an SiPM based IACT. This is the photon-stream.

Storage

We offer two storage formats. First the Json-Lines format, and second a dedicated binary format. Json-Lines is excellent to share data with colleagues or new students. Json is human readable and fortunately surprisingly efficient to store the photonstream. Many programming languages can read and write Json. Our dedicated binary format phs is fast to read and write, and it is only about 2/3 of the Json size.

Json-Lines

Json-Lines is a text file where each line is a valid Json object. Json turned out to store our photon-stream efficiently. Here we see one example event:

{"Night":20170119, "Run":229, "Event":1, "UnixTime_s_us":[1484895178,532244], "Trigger":4, "Az_deg":-63.25366479

Json-Lines run files are named YYYYmmnn_RR.phs.jsonl.gz . There is no run header. Each line in a phs.jsonl.gz file corresponds to one event. This way events can be concatenated and counted very easily.

Keys

"Night":YYYYmmnn

The FACT night integer. Here YYYY is the year A.D., mm is the month, and nn is the night of the observation. A night is different from a day. The night integer increases to the next night during 12:00 UTC o'clock rather than 00:00 UTC. The night integer is always 8 digits, e.g. 20170201 which is first of February 2017.

"Run":RRR

The unique run identifier of a night. The observations of a night are split into runs of usually 5 minutes. Since not all runs are observation runs, but e.g. calibration runs, the run identifiers in the high level photon-stream format are not necessary continuous, since calibration runs are missing. The run integer in the file name is always 3 digits, e.g. 20170201_021.phs.jsonl.gz is the twenty first run of the first night in February 2017.

"Event":eee

The event identifier of a run. In a run, the individual events have unique identifiers. The event integer is not fixed in its length e.g. "Event":4 is the fourth event in a run, and "Event":34845 is the thirty-four-thousands-and-eight-hundreds-forty-fifth event in a run.

"UnixTime_s_us":[1484895178,532244]

The moment when the event was recorded in unix time (keep in mind that unix time has leap seconds!). The first entry in the the array are the unix time seconds s, and the second entry are the additional micro seconds us.

double event_time = 1484895178.0 + 1e-6 * 532244.0

The time stamp is out of the FACT event builder program and can be off the actual trigger time by about 30ms. For high precision timing in the 5us range, the GPS time is needed, which unfortunately is not yet available.

"Trigger":xxxx

The trigger type of the FACT telescope. There are different trigger types for FACT, here in the high level format we only have left:

- 4: The self triggered mode, also called "physics trigger". These events are expected to contain light flashes and air showers.
- 1: External trigger input 1. Here the GPS module triggers the read out 59 times a minute. These events are expected to contain only night-sky-background.
- 2: External trigger input 2. The same as external trigger input 1, since the GPS module was switched from 1 to 2 once.
- 1024: A random trigger also called "pedestal trigger". These events are also expected to only contain nightsky-background.

For a full overview of the FACT trigger types, see the Phd of Patrick Vogler, table 4.3.b

"Az_deg":-63.253664797474336,"Zd_deg":33.06900475126648

The pointing direction of the FACT telescope in the moment the event was recorded. This is reconstructed from the aux (auxiliary) drive files based on the event time. " Az_deg " is the azimuth pointing in degrees, and " Zd_deg " is the zenith distance pointing in degrees.

"PhotonArrivals_500ps":[[],[],[]]

The actual photon-stream. A list of lists of arrival times of photons in units of 500ps. The outer list loops over all 1440 pixels of FACT and is ordered in Continuous Hardware ID (CHID). The inner lists loop over the arrival times of the individual photons for the corresponding pixel. The maximum number of photons in a pixel before the extraction of photons is aborted is 500. If there are 500 photons in a pixel, this pixel is saturated and meaningless. Since a single photon is now defined by only one sharp arrival time in contrast to a very long pulse, there is no need anymore to stick to a long region of interest in time and therefore the output of the photon-stream is truncated only to the region where the air-shower physics takes place, which is from 15ns to 65ns (I hardly ever saw air shower events beyond 45ns) on FACT's raw ROI of 150ns. So each event has an exposure time of 50ns. If you have any uncomfortable feelings about this truncation then let me remind you of the physics results which come out of the MAGIC telescope with its ROI of 30ns and only 625ps sampling.

"SaturatedPixels":[123,456]

A list of pixels in CHID to indicate that the corresponding pixel had an saturated analog time line out of the raw DRS4 chip. The maximum number of saturated pixels is 100, as the event is skipped then anyhow. Usually this list is empty. Such saturations happen not only for ultra high energy air showers, but also when the DRS4 calibration was not possible or is broken elseway.

Dedicated binary format

The phs format is a binary format with exactly the same content as the Json-Lines phs.json1 format. There is no run header of footer. This is just a list of events. Binary run files are named YYYYmmnn_RRR.phs.gz.

The content of the different event types is as follows:

Observation Event

- Descriptor
- Observation Event Identifier
- Observation Information
- Pointing
- Photon-Stream - Saturated Pixels
- Saturateu Pixeis

Photon-Stream (number photons + number pixel Byte)

The arrival time slice for a single photon is between 0 (0ns) and 100 (50ns) and thus fits comfortably into a single unsigned integer of eight bits width (uint8). A list of uint8 is a valid list of arrival times for the photons found in a single pixel. To separate the photon arrival time lists of the individual pixels, we introduce a dedicated next-pixel-symbol which is not a valid photon arrival slice i.e. the digit 255. The concept of a list of symbols separated from the next list by a dedicated symbol is very common to store digital text.

uint32 | Number of pixels plus photons | The size of the photon-stream in bytes. Photon arrival times in slices EXAMPLE. The actual shape and structure depend on the specific event. uint8 ----+-----+-----+-----+-------0 | A | B | C | 255 | <- Pixel CHID=0, 3 photons, arrival slices A, B, and C. 1 | XXX | XXX | 255 | +---+-2 | C | 255 | <- Pixel CHID=2, 1 photons, arriving in slice C. 3 | XXX | XXX | XXX | 255 | 4 | XXX | XXX | XXX | XXX | XXX | 255 | 5 | XXX | 255 | 6 | 255 | <- Pixel CHID=6, 0 photons, empty. + + . . . 7 | XXX | XXX | 255 | +----+ 1437 | XXX | 255 | 1438 | XXX | XXX | XXX | XXX | 255 | - - + - - - - - - - + - -1439 | D | E | 255 | <- last pixel CHID=1439, 2 photons at slices D and E. Pixel CHID

A list of lists of photon arrival time slices in CHID pixel order. The line break from one pixel to the next pixel is marked by the line break symbol $2^{8}-1 = 255$. This leaves 255 (0-254) slices to encode photon arrival times.

Memory representations

Depending on the computational task, the information in the photon-stream can be represented in different ways in memory which can ease the processing. These different representations can be converted into each other without information losses.

List-of-lists

The list-of-lists in-memory representation is an outer list of all pixels (CHID ordering) that loops over the extracted arrival time lists for each pixel. The list-of-lists in-memory representation is the most compact one. We use the list-of-lists in-memory representation for permanent storage.

Image-sequence

A two dimensional histogram along the the arrival time slices and the pixel directions. Each bin counts the number of single photons arriving at its corresponding pixel and corresponding arrival time slice. The image-sequence in-memory representation is suitable when a fixed event size is preferred. The histogram is always the same size in memory regardless of the number or structure of the photons. Slicing and integrating along the time axis can produce classic images with one intensity for each pixel.

Point-cloud

A list of three dimensional direction and time coordinates of all photons in the stream of an event. Two of the three dimensions describe the angular incoming direction of a photon, which correspond to a specific pixel. The third dimension is the arrival time of the photon. This point-cloud in-memory representation is ideal for plotting the 3D point cloud, or to perform the density based clustering to tell apart air-shower photons from night-sky-background photons. The term point-cloud was chosen because of a large community working on exactly such data structures, e.g. Point Cloud Library (PCL).

Known Limitations and outlook

The photon-stream pass4 was created based on best effort. However, we are aware of a few shortcomings which might be addressed in future passes. Here is a list of possible improvements for the future in no particular order.

Arrival time ordering

The List-of-list representations of photon-stream pass4 store the arrival times of the individual photons in the order of their extraction. This ordering information was not found to be of any use yet. If it was of any use it would mean that our single pulse extractor is not optimal as we know that all relevant information has to be in the independent photon arrival times and must not show up else where. On the other hand we found an argument to sort the arrival times in future passes. This is because of the density clustering (DBSCAN) used for air-shower photon classification. In the future, the runtime of a dedicated DBSCAN will profit from an ordered list of single photon arrival times.

Time-series calibration

When pass4 was implemented, it was assumed that the time-series used for the extraction was already treated with all known calibration steps of FACT. This turned out to be not the case. Now we know, that in none of the analysis chains (fact-tools, FACT-MARS) of FACT there exists a fully calibrated time-series. The pass4 is missing at least two calibration steps. First, it misses the individual time-series gain calibration of our amplifiers. And second, it misses a global time delay among the pixels. The global time delay is still under debate and we do not know it for all epochs. Anyhow both effects are 'minor'. We highly recommend for future passes to treat all known calibration steps on the time-series before starting the single pulse extraction. A fully calibrated time-series has the same sampling times for all pixels, and has an amplitude in units of single pulses which are common for the individual pixel.

Dropping the time-series baseline

In pass pass4 we put out an estimate for the baseline amplitude of the time-series after the single pulse extraction. It is the same argument as for the arrival time ordering. If it turns out that this baseline matters, something is wrong with either the extractor or with our time-series main-pulse extraction tools which can not tolerate floating baselines. We recommend to drop the baseline bs1 output files YYYYmmnn_RRR.bs1.json1.gz in the future passes for the sake of simplicity. So far we do not use it anyhow.

Try to move the 'output window' further to the front

1	<	length = 225	>	1
1	1		1	1
1		output window	1	1
Θ	20 <	- length=100 ->	245	300
	30	130		

In units of 500ps time slices.

In pass4 the output window of the photon-stream spans from 15ns to 65ns with respect to the whole recorded time series. This turned out to be sufficient. There are even hints that the window could be shortened in the end. However, the stating point at 15ns (30 time slices) is very close to the air-shower starting point. It is still acceptable but very close. We only have a small region in the beginning of our output window before the air-shower photons arrive. This was done to avoid artifact on the time-series. We can not simply move the start of the output window to improve this. We have two ways to improve here. First the artifacts in the beginning of the time-series (0ns - 10ns) need to be understood and corrected for. Second, the single pulse extractor needs to be improved to produce less artifacts at the beginning of its extraction window. Only this way the output window can move further to the front of the whole recorded time-series. We recommend to investigate methods which do not harm other aspects to move the output window further to the front.

Make the arrival time reconstruction benchmark a unit test

The implementation of the production grade pass4 single photon extractor has several unit tests. However, it does not have unit tests which redo the performance studies e.g. presented on the ICRC2017. Those tests were so far only done for the initial implementation of the single pulse extractor but not for the production grade one. We recommand to implement the arrival time reconstruction benchmark for typical observation conditions on FACT as a unit test before applying any changes to the extractor. Otherwise, it will be difficult to improve certain aspects without losing performance in other aspects.

Alternative Single Pulse Templates

In pass4 we use the SiPM single pulse template from the FACT-MARS simulation standard configuration. See extract below:

- # The number of sampling points is almost irrelevant because they 212
- # are equidistant, i.e. calculated and no search is necessary. 213
- 214 # Nevertheless, you must make sure that there are enough points 215 # to sample the function accurately enough.
- 216 # Attention: x in the function is given in slices, so if you change the sampling
- 217 # frequency you have to change also this function
- 218 PulseShape.Function.Name: (1.626*(1-exp(-0.3803*0.5*x))*exp(-0.0649*0.5*x))
- PulseShape.Function.Npx: 300 PulseShape.Function.Xmin: 0 219
- 220
- PulseShape.Function.Xmax: 300 221

The template pulse from our standard simulation configuration starts instantly at zero. The template from our performance paper starts slowly which conflicts with the single pulse extractor implementation of pass4. The pulse template of our performance paper was not evaluated yet for the single pulse extractor. We recommend to investigate which of those templates is suited best for a future single pulse extractor.

Accelerating DBSCAN air-shower photon classification

This is independent of pass4 but a general future wish. The air-shower photon classification using density clustering in the photon-stream turned out to be highly successful. We currently use the DBSCAN implementation of sklearn. This general implementation works great on our point-cloud photon-stream representation but has become the bottleneck with 50 events/s on a single thread. It might be beneficial to implement a non-general DBSCAN which exploits the previously available knowledge of the FACT image sensor geometry. This might accelerate the creation of the distance matrix between points internally created by DBSCAN. We already started a first investigation.

Accurate event times

This problem is not limited to the photon-stream. In pass4 the events have time stamps based on the unix time of the computer which ran the event builder. This unix time is expected to be based on the Network Time Protocol to reach a good absolute timing. However, in a crosscheck using a GPS clock, we find that the time stamps in our events have a time spread (standard deviation) of about 30ms. In principal we could improve here using the GPS trigger input of FACT. This was already done once for a small sample of Observations. We recommend to process more accurate times for all events in future passes to allow e.g. pulsar studies.

Acknowledgement

The exciting, yet unforeseen investigations on the Cherenkov-plenoscope would not have been possible without the support of Prof. Adrian Biland, and Prof. Felicitas Pauss. I thank both Adrian, and Felicitas for not only providing critics, but also resources and patience. In particular, Adrian's expert-critics on optics, cosmic-rays, and the geomagnetic-cutoff were thankfully received. I thank Max Ludwig Ahnen for enthusiastic discussions on possible observation-goals, and his inspiring thoughts on estimating Portal's sensitivity without an energyreconstruction. For crucial comments on project-management and programming, I want to thank Dominik Neise. Dominik's advice on social aspects of programming, data-accessibility, and literature, became key-catalysts for Portal's simulations. I thank Axel Arbet-Engels for his motivating thoughts and careful reasoning while approaching the Cherenkov-plenoscope. Axel's decision to dedicate his master-thesis to the measurement of the cosmic-ray's composition using the plenoptic methods presented here was a big push for my thesis, and I am very thankful for his choice. I want to thank Gareth Hughes for his introduction into instrument-response-functions on Cherenkov-telescopes. I thank Andreas H. Trabesinger for his comments on a possible manuscript-submission, and I thank Werner Lustermann for discussions on possible implementations of read-out-electronics. The comments by Maximilian Noethe, and Kai Bruegge on programming in general were gladly received.

I thank the department for civil, environmental and geomatic engineering at ETH-Zurich. In our search for expert-opinions, Prof. Eleni Chatzi, Prof. Mario Fontana, Adrian Egger, Georgios Zinas, and Spyridon Daglas got interested in the Cherenkov-Plenoscope. With ideas, time, and resources, they all contributed substantially to Portal's cable-robot-mount. The close collaboration with Spyridon Daglas during his master-thesis on Portal's cable-robot-mount was an inspiring introduction into civil-engineering which I am very thankful for. Rarely I met a person who could learn completely new concepts such as Cherenkov-astronomy, and new skills such as programming with the speed Spyridon Daglas did it.

I want to thank Prof. Werner Hofmann, Prof. James A. Hinton, and Prof. Felix Aharonian for sharing their excitement with me on the prospects of a plenoptic approach in Cherenkov-astronomy. This excitement is what persuaded me to continue my quest in gamma-ray-astronomy, and science in general for a bit longer. I want to thank Prof. Werner Hofmann in particular for: First, becoming the co-examiner of this thesis although I initially confronted him with nothing but 'strong claims'. And second, for encouraging me to present my findings on the Hillas Symposium 2018 in Heidelberg, a symposium in memory of the architect behind the Cherenkov-telescope. Of course, I am equally thankful for the organizers of the Hillas Symposium for having me as a plenary-speaker. Also, the critics by Prof. Wolfgang Rhode, and Dominik M. Elsaesser on my contribution for the Hillas Symposium were highly welcome.

In general, I want to thank ETH-Zurich for an outstanding phd-experience. Thanks to the kind supervision of Prof. Adrian Biland, I was free to dedicate my phd-thesis to the Cherenkov-plenoscope. Good supervisors sometimes have to protect their students from going on too risky, and too ambitious adventures. And I thank you Adrian for helping me to find the right balance for my adventure.

Further, I want to thank Bettina Lareida, Rosa Baechli, Caroline Keufer, and Gabriela Amstutz for administrative support inside and outside of ETH. I want to thank Bruno Zehr, Patrick Gomez, Ulf H. Roessler, Robert Becker, Diogo di Calafiori, Jean-Pierre Stucki, and Jan Soerensen for advice and discussions.

Although its not a part of this thesis, I want to thank Christian A. Monstein for fruitful discussions on a possible detection of cosmic gamma-rays using radioemission.

Finally, I want to thank my family and my wife Katrin Stratmann for sharing my excitement whenever my Cherenkov-plenoscope escalated to the next higher level in the scientific community.
