Abstract

An additive quaternary $[n, k, d]$ -code (length n , quaternary dimension k , minimum distance d) is a $2k$ -dimensional \mathbb{F}_2 -vector space of n -tuples with entries in $Z_2 \times Z_2$ (the 2-dimensional vector space over \mathbb{F}_2) with minimum Hamming distance d . We determine the optimal parameters of additive quaternary codes of dimension $k \leq 3$. The most challenging case is dimension $k = 2.5$. We prove that an additive quaternary $[n, 2.5, d]$ -code where $d < n - 1$ exists if and only if $3(n - d) \geq \lceil d/2 \rceil + \lceil d/4 \rceil + \lceil d/8 \rceil$. In particular we construct new optimal 2.5-dimensional additive quaternary codes. As a by-product we give a direct proof for the fact that a binary linear

$[3m, 5, 2e]_2$ -code for $e < m - 1$ exists if and only if the Griesmer bound $3(m - e) \geq \lceil e/2 \rceil + \lceil e/4 \rceil + \lceil e/8 \rceil$ is satisfied.

Keywords: Quaternary additive codes, projective spaces, optimal codes, binary linear codes.

1 Introduction

The concept of additive codes is a far-reaching and natural generalization of linear codes, see [2], Chapter 18. Here we restrict to the quaternary case.

Definition 1. *Let k be such that $2k$ is a positive integer. An additive quaternary $[n, k]$ -code C (length n , dimension k) is a $2k$ -dimensional subspace of \mathbb{F}_2^{2n} where the coordinates come in pairs of two. We view the codewords as n -tuples where the coordinate entries are elements of \mathbb{F}_2^2 and use the Hamming distance.*

We write the parameters of the code as $[n, k, d]$ where d is the minimum Hamming distance. Here k is the quaternary dimension. As an example, in case $k = 2.5$ the code is a 5-dimensional vector space over \mathbb{F}_2 . Additive codes are particularly interesting because of a link to quantum stabilizer codes, see [4, 5, 9]. We will also use the geometric construction of additive quaternary codes. In fact, a quaternary $[n, k, d]$ -code is equivalent to a multiset of n lines in $PG(2k - 1, 2)$ such that each hyperplane of $PG(2k - 1, 2)$ contains at most $s = n - d$ of those lines, in the multiset sense. Blokhuis and Brouwer [8] first suggested the problem of determining the optimum parameters of additive quaternary codes. In earlier work we determined all such optimal parameters when $n \leq 13$, see [2], Chapter 18 and [6]. For further results concerning larger lengths see [1, 7]. In the present work we determine all optimal parameters when the quaternary dimension is $k \leq 3$. Dimensions $k \leq 2$ are degenerate cases, see Section 2. Dimension 3 is easily dealt with as well, see Section 3. Our main result is Theorem 2 in Section 4 where the optimal parameters of 2.5-dimensional additive quaternary codes are determined. For $k > 1$ we prefer to work with the **species** $s = n - d$ instead of the minimum distance d . Define $n_k(s)$ to be the maximal length n such that an additive $[n, k, n - s]$ -code exists. For integer k , let $n_{k,lin}(s)$ be the maximal n such that a linear quaternary $[n, k, n - s]_4$ -code exists. In the present paper we determine $n_k(s)$ for $k \leq 3$ and all s . The following obvious lemma will be used to prove nonexistence results:

Lemma 1. *The concatenation of a quaternary additive $[n, k, d]$ -code and the binary linear $[3, 2, 2]_2$ -code is a binary linear $[3n, 2k, 2d]_2$ -code.*

2 Dimensions $k \leq 2$.

Clearly dimension $k = 1$ is a trivial case, the optimal parameters being $[n, 1, n]$. Dimension $k = 1.5$ is degenerate as well. The ambient space is the Fano plane and the optimal choice is to use each of its seven lines with multiplicity s . This shows $n_{1.5}(s) = 7s$. The corresponding codes have parameters $[7s, 1.5, 6s]$. Dimension $k = 2$ still is degenerate. In the linear case we have $n_{2,lin}(s) = 5s$. In fact we work in the projective line $PG(1, 4)$ and the optimal choice is to use each of its points with multiplicity s .

Proposition 1. *We have $n_2(s) = n_{2,lin}(s) = 5s$ for all s .*

Proof. Assume $n_2(s) > 5s$. We would have a $[5s + 1, 2, 4s + 1]$ -code. Lemma 1 would yield a binary linear $[15s + 3, 4, 8s + 2]_2$ -code. This contradicts the Griesmer bound. \square

3 The case of dimension $k = 3$.

The optimal parameters of linear quaternary 3-dimensional codes are of course known:

Proposition 2. *We have $n_{3,lin}(2) = 6, n_{3,lin}(3) = 9, n_{3,lin}(4) = 16,$*

$n_{3,lin}(5i) = 21i, n_{3,lin}(5i + 1) = 21i + 1$ and $n_{3,lin}(5i + \sigma) = 21i + 1 + 5(\sigma - 1)$

for $i \geq 1, \sigma \in \{2, 3, 4\}$.

Proof. For $d < 9$ this is easy to check. For larger d we can invoke a result by Hamada-Tamari [10] stating that linear $[n, 3, d]_q$ -codes for $d \geq (q - 1)^2$ exist if and only if the parameters satisfy the Griesmer bound (see [2], Theorem 17.7). This coincides with the statement of our proposition. \square

Theorem 1. *We have $n_3(s) = n_{3,lin}(s)$ for all s .*

Proof. Assume there is an additive 3-dimensional code with larger n and the same species. We illustrate with case $s = 5i$. We would have a $[21i + 1, 3, 16i + 1]$ -code. Lemma 1 yields a linear $[63i + 3, 6, 32i + 2]_2$ -code, which contradicts the Griesmer bound. The other cases are analogous. \square

4 The case of dimension 2.5.

Our main result is the following:

Theorem 2. *An additive quaternary $[n, 2.5, d]$ -code where $d < n - 1$ exists if and only if $3(n - d) \geq \lceil d/2 \rceil + \lceil d/4 \rceil + \lceil d/8 \rceil$.*

In the present section we prove Theorem 2. In the sequel use the abbreviation $d_l = \lceil d/l \rceil$. The necessity is obvious. In fact, Lemma 1 applied to an additive quaternary $[n, 2.5, d]$ -code yields a binary linear $[3n, 5, 2d]_2$ -code. The condition of Theorem 2 is the Griesmer bound as applied to this binary code. It remains to prove sufficiency: given d, n satisfying the condition of the theorem we need to construct an additive quaternary $[n, 2.5, d]$ -code. As before, let $s = n - d$. For each s consider the pair $D_s = (s, m_s)$ where m_s is the maximal n such that $n, d = n - s$ satisfy the condition in Theorem 2. We need to prove the existence of an $[m_s, 2.5, m_s - s]$ -code, for all $s \geq 2$. When such a code exists we say that we represented D_s . Here are some examples:

$$D_2 = (2, 8), D_3 = (3, 11), D_4 = (4, 16), D_5 = (5, 21), D_6 = (6, 26), D_7 = (7, 31).$$

Let C be an $[n, 2.5, d]$ -code and C' the code obtained by increasing each line multiplicity of C by 1. As $PG(4, 2)$ has 155 lines and $PG(3, 2)$ has 35 lines we see that C' is an $[n + 155, 2.5, d + 120]$ -code. Concerning the bound of the theorem we observe that $3(n - d) - d_2 - d_4 - d_8$ is invariant under the substitution $n \mapsto n + 155, d \mapsto d + 120$. This shows that we need prove the existence of an $[n, 2.5, d]$ -code only for $n < 155$. This means that it suffices to construct $D_2, D_3, \dots, D_{35} = (35, 155)$. Observe that there is an obvious sum construction which shows that the existence of codes $[m_1, 2.5, l_1]$ and $[m_2, 2.5, l_2]$ implies the existence of an $[m_1 + m_2, 2.5, l_1 + l_2]$ -code. This shows that if D_{s_1} and D_{s_2} can be constructed then also $D_{s_1} + D_{s_2}$ can be constructed. We see now that it suffices to construct D_2, \dots, D_7 as the remaining $D_s, s \leq 35$ follow from the sum construction. Here are some examples:

$$D_8 = D_6 + D_2, D_9 = D_7 + D_2, D_{10} = D_5 + D_5, D_{11} = D_9 + D_2, D_{12} = D_6 + D_6.$$

It remains to construct D_2, \dots, D_7 . Now D_2 implies D_4 as $D_2 + D_2 = D_4$ and $D_5 = (5, 21)$ is constructed as there is even a linear $[21, 3, 16]_4$ -code (corresponding to the points of $PG(2, 4)$). We are reduced to construct D_2, D_3, D_6, D_7 . Now $D_2 = (2, 8)$ corresponds to a $[8, 2.5, 6]$ -code. This is

the Blokhuis-Brouwer construction [8, 3]. In the same context an [11, 2.5, 8]-code was constructed. This is a representation of $D_3 = (3, 11)$. We are finally reduced to construct D_6 and D_7 .

A construction

Consider a chain

$$l_0 \subset E_0 \subset H_0 \subset PG(4, 2)$$

where l_0 is a line, E_0 a plane and H_0 a solid (hyperplane) in $PG(4, 2)$. Let \mathcal{V} be a set of 8 lines such that each point in $E_0 \setminus l_0$ is on precisely two lines of \mathcal{V} , each point outside H_0 is on precisely one line of \mathcal{V} . Also, let \mathcal{E} be a set of 8 lines partitioning the points outside E_0 (Blokhuis-Brouwer construction).

Definition 2. Let $C(g, h, v, e)$ be the additive 2.5-dimensional quaternary code described by the following multiset of lines: line l_0 with multiplicity g , the remaining lines of E_0 each with multiplicity h , the lines of \mathcal{V} with multiplicity v and the lines of \mathcal{E} with multiplicity e .

Clearly $C(g, h, v, e)$ has length $n = g + 6h + 8v + 8e$. Let $m(P)$ be the number of codelines (including multiplicities) that contain point P . If $P \in l_0$, then $m(P) = g + 2h$, if $P \in E_0 \setminus l_0$ then $m(P) = 3h + 2v$. If $P \in H_0 \setminus E_0$ then $m(P) = e$ whereas points P outside H_0 have $m(P) = v + e$. For each hyperplane H let $m(H) = \sum_{P \in H} m(P)$. By double counting we obtain

$$s(H) = (m(H) - n)/2$$

where $s(H)$ (the species of H) is the number of codelines contained in H . It follows that the numbers $n - s(H)$ are the nonzero weights of our code. The numbers $m(H)$ and $s(H)$ are easy to determine:

Lemma 2. If $l_0 \not\subset H$ then $m(H) = g + 8h + 12v + 12e$.

If $l_0 \subset H$ but $E_0 \not\subset H$ then $m(H) = 3g + 6h + 8v + 12e$.

If $E_0 \subset H \neq H_0$ then $m(H) = 3g + 18h + 16v + 8e$.

Finally $m(H_0) = 3g + 18h + 8v + 8e$.

Proof. This is a trivial calculation. In the first case above H has one point of l_0 , two further points in E_0 , four further points in H_0 and finally 8 affine points for a grand total $m(H) = g + 8h + 4v + 4e + 8(v + e)$. In the second case H contains three points on l_0 , no further point on E_0 , four further points on H_0 and eight affine points: $m(H) = 3g + 6h + 4e + 8(v + e)$. The remaining two cases are analogous. \square

Our basic formula yields:

Corollary 1. *The nonzero weights of the codewords of $C(g, h, v, e)$ are*

$$g + 5h + 6(v + e), 6h + 8v + 6e, 4v + 8e, 8(v + e).$$

$C(g, h, v, e)$ is an $[g + 6h + 8(v + e), 2.5, d]_4$ -code where

$$d = \text{Min}(w_1 = g + 5h + 6(v + e), w_2 = 6h + 8v + 6e, w_3 = 4v + 8e).$$

We see that $C(2, 0, 1, 2)$ is a $[26, 2.5, 20]$ -code and $C(1, 1, 0, 3)$ is a $[31, 2.5, 24]$ -code. This completes the proof of Theorem 2. Lemma 1 yields

Corollary 2. *A binary linear $[3m, 5, 2e]_2$ -code for $e < m - 1$ exists if and only if the Griesmer bound $3(m - e) \geq e_2 + e_4 + e_8$ is satisfied.*
