Point-mass sensitivity of gravimetric satellites

Robert Spero

robert.spero@jpl.nasa.gov Jet Propulsion Laboratory, Pasadena, CA 91109

Received 12 December 2020;

Abstract

Frequency-domain expressions are found for gradiometer and satellite-to-satellite tracking measurements of a point source on the surface of the Earth. The maximum signal-to-noise ratio as a function of noise in the measurement apparatus is computed, and from that the minimum detectable point mass is inferred. A point mass of magnitude $M_3 = 100$ Gt gives a signal-to-noise ratio of 3 when a GOCE-like gradiometer passes directly over the mass. On the satellite-to-satellite tracking mission GRACE-FO $M_3 = 1.3$ Gt for the microwave instrument and $M_3 = 0.5$ Gt for the laser ranging interferometer. The sensitivity of future GRACE-like missions with different orbital parameters and improved accelerometer sensitivity is explored, and the optimum spacecraft separation for detecting point-like sources is found. The future-mission benefit of improving the accelerometer sensitivity for measurement of non-gravitational disturbances is shown by the resulting reduction of M_3 , to as small as 7 Mt for 500 km orbital altitude and optimized satellite separation of 900 km.

1. Introduction

A global gravity map is the principal data product of satellite gravity missions. Previously CHAMP (Reigber et al. (2003)), GRACE (Tapley et al. (2004)), and GOCE (Drinkwater et al. (2006)) collected data to map the Earth's gravity, and GRAIL (Konopliv et al. (2013)) measured the Moon's gravity. Currently GRACE Follow-On (GRACE-FO, Landerer et al. (2020)) is extending the GRACE data record, with increased ranging precision afforded by its laser ranging interferometer (LRI, Abich et al. (2019)).

As pointed out by Watkins et al. (2015), the most commonly used method of analyzing satellite gravity data is based on global gravity fields expressed in terms of spherical harmonic basis functions. An alternative to spherical harmonics is the mass concentration, or mascon, model. Starting with Wong et al. (1971), the mascon approach was applied to singlesatellite lunar orbital measurements to infer the surface gravity of the moon. Mascons can be modeled as many discrete sources (Pollack (1973), Watkins et al. (2005)) that cover the globe, or used to solve for regional fields. Han (2013) applied mascons

0273-1177/ © 2020 COSPAR. Published by Elsevier Ltd All rights reserved.

to GRAIL data to solve for regional fields of the Moon.

Though they differ slightly in assumptions and results, the spherical harmonic and mascon methods are constructed to answer the same question: what is the gravity field that is most consistent with measurements? Here we address a different question: what is the limit to measurement precision of a pointlike mass on the surface? This is an artificial model, a single mascon, that is not directly applicable to the geodetic agenda of measuring the Earth's gravity. We do not attempt to replicate the global gravity-field inversion achieved by the usual manymascon analysis. Rather, the motivation for this analysis is twofold: to provide a single-number figure of merit, namely the minimum detectable isolated point mass perturbation, and to find the optimal filter for such a detection. The minimum detectable mass M_3 is defined as the point mass that a gives a signal-to-noise ratio $\rho = 3$ in a single orbital pass directly over the point mass. It is calculated by applying the Wiener optimal filter to the problem of detecting a signal of known waveform, against a background specified by instrument noise power spectral density (Wainstein and Zubakov (1970)). A comparison of

 M_3 for different orbital configurations and instrument sensitivities guides the design of future missions. Additionally, we find the optimum satellite separation in GRACE-like missions for a specified instrument noise power spectral density.

2. Gradiometer Mass Sensitivity

Consider a gradiometer flying directly over a point mass M at altitude h, Figure 1 left. At orbital altitude h = 330 km, the

Fig. 1. Measurement of gravitational field from a point mass M at along-track distance x, altitude h, and velocity v. *Left:* Vertical gradient g_z . *Right:* Differential acceleration a_R between spacecraft 1 and 2 with average separation L.

along-track velocity *v* is the orbital velocity $v_o = 7.7$ km/s and the along-track distance *x* changes at approximately constant rate, $x = v_o t$. The acceleration at the spacecraft in the vertical, *z* direction is $a_z = -GMz/(x^2 + z^2)^{3/2}$, and the gradient in the *z* direction is $g_z = da_z/dz = GM[3z^2(x^2 + z^2)^{-5/2} - (x^2 + z^2)^{-3/2}]$. *G* = Newton's constant of gravitation. Substituting $z \to h$ and $x \to v_o t$,

$$g_z(t) = \kappa_g M \left[3(1 + [f_h t]^2)^{-5/2} - (1 + [f_h t]^2)^{-3/2} \right]$$
(1)

where $\kappa_g M = GM/h^3 = 1.85 \times 10^{-3}$ mE with M = 1 Gt and $f_h = v_o/h = 23$ mHz; 1 mE = 1×10^{-12} s⁻². At t = 0, when the gradiometer is directly above the source mass, the gradient reaches its maximum value $g_z = 2\kappa_g M$. At $x = \pm \sqrt{2}h$, $g_z = 0$.

The Fourier transform of p(t) is defined by $\mathcal{F}[p(t)] \equiv p(f) = \int_{-\infty}^{\infty} dt \, p(t) \exp(-2\pi i f t)$. Applying the Fourier transform to $g_z(t)$:

$$g_z(f) = \kappa_g M \frac{4\pi f}{f_h^2} \left[K_1 \left(\frac{2\pi f}{f_h} \right) + \frac{2\pi f}{f_h} K_0 \left(\frac{2\pi f}{f_h} \right) \right]$$
(2)

where K_n is the modified Bessel function of the second kind, order *n*. From Abramowitz and Stegun (1964), Section 9.7.2, $K_n(z) \sim \sqrt{\pi/(2z)}e^{-z}$, where ~ indicates approximately equal for large *z*. At frequency $f \gg f_h$, the measurement response is attenuated approximately exponentially with *e*-folding frequency $f_h/(2\pi) = 3.7$ mHz. This corresponds to harmonic order $N = f_h/(2\pi f_1) = 20$, where $f_1 = 0.183$ mHz is the orbital frequency.

The signal-to-noise ratio ρ depends on the signal and the power spectral density of the gradiometer noise, $S_g(f)$. Define the frequency-dependent signal-to-noise-ratio density SNRD as

$$W_{g_z}(f) = \frac{|g_z(f)|^2}{S_g(f)}.$$
(3)

Fig. 2. Orbiting gradiometer vertical gradient response to a point mass. Upperleft: $g_z(t)$, z-direction gradient in time domain, Equation 1; Upper-right: $g_z(f)$ = Fourier transform, Equation 2; Lower: M_3 = Detectable mass with signal-to-noise = 3, Equation 5.

In general, ρ depends on what filtering is applied to the instrument output. After Flanagan and Hughes (1998), with optimum filtering the maximum signal-to-noise ratio per unit source mass ρ' is

$$\rho' = \sqrt{4 \int_0^\infty W'_{g_z}(f) df}.$$
(4)

Prime superscripts indicate quantities normalized by the source mass: $\rho' = \rho/M$ and $W'_{g_z}(f) = W_{g_z}(f)/M^2$. It follows that the minimum detectable point mass with $\rho = 3$ is

$$M_3 = \frac{3}{\sqrt{4\int_0^\infty W'_{g_z}(f)df}}.$$
 (5)

The lower panel of Figure 2 shows M_3 as a function of orbital altitude *h* for a gradiometer limited by white spectral noise $S_g(f) = 1 \text{ mE}/\sqrt{\text{Hz}}$ (approximated value for GOCE from Touboul et al. (1999), Touboul et al. (1999a)). At h = 330 km, $M_3 = 100 \text{ Gt}$ and the minimum observable gradient at the peak time t = 0 is $2\kappa_g M = 0.37 \text{ mE}$.

3. Sensitivity of GRACE-like measurements

The measurement configuration and signal parameters for the low-low satellite-to-satellite tracking (SST) of GRACE and GRACE-FO are shown in Figure 1, right. The primary signal is the along-track differential position of the spacecraft, measured by microwave ranging or laser interferometry.

3.1. Single Spacecraft Acceleration

For simplicity, the Flat-Earth approximation (Tapley (1997)) is used. This approximation neglects centrifugal acceleration,

which introduces an error of less than 20% at Fourier frequencies greater than 2 mHz (Ghobadi-Far et al. (2018), Figure 1; Müller (2017), Figure 1.7). In this approximation, the acceleration on spacecraft 1 flying over point mass M at along-track distance x is $a_1 = -GMx/(h^2 + x^2)^{3/2}$.

Define the acceleration per unit source mass, $a'_1 = a_1/M$. Then

$$a_1' = -\frac{Gtv_o}{(h^2 + v_o^2 t^2)^{3/2}} \tag{6}$$

Converting to frequency space,

$$a_{1}'(f) = \mathcal{F}[a_{1}'(t)] = \frac{4\pi i f G K_{0}\left(\frac{2\pi f}{f_{h}}\right)}{v_{o}^{2}}.$$
(7)

3.2. Range Acceleration Signal

The acceleration experienced by spacecraft 2 is the same as spacecraft 1 at distance L, but delayed by $\tau = L/v_o$. The resulting (along-track) range acceleration between the spacecraft (Figure 3, left) is similar to what Han (2013) computed for the response of the GRAIL spacecraft to regional lunar gravity. The peak range acceleration a_p^p is

$$a_R^p = \frac{GL}{\left(h^2 + (L/2)^2\right)^{3/2}} M \equiv \kappa_R M,$$
(8)

where $\kappa_R = GL(h^2 + (L/2)^2)^{-3/2}$.

Using the identity $\mathcal{F}(\text{delay }\tau) = \exp(-2\pi i f \tau)$, the range acceleration in the frequency domain, $a_R(f)$, is given by

$$a'_{R}(f) = a'_{1}(f)(1 - e^{-2\pi i f \tau})$$
 (9)

$$|a'_{R}(f)| = 2|a'_{1}(f)\sin(\pi f\tau)|$$
(10)

That is, in the frequency domain the range acceleration is the single-satellite acceleration multiplied by $2|\sin(\pi f\tau)|$. For $f \ll 1/\tau$, $|a_R(f)| \propto L$, which is the response for the spacecraft pair acting as a gradiometer. The response departs from that of a gradiometer at large *L*, most conspicuously in the form of high-frequency nulls where the signal vanishes. The first null is at $f_{\text{null}} = 1/\tau = 38$ mHz for low-Earth orbit and L = 200 km, as recognized by Wolff (1969). In degree-variance evaluations of measurement sensitivity, the first null is expressed as a maximum in geoid height error at degree $N = f_{\text{null}}/f_1 = 216$ for L = 200 km, and N = 86 for L = 500 km, where f_1 = orbital frequency = 0.176 mHz.

From Equations 7 and 10,

$$|a_R'(f)| = \frac{8\pi f G}{v_o^2} \left| K_0\left(\frac{2\pi f}{f_h}\right) \right| \left| \sin\left(\frac{2\pi f}{f_L}\right) \right|,\tag{11}$$

Fig. 3. Range acceleration resulting from a square mass centered under the flight along-track path. Orbital altitude h, average spacecraft separation L and source mass M are indicated in the title. The separate traces are for squares of side S indicated in the legend. *Left*: time domain, $a_R(t)$; *Right*: Fourier Transform, $a_R(f)$.

where

$$v_{o} = \text{orbital velocity} = 7.6 \text{ km/s}$$

$$h = \text{orbital altitude} = 500 \text{ km}$$

$$L = \text{spacecraft separation} = 200 \text{ km}$$

$$f_{h} = \frac{v_{o}}{h} = 15.2 \text{ mHz}$$

$$f_{L} = \frac{v_{o}}{L/2} = 76 \text{ mHz}$$

$$\tau = \frac{L}{v_{o}} = 26 \text{ s}$$

$$\kappa_{R} = \frac{GL}{(h^{2} + (L/2)^{2})^{3/2}} = 0.101 \text{ nm/s}^{2}/\text{Gt}.$$

These numerical values apply to GRACE-FO. The approximately exponential attenuation with frequency of $|a_R(f)|$ has *e*-folding frequency 2.5 mHz, corresponding to harmonic order N = 14.

To explore the valid realm of the point-mass approximation, Figure 3 shows the range acceleration signal from a squareshaped planar mass of side length S, computed by numerical integration. The S=1 km result is in agreement with the pointmass analytical calculation, which is valid at the 20% level for sources as large as S=300 km. Henceforth, we restrict our analysis to the signal from a point source.

Equation 11 gives the measurement impulse response; that is, the range acceleration frequency response to a point mass input. This facilitates the direct comparison of signal and noise amplitudes as computed in the following section, and yields an expression for the minimum detectable mass for GRACE-like measurements of point source perturbations to surface gravity.

3.3. Noise and Mass Sensitivity

Consider the range measurement made by the laser ranging interferometer (LRI) on GRACE-FO. Assuming the measurement resolution is limited by the thermal noise of the laser reference cavity (Numata et al. (2004)), the displacement noise root power spectral density (rpsd) \tilde{x}_{LRI} and strain rpsd \tilde{x}_{LRI}/L are given by

$$\tilde{x}_{\text{LRI}}(f)/L = x_c/\sqrt{f},\tag{12}$$

where x_c is a constant. For the LRI (Abich et al. (2019)), $x_c = 1 \times 10^{-15}$. The rpsd of the LRI range acceleration noise is

$$\sqrt{S_{\text{LRI}}(f)} = (2\pi f)^2 \cdot \tilde{x}_{\text{LRI}}(f).$$
(13)

Take for the accelerometer measurement noise rpsd on a single satellite of GRACE and GRACE-FO (Touboul et al. (1999))

$$\sqrt{S_{ACC_1}(f)} = \tilde{a}_0 \sqrt{1 + \left(\frac{f_k}{f}\right)^2}.$$
(14)

Estaimates of \tilde{a}_0 and f_k range from $3 \times 10^{-11} \text{ m/s}^2 / \sqrt{\text{Hz}}$ and 10 mHz, respectively (Hauk and Wiese (2020)) to $1 \times 10^{-10} \text{ m/s}^2 / \sqrt{\text{Hz}}$ and 5 mHz, respectively (Christophe et al. (2010), Conklin and Nguyen (2017)). We take as a compromise $\tilde{a}_0 = 7 \times 10^{-11} \text{ m/s}^2 / \sqrt{\text{Hz}}$ and $f_k = 5 \text{ mHz}$. Assuming that the acceleration measurements on the two satellites are uncorrelated, the total accelerometer noise is double: $S_{ACC} = 2S_{ACC_1}$.

Improved accelerometers in future missions (Christophe et al. (2010), Conklin and Nguyen (2017)) may have $\tilde{a}_0 = 7 \times 10^{-13} \text{ m/s}^2 / \sqrt{\text{Hz}}$.

The total instrument noise power spectral density is

$$S_a = S_{\rm ACC} + S_{\rm LRI}.$$
 (15)

Figure 4 shows $\sqrt{S_a}$ for different ranging instrument and accelerometer noise spectra. The MWI ranging noise is approximated by white displacement noise, $\tilde{x}_{MWI} = 6 \times 10^{-7} \text{ m}/\sqrt{\text{Hz}}$. This estimate is based on comparing MWI range measurements to simultaneous LRI range measurements. To guide the eye to the frequencies that have the largest signal, $|a_R(f)|$ for a 1 Gt point source from Figure 3 is overlaid as the solid black line. The units of $|a_R|$ are m/s.

As in Section 2, define the SNRD for range acceleration

$$W'_{a}(f) = \frac{|a_{R}(f)|^{2}/M^{2}}{S_{a}(f)}.$$
(16)

 $W_a(f) = W'_a M^2$ is shown in Figure 5 for several values of *L*. The oscillations with nulls at multiples of $1/\tau = v_o/L$ degrade ρ for *L* beyond an optimum spacecraft separation.

The optimal signal-to-noise ratio per unit mass is

$$\rho' = \sqrt{4 \int_0^\infty W_a'(f) df},\tag{17}$$

and the source mass that gives $\rho = 3$ is (cf. Equation 5)

$$M_3 = \frac{3}{\sqrt{4 \int_0^\infty W_a'(f) df}}.$$
 (18)

From Equations 11 through 16 and Equation 18, the GRACE-FO parameters with the microwave ranging instrument (MWI) and LRI give respectively $M_3 = 1.3$ Gt, 0.5 Gt.

Fig. 4. Total range acceleration noise rpsd $\sqrt{S_a}$ for various assumptions of instrument noise. The ranging noise for the "GRACE-FO MWI+ACC" is the white displacement noise of the microwave measurement on GRACE-FO, equal to 6×10^{-7} m/ $\sqrt{\text{Hz}}$. The other two noise curves assume the ranging noise of the LRI, Equation 12, shown as a dotted line. Two levels of $\tilde{a}_0/[\text{m/s}^2/\sqrt{\text{Hz}}]$ are assumed: 7×10^{-11} for the GRACE-FO curves, and 7×10^{-13} for a future mission such as Mass Change Mission (MCM). The solid black line is the signal spectrum $a_R(f)$ from a 1 Gt point mass, for h = 500 km and L = 200 km, units m/s. The values of M_3 for the three respective configurations are (Section 3.3) 1.3 Gt and 0.5 Gt and 7 Mt.

Fig. 5. Signal-to-noise ratio integrand of Equation 16, $W_a(f)$ for the "GRACE-FO LRI + ACC" noise of Figure 4, signal from orbital h = 500 km and source mass M = 1 Gt and three different values of spacecraft separation L. The integrated signal-to-noise ratios ρ from Equation 17 are indicated in the legend.

The corresponding detectable peak accelerations, $\kappa_R M_3$, are 0.13 nm/s², 0.047 nm/s².

Another assessment of mass sensitivity for SST laser ranging is inferred from Colombo and Chao (1992), who proposed a laser ranging mission that, with (h, L) = (600, 500) km was found by simulation to have sensitivity to weekly changes of 1 mm water height over a square region 400 km across, or mass sensitivity of 160 Mt. In comparison, we find for the LRI on GRACE-FO at the same (h, L), $M_3 = 400$ Mt. The two measurements have different assumed instrument sensitivity and averaging times (week-to-week vs. single-pass).

Figure 6 shows the mass sensitivity M_3 as a function of h and L for the LRI ranging instrument with two different levels of accelerometer sensitivity: $\tilde{a}_0 = 7 \times 10^{-11}$ and 7×10^{-13} m/s²/ $\sqrt{\text{Hz}}$. The lower row of Figure 6 shows the optimum L for a given h and the resulting M_3 . The optimum L for the LRI on GRACE-FO, operating at h = 500 km, is

2

L = 900 km, which would give $M_3 = 200$ Mt. That reflects a potential factor of 2.5 improvement over $M_3 = 500$ Mt for the nominal satellite separation of L = 200 km. A future mission with the improved \tilde{a}_0 , h = 500 km, and optimal satellite separation L = 900 km has $M_3 = 7$ Mt.

Fig. 6. Mass sensitivity of the LRI measurement on GRACE-FO *left*, and of a future GRACE-like mission *right*. Upper row shows isomass M_3 contours, in Mt, from Equation 18. Equation 12 specifies the ranging noise, and accelerometer noise is given by Equation 14 with $\tilde{a}_0 = (7 \times 10^{-11}, 7 \times 10^{-13})$ m/s²/ $\sqrt{\text{Hz}}$, with fixed $f_k = 5$ mHz. Lower row shows the optimum L as a function of h, (blue, left axis) and the resulting sensitivity M_3 (red, right axis).

3.4. Optimal filter

. . .

The filter that gives maximum signal-to-noise ratio is (Wainstein and Zubakov (1970), Chapter 3)

$$G(f) = \frac{a_R^*(f)}{S_a(f)},$$
(19)

with * denoting complex conjugation. The filter's input is the measured range acceleration. G(f) is an example of a filter for extracting a signal of known waveform, in this case the range acceleration resulting from flying over a point mass. Dropping the multiplicative constants, the filter magnitude is

$$|G(f)| = \frac{\left| fK_0\left(\frac{2\pi f}{f_h}\right) \sin\left(\frac{2\pi f}{f_L}\right) \right|}{S_a(f)}.$$
(20)

Normalized |G(f)| for the MWI and LRI on GRACE-FO are shown in Figure 7.

Ghobadi-Far et al. (2018) analyzed the GRACE-FO MWI signal in terms of the line-of-sight gravity difference, and applied the same analysis method to the GRACE-FO LRI signal in Ghobadi-Far et al. (2020). In their analysis of MWI data, Ghobadi-Far et al. (2018) defined the gravimetric quantity $\delta g_{12}^{\text{LOS}}$, or line-of-sight (LOS) gravity difference, which differs from the range acceleration residual $\delta \ddot{\rho}$ by Δ_0 , the residual centrifugal acceleration:

$$\delta g_{12}^{\text{LOS}} = \delta \ddot{\rho} + \Delta_0. \tag{21}$$

Residuals are relative to a reference field. The admittance Z(f) is defined as the ratio of power spectra,

$$Z(f) = \frac{S_{\delta\ddot{\rho},\delta\ddot{g}_{12}^{\text{LOS}}}(f)}{S_{\delta\ddot{\rho},\delta\ddot{\rho}}(f)},$$
(22)

where $S_{\delta\bar{\rho},\delta\bar{\rho}}(f)$ is the power spectrum of the MWI range acceleration measurement and $S_{\delta\bar{\rho},\delta g_{12}^{\text{LOS}}}(f)$ is the cross-power spectrum between the range acceleration and the LOS gravity difference. Keeping the shorthand notation $p(f) = \mathcal{F}[p(t)], Z(f)$ is a filter that transforms residual range acceleration $\delta\bar{\rho}(f) = a_R(f)$ to $\delta g_{\text{E}}^{\text{LOS}}(f)$, an estimate of $\delta g_{12}^{\text{LOS}}(f)$:

$$\delta g_{\rm F}^{\rm LOS}(f) = Z(f)\delta\ddot{\rho}(f). \tag{23}$$

Z(f), normalized to have a maximum value of 1, is shown as the dashed trace in Figure 7. Z(f) is the optimal filter to apply to MWI range acceleration, based on the measurement data that includes signal from the gravity field. It applies to extracting the best SNR from a residual regional or global field and does not explicitly depend on instrument noise spectra.

In contrast, G(f) is fine-tuned to the problem of detecting the specific waveform of a point mass, in the presence of known measurement noise. Since a point mass generates a field with the highest possible frequency content, the G(f) passband starts higher in frequency than Z(f). The LRI G(f) passband is higher than for the MWI because the LRI measurement has reduced noise at high frequency.

A practical use for the G(f) filter is searching for unknown point-like features, such as underground water storage of 100 km spatial extent. The filter would be applied to range acceleration measurements after subtracting the effect of the known field, including time-varying gravity, and nongravitational accelerations.

Fig. 7. Transfer functions for range acceleration data. The blue trace that peaks at 2.6 mHz is |G(f)| for the MWI on GRACE-FO, and the red trace that peaks at 5.7 mHz is for the LRI on GRACE-FO. Z(f) is the admittance filter from Ghobadi-Far et al. (2018) Figure 2(b), and applies to the MWI on GRACE-FO. All curves are normalized to give maximum value of 1.

4. Conclusion

We derived the optimum sensitivity of orbiting gravimetric satellites to a point source, that is a single mascon. The signalto-noise ratio is found as a function of instrument noise and orbital parameters. The signal is converted to frequency space by the Fourier transform, and the signal-to-noise ratio is derived from optimal filtering a signal of known waveform. This analysis differs from the conventional approach of spherical harmonic expansion to characterize the field from an arbitrary mass distribution. Such an expansion requires a very large harmonic order to accurately approximate the field from a point source, as shown in Appendix A.

The frequency response of an orbiting gradiometer to a point mass directly under the flight track is approximated by Equation 2 that depends only on the orbital altitude and the magnitude of the point mass. Likewise, for an SST-based measurement of the gravitational field, the range acceleration is approximated by Equation 11 that includes dependency on the average satellite separation. Applying Wiener optimal filter theory, these responses and the noise spectra of the ranging measurement and of accelerometer-based measurement of non-gravitational forces give ρ , the maximum achievable signal-to-noise ratio. The resolvable mass M_3 is defined as the magnitude of the point mass that gives $\rho = 3$. M_3 is the ultimate mass sensitivity, and realistic non-point mass distributions that are not directly under the flight track will give larger M_3 in practice. Nonetheless, M_3 provides a figure of merit for comparing future missions with different orbits and instrument sensitivities to guide the design of such missions. For SST measurements M_3 has a minimum value at a calculable satellite separation L, giving the optimum separation for discovering point-like (meaning less than approximately 300 km) features such as subsurface water storage. Equation 20 specifies the optimal filter for such a search. As a caveat, the M_3 metric and its L optimization does not apply to large-scale gravimetry, such as required by oceanography.

Appendix A. Multipole expansion and the Wahr equation for surface density

The gravitational potential is conventionally expressed as the multipole expansion (Kaula (1966), Kaula (2013), Chao and Gross (1987))

$$U(r,\theta,\phi) = \frac{GM_e}{a} \sum_{n=0}^{\infty} \sum_{m=0}^{n} \left(\frac{a}{r}\right)^{n+1} \overline{P}_{nm}(\cos\theta)$$
(A.1)
 $\times (\overline{C}_{nm} \cos m\phi + \overline{S}_{nm} \sin m\phi).$

As illustrated in Figure A.8 (r, θ, ϕ) = (distance from the center of the Earth, co-latitude, longitude), (a, M_e) = (Earth radius,

Fig. A.8. Coordinate system for the spherical harmonic expansion of geopotential, Kaula (2013). The satellite constellation position, defined as the center of mass for a gradiometer or (illustrated) the center of the line of sight between two SST satellites relative to the center of the Earth, is $\vec{r}(r, \theta, \phi)$, where *r* is the distance from the center of the Earth, θ is the co-latitude, and ϕ is the longitude.

Earth mass), and \overline{P}_{nm} is the fully-normalized associated Legendre function. The field is entirely specified by the Stokes coefficients ($\overline{C}_{nm}, \overline{S}_{nm}$).

For a known mass distribution $dM = \rho(r', \theta', \phi')dV'$ with primes designating the source mass coordinates, $(\overline{C}_{nm}, \overline{S}_{nm})$ are evaluated as the volume integral Bettadpur (2018)

$$\left[\frac{\overline{C}_{nm}}{\overline{S}_{nm}}\right] = \frac{1}{(2n+1)M_e} \int_{V'} dM \left(\frac{r'}{a}\right)^n \overline{P}_{nm}(\lambda') \begin{bmatrix}\cos m\phi'\\\sin m\phi'\end{bmatrix}, (A.2)$$

where $\lambda' = \cos \theta'$. For a point mass at r' = a

$$\left[\frac{\overline{C}_{nm}}{\overline{S}_{nm}}\right] = \frac{M}{(2n+1)M_e}\overline{P}_{nm}(\lambda') \begin{bmatrix}\cos m\phi'\\\sin m\phi'\end{bmatrix}.$$
 (A.3)

A single point mass can be placed at the north pole, $(\theta', \phi') = (0, 0)$ without loss of generality. Then

$$\left[\frac{\overline{C}_{nm}}{\overline{S}_{nm}}\right] = \frac{M}{(2n+1)M_e}\overline{P}_{nm}(1)\begin{bmatrix}1\\0\end{bmatrix}.$$
(A.4)

The relationship between the fully normalized Legendre function \overline{P}_{nm} and the associated Legendre function P_{nm} is

$$\overline{P}_{nm} = \sqrt{\frac{(2 - \delta_{m0})(2n+1)(n-m)!}{(n+m)!}} P_{nm},$$
(A.5)

where δ_{mn} is the Kronecker delta. Since $P_{nm}(1) = \delta_{m0}$, $\overline{P}_{nm}(1) = \delta_{m0} \sqrt{2n+1}$. For a point mass at the pole Equation A.3 reduces to

$$\left[\frac{\overline{C}_{nm}}{\overline{S}_{nm}}\right] = \frac{M}{M_e} \frac{1}{\sqrt{2n+1}} \begin{bmatrix} \delta_{m0} \\ 0 \end{bmatrix}.$$
 (A.6)

The potential from Equations A.1 and A.6 is independent of ϕ and is given by the multipole expansion

$$U(r,\theta) = \frac{GM}{a} \sum_{n=0}^{\infty} \left(\frac{a}{r}\right)^{n+1} P_n(\cos\theta), \qquad (A.7)$$

the familiar expansion from electrostatics for the azimuthally symmetric electric field from a point charge (Jackson (2007)) and from gravitational potential theory (Blakely (1996), Section 6.4.2).

The Wahr equation for surface density from $(\overline{C}_{nm}, \overline{S}_{nm})$ (Wahr et al. (1998)) is

$$\sigma(\theta', \phi') = \frac{a\rho_{\text{ave}}}{3} \sum_{n=0}^{\infty} \sum_{m=0}^{n} \overline{P}_{nm}(\cos \theta') \frac{2n+1}{1+k_n} \times (\overline{C}_{nm} \cos m\phi' + \overline{S}_{nm} \sin m\phi'), \qquad (A.8)$$

where k_n = Love number.

To study the error of a finite-degree spherical harmonic approximation to a point mass, consider a spherical cap in the limit of small cap size. The spherical cap is centered at coordinates (θ', ϕ') and its angular radius is α and $\lambda \equiv \cos \alpha$. As computed by Pollack (1973), the Stokes coefficients are

$$\left[\frac{\overline{C}_{nm}}{\overline{S}_{nm}}\right] = -\frac{M}{M_e} \frac{P_{n+1} - P_{n-1}}{(2n+1)^2(1-\lambda)} \overline{P}_{nm}(\cos\theta') \left[\frac{\cos m\phi'}{\sin m\phi'}\right], (A.9)$$

where we use the shorthand $P_j(\lambda) = P_j$. For a spherical cap at the north pole,

$$\left[\frac{\overline{C}_{nm}}{\overline{S}_{nm}}\right] = -\frac{M}{M_e} \frac{P_{n+1} - P_{n-1}}{(2n+1)^{3/2}(1-\lambda)} \begin{bmatrix} \delta_{m0} \\ 0 \end{bmatrix}.$$
 (A.10)

The spherical cap reduces to a point mass in the limit of $\alpha = 0$, or $\lambda = 1$; substituting

 $\lim_{\lambda \to 1} [P_{n+1} - P_{n-1}] = (\lambda - 1)(2n + 1) = \text{into Equation A.10}$ gives Equation A.6.

By comparing expressions similar to Equation A.1 and Equation A.8, Dickey et al. (1997) identifies

$$\hat{\overline{C}}_{nm} + \hat{\overline{S}}_{nm} = \frac{\rho_{\text{ave}}}{3\rho_w} \frac{2n+1}{1+k_n} (\overline{C}_{nm} + \overline{S}_{nm})$$
(A.11)

where ρ_w is the density of water as the transformation to convert geoid expansion coefficients $(\overline{C}_{nm}, \overline{S}_{nm})$ to mass expansion coefficients $(\overline{C}_{nm}, \overline{S}_{nm})$, p. 101 their Equation (B5).

At the pole, from Equation A.8, dropping the n = 0 term that represents the total potential of the Earth, and neglecting the Earth's elasticity by setting $k_n = 0$,

$$\sigma = \frac{a\rho_{\text{ave}}}{3} \sum_{n=1}^{\infty} \overline{P}_{nm}(1)(2n+1)\overline{C}_{nm}.$$
 (A.12)

From Equation A.10,

$$\sigma = -\frac{M}{M_e} \frac{a}{1-\lambda} \frac{\rho_{\text{ave}}}{3}$$

$$\times \sum_{n=1}^{\infty} \overline{P}_{nm}(1) \frac{2n+1}{(2n+1)^{3/2}} (P_{n+1} - P_{n-1})$$

$$= -\frac{M}{M_e} \frac{a}{1-\lambda} \frac{\rho_{\text{ave}}}{3} \sum_{n=1}^{\infty} P_{n+1} - P_{n-1}$$

$$= \frac{M}{M_e} \frac{a\rho_{\text{ave}}}{3} T_{\infty}.$$
(A.13)

The quantity T_{∞} is the $N = \infty$ limit of the truncated sum, defined as

$$T_{N}(\lambda) = \frac{1}{1-\lambda} \sum_{n=1}^{N} P_{n-1} - P_{n+1}$$

= $\frac{1}{1-\lambda} (P_{0} + P_{1} - (P_{N} + P_{N+1}))$
= $\frac{1+\lambda - (P_{N} + P_{N+1})}{1-\lambda}.$ (A.14)

For a small spherical cap, $\alpha \ll 1$ (and $\lambda = \cos \alpha$ slightly $\ll 1$), the cap area is $A = \pi (a\alpha)^2$. Using $\sigma = M/A$ and $\rho_{ave} = 3M_e/(4\pi a^3)$, Equation A.13 is equivalent to

$$\frac{\alpha^2 T_{\infty}(\cos \alpha)}{4} - 1 = 0.$$
(A.15)

The fractional error in σ due to truncation of the summation Equation A.13 at order *N* is

$$\epsilon_N = \frac{\alpha^2 T_N(\cos \alpha)}{4} - 1 \approx -P_N(\cos \alpha). \tag{A.16}$$

See Figure A.9 for ϵ_N with small spherical caps of two different sizes. The slow reduction of $|\epsilon_N|$ with increasing *N* shows that the unfiltered spherical harmonic expansion is ill-suited to characterize the field from a point-like source. The truncation error is often reduced by applying a spectral localizing filter (Panet et al. (2013), Appendix 2); see also Wahr et al. (1998), Swenson and Wahr (2002), Seo et al. (2005), and Werth et al. (2009).

Fig. A.9. Truncation error, Equation A.16, in representing the field from a mass of small spatial extent by spherical harmonic expansion of order *N*. The dashed lines follow the large *N* asymptote envelope, $\pm P_N(\cos \alpha) \sim \pm \sqrt{2/(\pi N \sin \alpha)}$.
