Momentum-based Accelerated Q-learning

Bowen Weng, Lin Zhao, Huaqing Xiong and Wei Zhang

Abstract-This paper studies accelerated algorithms for Qlearning. We propose an acceleration scheme by incorporating the historical iterates of the Q-function. The idea is conceptually inspired by the momentum-based acceleration methods in the optimization theory. Under finite state-action space settings, the proposed accelerated Q-learning algorithm provably converges to the global optimum with a rate of $\mathcal{O}(1/\sqrt{T})$. While sharing a comparable theoretic convergence rate with the existing Speedy Q-learning (SpeedyQ) algorithm, we numerically show that the proposed algorithm outperforms SpeedyQ via playing the FrozenLake grid world game. Furthermore, we generalize the acceleration scheme to the continuous state-action space case where function approximation of the Q-function is necessary. In this case, the algorithms are validated using commonly adopted testing problems in reinforcement learning, including two discrete-time linear quadratic regulation (LOR) problems from the Deepmind Control Suite, and the Atari 2600 games. Simulation results show that the proposed accelerated algorithms can improve the convergence performance compared with the vanilla Q-learning algorithm.

I. INTRODUCTION

Reinforcement learning (RL) aims to study how an agent learns a policy through interacting with its environment to minimize the accumulative loss for a task. RL has received dramatically growing attention and gained success in various tasks, such as playing video games [13], bipedal walking [6] and studying control systems [12], to name a few. This paper focuses on the Q-learning algorithm which is a model-free RL algorithm to find an estimate of the optimal action value function.

Ever since the first proposal of the Q-learning algorithm in 1989 [24], the method has been studied extensively in the finite state-action space. When the size of the state-action space is relatively small, the Q-function can be explicitly represented as a tabular function leading to a convenient proof of convergence [11].

When the state-action space is continuous or considerably large, Q-learning usually requires function approximations. Lewis et. al. studied the Q-learning problem for linear control systems [1] and extended the method to the continuous time domain [21], [23]. They consider value iteration with appropriate sampling and customized Q-function structure. The step of *target update* was later introduced in the Deep Q-Network (DQN) learning [13] with the Q-function being parameterized as a deep neural network. DQN has gained great success in playing video games [16] that significantly exceeds human-level of performance. This also leads to various improved algorithms for Q-learning [22] and for general RL [19].

Besides the exploration on the improved Q-learning algorithms with better performance in applications, another line of research lies in the convergence analysis of variants of the Q-learning algorithms [3], [4], [5], [7], [9]. Given that the training speed largely determines how an algorithm can contribute to the real application, accelerating the convergence is always of great interest. Optimization theory has provided effective schemes of acceleration with theoretic guarantees. One of the most popular schemes is based on the so-called momentum idea by involving more historical information into the update. Momentum-based algorithms, including Heavy-ball (HB) [17], Nesterov's accelerated gradient (NAG) [15], have been proved to be able to accelerate the convergence when loss functions are strongly convex [10], [15]. Under general convex or nonconvex settings, the acceleration of these algorithms has not been established theoretically. Nevertheless, its convergence can still be guaranteed for specific classes of nonconvex loss functions [25] and numerical results also show great success [2], [8]. A successful application of the momentum to accelerate Q-learning is the so-called Speedy Q-learning (SpeedyQ) [3]. It is provably better than the vanilla Qlearning assuming a finite state-action space.

Our contribution in this paper is twofold. First, we propose a new accelerated Q-learning scheme which is inspired by the general momentum-based optimization algorithms. Under the finite state-action space and the synchronous sampling settings [9], we prove the upper bounds of the convergence rate which is comparable to that of SpeedyQ. Furthermore, using a popular grid world game, we numerically show that the proposed acceleration scheme can outperform SpeedyQ under the same settings as considered in the theoretical derivations. Second, we also generalize our acceleration scheme to the continuous state-action space case, where the Q-function is usually approximated by parametric functions. In this case, we numerically evaluate the proposed algorithms in various challenging tasks, including two linear quadratic regulation problems from the Deepmind Control Suite [20] and the Atari 2600 video games. A significant improvement of the performance over the vanilla Q-learning is shown by the simulation results.

The rest of the paper is organized as follows. Section II introduces the background of Q-learning and SpeedyQ. Sec-

tion III proposes a new acceleration scheme, followed by the convergence analysis and numerical performance comparison with SpeedyQ. In Section IV, we generalize our acceleration scheme to the case where the state-action space is continuous or considerably large. We also provide numerical results to show the promising applications of our algorithms in more complicated applications.

II. PRELIMINARIES

In this section, we provide the background of Q-learning. We also briefly revisit the SpeedyQ algorithm for comparison in later sections.

A. Q-learning

We consider the standard reinforcement learning settings, where a learning agent (e.g. controller or control policy) interacts with a (possibly stochastic) environment (e.g. process or system dynamics, etc.). This interaction is usually modeled as a discrete-time discounted Markov Decision Processes (MDPs), described by a quintuple $(\mathcal{X}, \mathcal{U}, P, R, \gamma)$, where \mathcal{X} is the state space, \mathcal{U} is the action space, P : $\mathcal{X} \times \mathcal{U} \times \mathcal{X} \mapsto [0, 1]$ is the probability kernel for the state transitions, e.g., $P(\cdot|x, u)$ denotes the probability distribution of the next state given current state x and action u. In addition, $R : \mathcal{X} \times \mathcal{U} \mapsto [0, R_{\max}]$ is the reward function (or negative of the cost function) mapping station-action pairs to a bounded subset of \mathbb{R} , and $\gamma \in (0, 1)$ is the discount factor. The optimal stationary policy $\pi^* : \mathcal{X} \mapsto \mathcal{U}$ of MDP is defined as the solution of following optimization problem:

$$\begin{array}{ll} \underset{\pi}{\text{maximize}} & J_{\pi}(x_0) = \mathbb{E}_P \left\{ \sum_{k=0}^{\infty} \gamma^k R(x_k, \pi(x_k)) \right\}, \\ \text{subject to} & x_{k+1} \sim P(\cdot | x_k, \pi(u_k)), \end{array}$$
(1)

where \mathbb{E}_P denotes the expectation with respect to the transition probability P. The above optimization problem seeks to maximize the expected accumulated discounted rewards over different policies π .

A stationary policy π induces a Q-function Q^{π} which satisfies the *Bellman equation*:

$$Q^{\pi}(x,u) := R(x,u) + \gamma \mathbb{E}_P Q^{\pi}(x',\pi(x')),$$

where $x' \sim P(\cdot|x, u)$ denotes the next state.

The Bellman operator \mathcal{T} is defined pointwisely as

$$\mathcal{T}Q(x,u) = R(x,u) + \gamma \mathbb{E}_P \max_{u' \in U(x')} Q((x',u'), \quad (2)$$

which can be shown to be a contractive in the supremum norm (i.e., $\|Q\|:=\sup_{x,u}|Q(x,u)|)$

$$\left\|\mathcal{T}Q(x,u) - \mathcal{T}Q'(x,u)\right\| \leq \gamma \left\|Q(x,u) - Q'(x,u)\right\|, \quad (3)$$

and its unique fixed point is the optimal Q-function Q^* , i.e., $\mathcal{T}Q^*(x, u) = Q^*(x, u)$, which also satisfies the *optimal Bellman equation* [5]:

$$Q^{\star}(x,u) = R(x,u) + \gamma \mathbb{E}_{P} \max_{u' \in U(x')} Q^{\star}(x',u'), \quad (4)$$

Therefore, starting with an arbitrary Q-function, we can apply the Bellman operator \mathcal{T} iteratively to learn Q^* .

Let $J^{\star}(x) := J_{\pi^{\star}}(x)$ be the optimal value function when applying the optimal policy π^{\star} . It relates to Q^{\star} as follows

$$J^{\star}(x) = \max_{u \in U(x)} Q^{\star}(x, u), \forall x \in \mathcal{X},$$
(5)

where U(x) denotes the admissible set of actions at state x. Hence, the optimal policy can be obtained from the optimal Q-function as:

$$\pi^{\star}(x) = \underset{u \in U(x)}{\operatorname{argmax}} Q^{\star}(x, u), \forall x \in \mathcal{X}$$
(6)

Note that the knowledge of the transition probability P is not needed in (6), which is the advantage of Q learning.

In practice, exact evaluation of the Bellman operator (2) is usually infeasible due to the lack of the knowledge of the system dynamics (i.e. the transition probabilities). Instead, the *empirical Bellman operator* is evaluated using samples [11]. Specifically, for the kth round of iteration at state-action pair (x, u), we sample the next state $y_k \sim P(\cdot|x, u)$, and then evaluate the empirical Bellman operator \mathcal{T}_k as

$$\mathcal{T}_k Q_k(x, u) = R(x, u) + \gamma \max_{u' \in U(y_k)} Q_k(y_k, u'), \quad (7)$$

where note that the subscript of \mathcal{T}_k is to track that of samples y_k . As an example, the vanilla Q-learning is implemented as

$$Q_{k+1} = Q_k - \alpha_k (Q_k - \mathcal{T}_k Q_k), \tag{8}$$

where α_k is the step size and we omit the dependence on (x, u) hereafter when no confusion can arise.

B. Speedy Q-learning

In optimization and deep learning, momentum-based schemes, including Heavy-ball (HB) [17] and Nesterov's accelerated gradient (NAG) [15], have been widely used to accelerate the convergence of gradient based algorithms. Such schemes also inspired some improved Q-learning algorithms such as SpeedyQ [3], which follows the update as:

$$Q_{k+1} = Q_k + \alpha_k (\mathcal{T}_k Q_k - Q_k) + (1 - \alpha_k) (\mathcal{T}_k Q_k - \mathcal{T}_k Q_{k-1}),$$
(9)

where $\alpha_k = \frac{1}{k+1}$. Compared with (8), SpeedyQ added a momentum term $\mathcal{T}_k Q_k - \mathcal{T}_k Q_{k-1}$. This is a straightforward setup considering the history momentum. In the following section, we further explore the accelerated Q-learning framework with a more sophisticated design.

III. ACCELERATED Q-LEARNING

In this section, we propose a new class of accelerated Qlearning (AQL) algorithms inspired by general momentumbased optimization algorithms. A generic form of AQL is given by

$$S_{k} = (1 - a_{k})Q_{k-1} + a_{k}\mathcal{T}_{k}Q_{k-1},$$

$$P_{k} = (1 - a_{k})Q_{k} + a_{k}\mathcal{T}_{k}Q_{k},$$

$$Q_{k+1} = P_{k} + b_{k}(P_{k} - S_{k}) + c_{k}(Q_{k} - Q_{k-1}).$$
(10)

where a_k, b_k, c_k are the step sizes or learning rates. In this paper, we will mainly consider the synchronous sampling, where all the state-action pairs are updated simultaneously

at each iteration round [9]. The pseudo code of the implementation is listed in Algorithm 1. Note that we used the notation $\mathcal{M}Q_k(y_k) := \max_{u \in U(y_k)} Q_k(y_k, u)$.

Algorithm 1 Synchronous Accelerated Q-learning

Input: Initial action-value function Q_0 and $Q_{-1} = Q_0$, discount factor γ , parameter $m \ge \frac{1}{\gamma}$, and maximum iteration number Tfor $k = 0, 1, 2, \dots, T - 1$ do $a_k = \frac{1}{k+1}, \ b_k = k - m - 1, \ c_k = \frac{-k^2 + (m+1)k+1}{k+1};$ for each $(x, u) \in \mathcal{X} \times U(x)$ do Generate the next state sample $y_k \sim P(\cdot|x, u);$ $\mathcal{T}_k Q_{k-1}(x, u) = R(x, u) + \gamma \mathcal{M} Q_{k-1}(y_k);$ $\mathcal{T}_k Q_k(x, u) = R(x, u) + \gamma \mathcal{M} Q_k(y_k);$ $S_k(x, u) = (1 - a_k)Q_{k-1}(x, u) + a_k \mathcal{T}_k Q_{k-1}(x, u)$ $P_k(x, u) = (1 - a_k)Q_k(x, u) + a_k \mathcal{T}_k Q_k(x, u)$ $Q_{k+1}(x, u) = P_k(x, u) + b_k (P_k(x, u) - S_k(x, u))$ $+ c_k(Q_k(x, u) - Q_{k-1}(x, u))$ end for

end for Output: Q_T

To facilitate the analysis, we rewrite (10) in a more compact way as

$$Q_{k+1} = (1-a_k)Q_k + [b_k(1-a_k)+c_k](Q_k - Q_{k-1}) + a_k [(1+b_k)\mathcal{T}_kQ_k - b_k\mathcal{T}_kQ_{k-1}].$$
(11)

Comparing (11) with the SpeedyQ given in (9), we notice that first, SpeedyQ only contains $\mathcal{T}_k Q_{k-1}$ in the update without explicitly using the historical information Q_{k-1} . This additional term in our algorithm may help attenuate possible large overshoots during the iteration. Second, (9) simply involves $\mathcal{T}_k Q_k - \mathcal{T}_k Q_{k-1}$ as the only momentum term, while our algorithm designs this part in a more careful manner. That is, we first use two consecutive outputs of the empirical Bellman operators to update the Q-function and obtain S_k and P_k . Intuitively, since S_k and P_k are derived by the update of the vanilla Q-learning, selecting $S_k - P_k$ as the additional momentum term can contribute to a better estimation of the optimal Q-function while preserving the acceleration. This intuition is also verified in our numerical results, which will be shown later. Before that, we first provide convergence analysis of the proposed algorithm.

A. Convergence Rate Analysis of AQL

Our analysis is based on the finite state-action space assumption, which is the same as in [3].

Assumption 1: The state space \mathcal{X} and the action space \mathcal{U} are finite sets with cardinalities $|\mathcal{X}|$ and $|\mathcal{U}|$, respectively. We denote $n = |\mathcal{X}| \cdot |\mathcal{U}|$.

Our analysis starts with analyzing the errors of approximating the exact Bellman operator \mathcal{T} with empirical Bellman operators \mathcal{T}_k . These stochastic errors and their evaluations over time are major challenges in proving convergence and deriving convergence rate. For convenience, we denote all \mathcal{T}_k terms in (11) by

$$\mathcal{D}_{k}\left[Q_{k}, Q_{k-1}\right] := (1+b_{k})\mathcal{T}_{k}Q_{k} - b_{k}\mathcal{T}_{k}Q_{k-1}, \qquad (12)$$

for all $k \ge 0$. Note that (12) is a function of all samples $\{y_1, y_2, \cdots, y_k\}$ for all station-action pair (x, u) up to round k. Let \mathcal{F}_k denote the filtration generated by the sequence of these random variables $\{y_1, y_2, \cdots, y_k\}$. Then if we define $\mathcal{D}[Q_k, Q_{k-1}]$ as the conditional expectation of $\mathcal{D}_k[Q_k, Q_{k-1}]$ given \mathcal{F}_{k-1} , we obtain by the definition of \mathcal{T} that

$$\mathcal{D}[Q_k, Q_{k-1}] := \mathbb{E}_P \left(\mathcal{D}_k \left[Q_k, Q_{k-1} \right] | \mathcal{F}_{k-1} \right)$$
$$= (1 + b_k) \mathcal{T} Q_k - b_k \mathcal{T} Q_{k-1}.$$

Now define the error between \mathcal{D}_k and \mathcal{D}

$$\varepsilon_k := \mathcal{D}\left[Q_k, Q_{k-1}\right] - \mathcal{D}_k\left[Q_k, Q_{k-1}\right]. \tag{13}$$

Clearly $\mathbb{E}_P(\epsilon_k | \mathcal{F}_{k-1}) = 0$. This shows that $\forall (x, u) \in \mathcal{X} \times U(x)$, the sequence of estimation error $\{\epsilon_k(x, u)\}_{k=0}^T$ is a martingale difference sequence with respect to the filtration \mathcal{F}_k . In other words, if we denote

$$E_k(x,u) := \sum_{j=0}^k \epsilon_j(x,u), \qquad (14)$$

then E_k is a martingale with respect to \mathcal{F}_k , $\forall (x, u) \in \mathcal{X} \times U(x)$ and $\forall k \ge 0$.

To proceed, we need the following assumption.

Assumption 2: The Q-function is uniformly bounded throughout the learning process. That is, $\exists V_{\max}$, such that $\|Q_k\| \leq V_{\max}, \forall k \geq 0$. Without loss of generality, we further let $R_{\max} + \gamma V_{\max} = V_{\max}$.

Based on Assumption 2, we can further obtain the uniform bounds of \mathcal{D}_k and ϵ_k as shown in the following lemma. All proofs are collected in the Appendix.

Lemma 1: Given Assumption 2 and AQL as Algorithm 1, $\mathcal{D}_k[Q_k, Q_{k-1}]$ and ϵ_k are uniformly bounded for all $k \ge 0$. Specifically, $\exists D_{\max} > 0$, s.t. $\|\mathcal{D}_k[Q_k, Q_{k-1}]\| \le D_{\max}, \|\epsilon_k\| \le 2D_{\max}, \forall k \ge 0$.

The uniform bounds proved in Lemma 1 are critical in the derivation of the main theorem below.

Theorem 1: Given Assumption 1, 2 and fixing γ, m with $\gamma m \ge 1$ in AQL as Algorithm 1, with probability at least $1 - \delta$, the output of AQL satisfies:

$$\|Q^{\star} - Q_T\| \leqslant \frac{2(\gamma R_{\max} + hV_{\max}) + D_{\max}\sqrt{8(T-m)\log\frac{2n}{\delta}}}{T(1-\gamma)}$$
(15)

where D_{max} is from Lemma 1 and $h = \gamma(m+1) + 1$.

Combining Theorem 1 and the Borel-Cantelli lemma we know Q_T converges to Q^* with the rate $\mathcal{O}(\sqrt{1/T})$ almost surely. We further comment that the asymptotic convergence rate is comparable to that of SpeedyQ [3]. Recalling our intuition for the difference of the update rules, we expect AQL can actually outperform SpeedyQ. We numerically verify this in the following.

B. Numeric Comparison with SpeedyQ

Given the analytical convergence rate derived above is also comparable to SpeedyQ. We seek to explore extra experiments to verify that our algorithm actually outperforms SpeedyQ. We emphasize that the settings in this section are consistent with those of AQL in algorithm 1 and SpeedyQ in [3, Algorithm1]. Thus the numerical results should be able to give a convincing comparison between two algorithms. Note that the choice of m is not explicitly specified with only a lower bound. We try 3 different selections of m and observe stable performance in convergence, which also aligns with the theoretical analysis. To evaluate the algorithms in the finite state-action space, we apply them to the popular FrozenLake grid world games.

FrozenLake is a classic baseline problem for Q-learning. An agent controls the movement of a character in a grid world. Some tiles of the grid are walkable, and others lead to the agent falling into the water. Additionally, the movement direction of the agent is uncertain and only partially depends on the chosen direction. The agent is rewarded for finding a feasible path to a goal tile. The environment for FrozenLake is a 4×4 grid world. We consider two sub-tasks, the FrozenLake (Fig. 1a) and the FrozenLake8x8 (Fig. 1b) with a bigger grid world . In both Frozenlake tasks, "S" is the safe starting point, "F" is the safe frozen surface, "H" stands for the hole that terminates the game, and "G" is the target state that comes with an immediate reward of 1. This forms a problem with state space size of 16 (64 for FrozenLake8x8), action space size of 4 and reward space $R = \{0, 1\}$.

Considering the randomness embedded in the MDP of both FrozenLake games, we evaluate the performance of each algorithm with 20 different random seeds and then illustrate the average loss and standard deviation in Fig. 1a and Fig. 1b. For evaluation purpose, we have access to the true transition probability, and can find the ground truth optimal Q-function Q^* using dynamic programming. In both games, the loss at step k is then defined as $||Q_k - Q^*||$. It can be seen from the results that AQL with various choices of m all can converge faster than Speedy Q-learning.

IV. GENERALIZATION TO PARAMETRIC AQL

In this section, we generalize our acceleration scheme to the case where the state-action space is considerably large or even continuous. Numerical verification of the performance of the proposed algorithms is then provided with various tasks.

A. AQL with Q-function approximation

We consider the same MDP problem as that in Section II, but in a continuous state-action space $\mathcal{X} \times \mathcal{U}$. In this case, it is often impossible or extremely difficult to write the Qfunction as an explicit tabular function w.r.t each state-action pair, and thus the update rule of (8) is no longer applicable.

To handle this problem, we consider a parametric function $\hat{Q}(x, u; \theta)$ as an approximation of the Q-function. The parameter vector θ is of finite and relatively lower dimension and thus easier to implement. The approximation architectures can be rich through different choices of the function class, such as linear function approximation [5] and neural networks [14]. Instead of updating the estimating Q-function directly as (8), here we can only iteratively update the parameter θ . This kind of Q-learning is referred as parametric Q-learning (PQL), which follows the update rule as

$$\theta_{k+1} = \theta_k - \alpha_k \Delta_k \frac{\partial}{\partial \theta_k} \hat{Q}_k(x, u; \theta_k), \qquad (16)$$

where

$$\Delta_k = \hat{Q}_k(x, u; \theta_k) - R(x, u) - \gamma \max_{u' \in U(x')} \hat{Q}_k(x', u'; \theta_k).$$
(17)

Then we can generalize the proposed acceleration scheme to the vanilla PQL in (16). We refer the AQL in this case as parametric AQL (PAQL) given by

$$\xi_{k} = \theta_{k-1} - a_{k} \Delta_{k-1} \frac{\partial}{\partial \theta_{k-1}} \hat{Q}_{k-1}(x, u; \theta_{k-1}),$$

$$\zeta_{k} = \theta_{k} - a_{k} \Delta_{k} \frac{\partial}{\partial \theta_{k}} \hat{Q}_{k}(x, u; \theta_{k}),$$

$$\theta_{k+1} = \zeta_{k} + b_{k} (\zeta_{k} - \xi_{k}) + c_{k} (\theta_{k} - \theta_{k-1}).$$
(18)

Notice that when we take $b_k = 0$, then the update (10) only involves one-step historical information θ_{k-1} . This applies the same idea as HB and thus is referred as HBPAQL. When taking $b_k \neq 0$, we also involve ξ_k into the update, which is motivated by the idea of NAG and thus denoted as NesPAQL.

In the following, we evaluate PAQL in two discretetime LQR problems from the Deepmind Control Suite [20] and Atari 2600 games, where the function approximation architectures are linear functions and neural networks, respectively. Throughout this section, we adopt ϵ -greedy [14] and prioritized experience replay [18] for exploration and sampling, both of which are common techniques in RL with parametric approximation.

Fig. 2: Testing tasks for PAQL, from left to right: LQR with 2 Masses and 1 Linear Actuators, LQR with 6 Masses and 2 Linear Actuators, Pong and Boxing from Atari 2600 Games.

B. Linear Quadratic Regulation

The problem of infinite-horizon discrete-time LQR considers a linear system

$$x_{k+1} = Ax_k + Bu_k,\tag{19}$$

with cost function in a quadratic form as

$$J = \sum_{t=0}^{\infty} \left(x_k^T Q x_k + u_k^T R u_k + 2 x_k^T N u_k \right).$$
 (20)

Let the positive definite P be the unique solution to the discrete-time algebraic Riccati equation (DARE)

$$P = A^{T} P A - (A^{T} P B + N)(R + B^{T} P B)^{-1}(B^{T} P A + N^{T}) + Q.$$
(21)

We have the optimal control as $u_k^{\star} = -K^{\star}x_k$ with

$$K^{\star} = (R + B^T P B)^{-1} (N^T + B^T P A).$$
(22)

Following the procedure established in section IV-A, we parameterize a Q-function which is linear w.r.t a matrix parameter H in the form of

$$Q(x,u;H) = \begin{bmatrix} x \\ u \end{bmatrix}^T \begin{bmatrix} H_{xx} & H_{xu} \\ H_{ux} & H_{uu} \end{bmatrix} \begin{bmatrix} x \\ u \end{bmatrix}.$$
 (23)

The stationary linear policy corresponding to the Q-function (23) satisfies u = -Kx, $K = H_{uu}^{-1}H_{ux}$. We evaluate the performance of various PAQL algorithms at each iterate k with the Euclidean norm $||K_k - K^*||_2$.

In this section, the linear system is constructed as a coupled mass damper system with n masses, serially connected through linear joints (see Fig. 2) with m joints being actuated. The system has the state dimension of 2n with position state x_p and velocity state x_v . The action dimension is m. The reward is quadratic with respect to the position and controls, i.e. $R = \frac{1}{2}x_p^TQx_p + \eta \frac{1}{2}u^TRu$ with control cost coefficient $\eta = 0.1$. The system is a default RL benchmark from the Deepmind control suite [20]. We consider two subtasks, the "LQR-2-1" with n = 2, m = 1 and the "LQR-6-2" with n = 6, m = 2 which take 4269 and 11840 iterates respectively to converge to K^* through DARE.

We compare the performance of proposed the PAQL algorithms with the vanilla Q-learning in Fig 3a and Fig. 3b. For both tasks, we let $a_k = 0.9$, $b_k = 0.2$, $c_k = 0.2$, $\forall k$ for corresponding algorithms. The learning process of DARE is also included. Direct comparison regarding the training time with DARE is not fair given that DARE requires system dynamics but Q-learning methods are model-free. In our illustration, we exclude the sampling time and consider the number of value iterations required to achieve certain level of desired performance (Table I).

TABLE I: Iterates for Converging to $||K_k - K^*||_2 \leq 0.1$

Task	DARE	Q-learning	HBPAQL	NesPAQL
LQR_2_1	769	515	229	205
LQR_6_2	2768	1094	235	241

C. Atari 2600 games

We further evaluate the performance of PAQL with two Atari 2600 games. It is a challenging RL benchmark task that takes high-dimensional high-frequency video sequence $(dim(\mathcal{X}) = 84 \times 84 \times 4)$ as state and real video game control keys as action. The performance for each algorithm is justified empirically by the average return of 100 trails of episodes. The Q-function is parameterized as a deep convolutional neural network. Hyper-parameters are set as $a_k = 0.9, b_k = 0.2, c_k = 0.2, \forall k$. The algorithm is implemented based on the open.ai baseline, which is a set of high-quality implementations of RL algorithms. The original DQN implementation and its variants are roughly on par with scores in published papers, which mostly exceeds expert level of human play. Results are illustrated in Fig. 3c.

The Q-function is structured with millions of parameters (i.e., the weights of deep neural networks). The sampling and target learning with SGD both consume a significant amount of time and computational power. On a dual-GPU machine with the PAQL algorithm, the training for the game Pong takes 0.6 million samples in 15 minutes. For the Boxing game to achieve the illustrated results, PAQL takes 2 million samples in 40 minutes. On the contrast, DQN would require at least 4 million samples to acquire similar performance.

Fig. 3: Comparing Various Methods for LQR and Atari 2600 Games.

V. CONCLUSION

We proposed a set of momentum-based accelerated Qlearning algorithms, which are provably converging faster than vanilla Q learning in finite state-action space if it is stable. We empirically evaluate the algorithms and verify that the proposed algorithms can accelerate the convergence in comparison to SpeedyQ and vanilla Q-learning on various challenging tasks under both finite and continuous stateaction spaces settings.

Our future work includes providing theoretical guarantee of the stability of the proposed algorithm in the finite stateaction space case (see Assumption 2, although we never found unstable cases in our simulation). For the continuous state-action space, it is also important to study the stability of the proposed iteration scheme when using a general nonlinear approximation architecture such as neural networks. Moreover, further extensions of this work include exploring more complicated adaptive acceleration schemes to improve the convergence performance, which will be our future interests.

Appendix

Maximal Hoeffding-Azuma Inequality:

Lemma 2: Let $\{M_1, M_2, \ldots, M_T\}$ be a martingale difference sequence with respect to a sequence of random variables $\{X_1, X_2, \ldots, X_T\}$ (i.e. $\mathbb{E}(M_{k+1}|X_1, X_2, \ldots, X_k) =$ $0, \forall 1 \leq k \leq T$) and uniformly bounded by $\overline{M} > 0$. If we define $S_k = \sum_{i=1}^k M_i$, then for any $\varepsilon > 0$, we have

$$\mathbb{P}\left(\max_{1\leqslant k\leqslant T}S_k>\varepsilon\right)\leqslant \exp\left(\frac{-\varepsilon^2}{2T\bar{M}^2}\right).$$

Proof of Lemma 1:

Proof: When k = 0,

$$\begin{aligned} |\mathcal{D}_0 [Q_0, Q_{-1}]| &= ||\mathcal{T}_0 Q_0|| \le ||R|| + \gamma ||\mathcal{M} Q_0(y_0)|| \\ \leqslant R_{\max} + \gamma V_{\max} = V_{\max} := \bar{B}_0 \end{aligned}$$

Now, considering $k \ge 1$ we have

$$\begin{aligned} &\|\mathcal{D}_{k}\left[Q_{k},Q_{k-1}\right]\|\\ &\leqslant \|R\|+\gamma\|(1+b_{k})\mathcal{M}Q_{k}-b_{k}\mathcal{M}Q_{k-1}\|\\ &=R_{\max}+\gamma\|(1+b_{k})\mathcal{M}(Q_{k-1}\\ &-\alpha_{k-1}Q_{k-2}+\alpha_{k-1}\mathcal{D}_{k-1}\left[Q_{k-1},Q_{k-2}\right]\right)\\ &-b_{k}\mathcal{M}Q_{k-1}\|\\ &\leqslant R_{\max}+\gamma\|Q_{k-1}\|+\gamma|1+b_{k}|a_{k-1}\|Q_{k-2}|\\ &+\gamma|1+b_{k}|\alpha_{k-1}\|\mathcal{D}_{k-1}\left[Q_{k-1},Q_{k-2}\right]\|\,,\end{aligned}$$

where the first inequality follows from the triangle inequality and the second follows due to the triangle inequality and the definition of the infinity norm.

By the choice of the hyper-parameters in Algorithm 1, we know $|1 + b_k|a_{k-1} = \frac{|k-m|}{k}$. Then we consider two cases: $1 \le k < \frac{m}{2}$ and $k \ge \frac{m}{2}$. The first case only contains finite steps, and in the second case, we can simply bound $|1 + b_k|a_{k-1} = \frac{|k-m|}{k} \le 1$.

When $1 \leq k < \frac{m}{2}$, i.e. when $1 < |1+b_k|a_{k-1} = \frac{|k-m|}{k} \leq m$, we have

$$\begin{split} &\|\mathcal{D}_{k}\left[Q_{k},Q_{k-1}\right]\|\\ \leqslant &R_{\max}+\gamma \|Q_{k-1}\|+\gamma|1+b_{k}|a_{k-1}\|Q_{k-2}\|\\ &+\gamma|1+b_{k}|\alpha_{k-1}\|\mathcal{D}_{k-1}\left[Q_{k-1},Q_{k-2}\right]\|\\ = &R_{\max}+\gamma \|Q_{k-1}\|+\gamma \frac{m-k}{k}\|Q_{k-2}\|\\ &+\gamma \frac{m-k}{k}\|\mathcal{D}_{k-1}\left[Q_{k-1},Q_{k-2}\right]\|\\ \leqslant &R_{\max}+\gamma V_{\max}+\gamma m V_{\max}+\gamma m \|\mathcal{D}_{k-1}\left[Q_{k-1},Q_{k-2}\right]\|\\ \leqslant &(1+\gamma m) V_{\max}\sum_{i=0}^{k-1}(\gamma m)^{i}+(\gamma m)^{k} \|\mathcal{D}_{0}\left[Q_{k-1},Q_{k-2}\right]\|\\ \leqslant &\frac{(1+\gamma m)((\gamma m)^{k-1}-1)V_{\max}}{\gamma m-1}+(\gamma m)^{k} V_{\max}, \end{split}$$

where the third inequality follows from Assumption 2. Since $\gamma m \ge 1$, in this case D_k can be uniformly bounded as

$$\begin{aligned} \|\mathcal{D}_{k}[Q_{k},Q_{k-1}]\| \\ &\leq \left(\frac{(1+\gamma m)((\gamma m)^{\lfloor m/2 \rfloor - 1} - 1)}{\gamma m - 1} + (\gamma m)^{\lfloor m/2 \rfloor}\right) V_{\max} := \bar{B} \end{aligned}$$

where $\lfloor * \rfloor$ denotes the largest integer that is no larger than *. Then we consider when $k \ge \frac{m}{2}$, i.e. when $|1 + b_k|a_{k-1} = \frac{|k-m|}{k} \le 1$:

$$\begin{aligned} &\|\mathcal{D}_{k}\left[Q_{k},Q_{k-1}\right]\|\\ \leqslant &R_{\max} + \gamma \|Q_{k-1}\| + \gamma |1 + b_{k}|a_{k-1}\| Q_{k-2}\|\\ &+ \gamma |1 + b_{k}|\alpha_{k-1}\| \mathcal{D}_{k-1}\left[Q_{k-1},Q_{k-2}\right]\|\\ \leqslant &R_{\max} + \gamma \|Q_{k-1}\| + \gamma \|Q_{k-2}\|\,, \end{aligned}$$
(24)

Notice that the second inequality follows due to $|1 + b_k|a_{k-1} = \frac{|k-m|}{k} \leq 1$, which is the main difference from the previous case. Then we can further bound

$$\begin{aligned} \|\mathcal{D}_{k} [Q_{k}, Q_{k-1}]\| \\ \leqslant R_{\max} + 2\gamma V_{\max} + \gamma \|\mathcal{D}_{k-1} [Q_{k-1}, Q_{k-2}]\| \\ \leqslant R_{\max} \sum_{i=0}^{k-\lfloor m/2 \rfloor} \gamma^{i} + 2V_{\max} \sum_{i=1}^{k-\lfloor m/2 \rfloor} \gamma^{i} \\ + \gamma^{k-\lfloor m/2 \rfloor} \|\mathcal{D}_{\lfloor m/2 \rfloor} [Q_{0}, Q_{-1}]\| \\ \leqslant \frac{(R_{\max} + 2\gamma V_{\max})}{1 - \gamma} + \bar{B}_{1} \\ = \frac{1 + \gamma}{1 - \gamma} V_{\max} + \bar{B}_{1} := \bar{B}_{2}, \end{aligned}$$
(25)

where the first inequality follows from Assumption 2. Observe that clearly $\bar{B}_0 < \bar{B}_1 < \bar{B}_2$. Then we can uniformly bound $||D_k||$ as

$$\left\|\mathcal{D}_{k}\left[Q_{k}, Q_{k-1}\right]\right\| \leqslant \bar{B}_{2} := D_{\max}, \ \forall k \ge 0.$$

The bound on ϵ_k follows directly from its definition as

$$\begin{aligned} \|\epsilon_k\| &= \|\mathbb{E}_P\left(\mathcal{D}_k\left[Q_k, Q_{k-1}\right](x, u) | \mathcal{F}_{k-1}\right) - \mathcal{D}_k\left[Q_k, Q_{k-1}\right] \| \\ &\leq 2 \left\|\mathcal{D}_k\left[Q_k, Q_{k-1}\right]\right\| \leq 2D_{\max}. \end{aligned}$$

Thus we conclude our proof.

Proof of Theorem 1:

We first prove two lemmas that will lead to the main results. The first lemma derives the dynamics of Q_k in terms of E_k , which will be handy later.

Lemma 3: For any $k \ge 1$ and given AQL as in Algorithm 1, we have

$$Q_{k} = \frac{1}{k} (Q_{k-1} - Q_{0} + (k - m - 1)\mathcal{T}Q_{k-1}) + \frac{1}{k} ((m+1)\mathcal{T}Q_{0} - E_{k-1})$$
(26)

Proof: First we rewrite (11) by the definition of D_k and ϵ_k as

$$Q_{k+1} = (1-a_k)Q_k + [b_k(1-a_k)+c_k] (Q_k - Q_{k-1}) + a_k [(1+b_k)\mathcal{T}_kQ_k - b_k\mathcal{T}_kQ_{k-1}] = (1-a_k)Q_k + [b_k(1-a_k)+c_k] (Q_k - Q_{k-1}) + a_k\mathcal{D}_k [Q_k, Q_{k-1}] = (1-a_k)Q_k + [b_k(1-a_k)+c_k] (Q_k - Q_{k-1}) + a_k (\mathcal{D} [Q_k, Q_{k-1}] - \epsilon_k).$$
(27)

Then we prove the lemma by plugging in the choice of ¹, the hyper-parameters and using induction. For k = 1, $Q_1 = \mathcal{T}_1 Q_0 = \mathcal{T} Q_0 - E_1$, Thus (26) holds when k = 1. Now under the assumption that (26) holds for k we prove it also holds for k + 1.

$$\begin{aligned} Q_{k+1} \\ &= \frac{1}{k+1}Q_k - \frac{1}{k+1}Q_{k-1} + \frac{k}{k+1}Q_k \\ &+ \frac{1}{k+1}\left[(k-m)\mathcal{T}_kQ_k - (k-m-1)\mathcal{T}_kQ_{k-1}\right] \\ &= \frac{1}{k+1}Q_k - \frac{1}{k+1}Q_{k-1} + \frac{1}{k+1}(Q_{k-1} - Q_0 \\ &+ (k-m-1)\mathcal{T}Q_{k-1} + (m+1)\mathcal{T}Q_0 - E_{k-1}) \\ &+ \frac{1}{k+1}\left[(k-m)\mathcal{T}_kQ_k - (k-m-1)\mathcal{T}_kQ_{k-1}\right] \\ &= \frac{1}{k+1}Q_k - \frac{1}{k+1}Q_{k-1} + \frac{1}{k+1}(Q_{k-1} - Q_0 \\ &+ (k-m-1)\mathcal{T}Q_{k-1} + (m+1)\mathcal{T}Q_0 - E_{k-1}) \\ &+ \frac{1}{k+1}\left[(k-m)\mathcal{T}Q_k - (k-m-1)\mathcal{T}Q_{k-1} - \epsilon_k\right] \\ &= \frac{1}{k+1}(Q_k - Q_0 + (k-m)\mathcal{T}Q_k + (m+1)\mathcal{T}Q_0 - E_k), \end{aligned}$$

which shows (26) holds for k + 1, and therefore it holds for all $k \ge 1$.

The second lemma derives the propagation of the errors ϵ_k in the process of Q function iteration, which can be proved conveniently using Lemma 3.

Lemma 4: Given Assumption 2 and fixing γ, m with $\gamma m \ge 1$ in AQL as Algorithm 1, for all $k \ge m + 1$, we have

$$\|Q^{\star} - Q_k\| \leq 2 \frac{\gamma R_{\max} + hV_{\max}}{k(1-\gamma)} + \frac{1}{k} \sum_{i=0}^{k-m-1} \gamma^i \|E_{k-i}\|,$$
(28)

where
$$h = \gamma(m + 1) + 1$$
.

Proof: For $k \ge m + 1$, expand Q_k using (26) in Lemma 3, and we have

$$\begin{split} \|Q^{\star} - Q_{k}\| \\ &= \frac{1}{k} \|Q_{k-1} - Q_{0} + (k - m - 1)(\mathcal{T}Q^{\star} - \mathcal{T}Q_{k-1}) \\ &+ (m + 1)(\mathcal{T}Q^{\star} - \mathcal{T}Q_{0}) + E_{k}\| \\ &\leq \frac{\gamma(k - m - 1) + 1}{k} \|Q^{\star} - Q_{k-1}\| \\ &+ \frac{\gamma(m + 1) + 1}{k} \|Q^{\star} - Q_{0}\| + \frac{\|E_{k}\|}{k} \\ &\leq \frac{\gamma(k - 1)}{k} \|Q^{\star} - Q_{k-1}\| + \frac{2h}{k} V_{\max} + \frac{\|E_{k}\|}{k} \\ &\leq \frac{\gamma^{k - m}}{k} \|Q^{\star} - Q_{m}\| + \frac{2hV_{\max}}{k} \sum_{i=0}^{k - m - 1} \gamma^{i} \\ &+ \sum_{i=0}^{k - m - 1} \frac{\gamma^{i}}{k} \|E_{k-i}\| \\ &\leq 2\frac{\gamma R_{\max} + hV_{\max}}{k(1 - \gamma)} + \frac{1}{k} \sum_{i=0}^{k - m - 1} \gamma^{i} \|E_{k-i}\|, \end{split}$$

where the first inequality follows from the triangle inequality and the contraction property (3), and the second inequality holds due to $\gamma m \ge 1$ and Assumption 2 and $h = \gamma (m + 1) + 1$.

Now we are ready to prove the main results of Theorem 1. The proof builds on the results of Lemma 4 and makes uses of the Maximal Hoeffding-Azuma Inequality (see Lemma 2).

Proof: Plugging k = T in (28) in Lemma 4 and obtain

$$\|Q^{\star} - Q_T\| \leq 2\frac{\gamma R_{\max} + hV_{\max}}{T(1-\gamma)} + \frac{1}{T} \sum_{i=0}^{T-m-1} \gamma^i \|E_{T-i}\|$$

It suffices to bound the second term. Observe that

$$\frac{1}{T} \sum_{i=0}^{T-m-1} \gamma^{i} \| E_{T-i} \| \leq \frac{1}{T} \sum_{i=0}^{T-m-1} \gamma^{i} \max_{0 \leq i \leq T-m-1} \| E_{T-i} \|$$
$$\leq \frac{\max_{0 \leq i \leq T-m-1} \| E_{T-i} \|}{(1-\gamma)T}.$$
(29)

In remains to bound $\max_{0 \le i \le T-m-1} ||E_{T-i}||$. For the sake of convenience, we denote K = T-m-1. Notice that $\max_{0 \le i \le K} ||E_{T-i}|| = \max_{(x,u)} \max_{0 \le i \le K} ||E_{T-i}(x,u)|$. For a given (x, u) and $\varepsilon > 0$, we have

$$\mathbb{P}\left(\max_{0\leqslant i\leqslant K} |E_{T-i}(x,u)| > \varepsilon\right) \\
= \mathbb{P}\left(\left\{\max_{0\leqslant i\leqslant K} (E_{T-i}(x,u)) > \varepsilon\right\} \\
\bigcup \left\{\max_{0\leqslant i\leqslant K} (-E_{T-i}(x,u)) > \varepsilon\right\}\right) \quad (30) \\
= \mathbb{P}\left(\max_{0\leqslant i\leqslant K} (E_{T-i}(x,u)) > \varepsilon\right) + \\
\mathbb{P}\left(\max_{0\leqslant i\leqslant K} (-E_{T-i}(x,u)) > \varepsilon\right),$$

where D_{\max} is derived in Lemma 1. Since $\{\epsilon_k(x, u)\}_{k \ge 0}$ is a martingale difference sequence w.r.t the filtration \mathcal{F}_k as

defined previously, we can apply the Maximal Hoeffding-Azuma inequality (see Lemma 2) as

$$\mathbb{P}\left(\max_{0\leqslant i\leqslant K}(E_{T-i}(x,u))>\varepsilon\right)\leqslant \exp\left(\frac{-\varepsilon^2}{8(K+1)D_{\max}^2}\right)$$
$$\mathbb{P}\left(\max_{0\leqslant i\leqslant K}(-E_{T-i}(x,u))>\varepsilon\right)\leqslant \exp\left(\frac{-\varepsilon^2}{8(K+1)D_{\max}^2}\right).$$

Then we can further bound (30) as

$$\mathbb{P}\left(\max_{0\leqslant i\leqslant K} |E_{T-i}(x,u)| > \varepsilon\right) \leqslant 2\exp\left(\frac{-\varepsilon^2}{8(K+1)D_{\max}^2}\right).$$

Since we consider a finite state-action space where the size of state-action pairs is bounded by n as Assumption 1, we can eventually use the union bound to obtain

$$\mathbb{P}\left(\max_{0\leqslant i\leqslant K} \|E_{T-i}\| > \varepsilon\right) \leqslant 2n \exp\left(\frac{-\varepsilon^2}{8(K+1)D_{\max}^2}\right)$$

By letting $\delta = 2n \exp\left(\frac{-\varepsilon^2}{8TD_{\max}^2}\right)$ we have

$$\mathbb{P}\left(\max_{0\leqslant i\leqslant K} \|E_{T-i}\| \leqslant D_{\max}\sqrt{8(K+1)\log\frac{2n}{\delta}}\right) \ge 1-\delta,$$

where K = T - m - 1. By plugging the above probability bound in (29) we conclude our results.
