## 1 Introduction

A common goal in areas of science and engineering that rely on making accurate assessments of performance and risk (e.g. aerospace engineering, finance, geophysics, operations research) for complex systems is to be able to guarantee the quality of the assessments being made. Very often, the knowledge of the system is incomplete or contains some form of uncertainty. There can be uncertainty in the form of the governing equations, in information about the parameters, in the collected data and measurements, and in the values of the input variables and their bounds. One of the most common cases is that initial conditions and/or boundary conditions are known only to a certain level of accuracy. Even in the case where the dynamics of a system is known exactly at a fine-grained level, computationally more tractable coarse-grained models of the system often have to be derived under approximation, and thus contain uncertainty. One way to refine a model of a system under uncertainty is to perform experiments to help solidify what is known about the parameters and/or the form of the governing equations. Sampling methods (such as Monte Carlo) can be used to determine the predictive capacity of the models under the resulting uncertainty. Unfortunately, this determination can be computationally costly, inaccurate, and in many cases impractical.

One promising approach to dealing with this challenge is Optimal Uncertainty Quantification (OUQ) developed by Owhadi et al [11, 13, 8]. OUQ integrates the knowledge available for both mathematical models and any knowledge that constrains outcomes of the system, and then casts the problem as a constrained global optimization problem in a space of probability measures; this optimization is made tractable by reducing the problem to a finite-dimensional effective search space of discrete probability distributions, parameterized by positions and weights. Much of the early work with OUQ has been to provide rigorous certification for the behavior of engineered systems such as structures under applied stresses or metal targets under impact by projectiles [11, 6].

## 2 OUQ for Model Validation and Experiment Design

The need to make possibly critical decisions about complex systems with limited information is common to nearly all areas of science and industry. The design problems used to formulate statistical estimators are typically not well-posed, and lack a well-defined notion of solution. As a result, different teams with the same goals and data will find vastly different statistical estimators, solutions, and notions of uncertainties. We claim that the recently developed OUQ theory, combined with recent software enabling fast global solutions of constrained non-convex optimization problems, provides a methodology for rigorous model certification, validation, and optimal design under uncertainty. This OUQ-based methodology is especially pertinent in the context of beamline science, where data analysis generally (1) lacks full automation, (2) requires an expert, and (3)commonly utilizes phenomenological profile functions with loosely-defined statements of validity. The lack of automated analysis and rigorously validated models create a bottleneck in the scientific throughput of beamline science. For example, instrument scientists generally use very conservative back-of-the-envelope estimates to ensure sufficient beamtime is allocated to produce high-quality data. Consequently, a significant portion of the beamtime that could be used for new science is wasted.

The validation of a statistical estimators against real-world data generally is a laborious manual process. Significant human effort is spent cleaning and reducing data, as well as selecting, training, and validating the statistical estimators for each special-case. High-performance computing (HPC), however, offers an alternative approach: posing the construction of an optimal statistical estimators as an at-scale optimization problem. In this new paradigm, human intellectual effort goes into the design of an over-arching optimization problem, instead of being spent on manual derivation and validation of a statistical estimators. We propose a methodology for optimal design/planning under uncertainty, where our tools enable the determination of the impact of any new piece of information on all possible valid outcomes. Our vision is that HPC combined with OUQ will stimulate the emergence of a new paradigm where the parameter space to conduct key experiments is numerically designed and optimized. We leverage the mystic optimization framework [7, 9] to impose constraining information from different sources on the search space of an optimizer, where the solution produced respects all constraints from the different data/models/etc. Once all available information has been encoded as constraints, the numerical transform generated from these constraints guarantees that any solution is valid with respect to the constraints. We can then use this methodology, for example, in the validation of phenomenological models against high-fidelity materials theory codes, or in the calculation of the minimum beamtime required to ensure data has met a high-quality threshold, or in other design of experiments questions.

# 3 Outline

In the remainder of this manuscript, we demonstrate utility of the OUQ approach to understanding the behavior of a system that is governed by a partial differential equation (and more specifically, by Burgers' equation). In particular, we solve the problem of predicting shock location when we only know bounds on viscosity and on the initial conditions. We will calculate the bounds on the probability that the shock location occurs at a distance greater than some selected target distance, given there is uncertainty in the location of the left boundary wall. Through this example, we demonstrate the potential to apply OUQ to complex physical systems, such as systems governed by coupled partial differential equations. We compare our results to those obtained using a standard Monte Carlo approach, and show that OUQ provides more accurate bounds at a lower computational cost. As OUQ can take advantage of solution-constraining information that Monte Carlo cannot, and requires fewer assumptions on the form of the inputs, the predicted bounds from OUQ are more rigorous than those obtained with Monte Carlo. We conclude with a brief discussion of how to extend this approach to more complex systems, and note how to integrate our approach into a more ambitions program of optimal experimental design.

#### 4 Burgers' Equation with a Perturbed Boundary

For a viscous Burgers' equation:

$$u_t + uu_x - vu_{xx} = 0$$

with  $x \in [-1, 1]$  and viscosity v > 0, we have:

$$u(-1) = 1 + \delta$$
$$u(1) = -1$$

where  $\delta > 0$  is a perturbation to the left boundary condition. The solution has a transition layer, which is a region of rapid variation, and has location z, defined as the zero of the solution profile u(z) = 0 which varies with time and at steady state is extremely sensitive to the boundary perturbation [15]. The exact solution of Burgers' equation with the small *deterministic* perturbed boundary condition, at a steady state, is:

$$u(x) = -A \tanh(\frac{A}{2v}(x - z_*))$$

Here,  $z_*$  is defined as the location of the transition layer where  $u(z_*) = 0$ , and the slope at  $z_*$  is  $-A = \frac{\partial u}{\partial x}|_{x=z_*}$ . We can solve for the two unknowns  $z_*$  and A with:

$$A \tanh(\frac{A}{2v}(1-z_*)) - 1 = 0$$

$$A \tanh(\frac{A}{2v}(1+z_*)) - 1 - \delta = 0$$
(1)

#### 5 Solving for Location of the Transition Layer

The equations in (1) are considered difficult to solve exactly due to the high nonlinearity of the solution space. Solving the viscous Burgers' equation with approximate numerical methods can still be difficult, as the aforementioned supersensitivity of the solution can lead to a large variance in solved  $z_*$  for a distribution of input  $\delta$  and v. We will use the **mystic** optimization framework to solve for  $z_*$  and A directly, and will compare to approximate numerical results obtained by Xiu [15].

We use an ensemble (mystic.solvers.lattice) of Nelder-Mead optimizers to solve objective for  $z_*$  and A, for the given bounds, v, and  $\delta$ . The bounds and objective are defined as in Figure 1, bounding  $z_*$  in [0, 1], and with an objective to find the minimum of  $\sum_{i=0}^{1} abs(eqns_i)$ . Values for solved  $z_*$  are presented in Table 1, and reproduce exactly the results of numerical solution of the exact formula found by Xiu. Xiu notes that iterative methods were used to solve the system of nonlinear equations, and that the convergence is very sensitive to the choice of initial guess. With mystic.solvers.lattice, the solution is found reliably for  $z_*$  in [0, 1] and A unbounded, where convergence with mystic is between  $1.1e^{-16}$  and  $8.6e^{-18}$  for all given combinations of v and  $\delta$ . On a 2.7 GHz Macbook with an Intel Core i7 processor and 16 GB 1600 MHz DDR3 memory, running python 2.7.14 and mystic 0.3.2, solutions to (1) are found in ~ 0.15 seconds.

#### 6 Monte Carlo Sampling of Transition Layer Futures

If we assume the location of the left wall  $\delta$  is a uniform random variable in  $(0, \epsilon)$ :

$$\delta \sim U(0,\epsilon),$$

we can then repeatedly solve for location of the transition layer  $z_*$  where  $u(z_*) = 0$ , using Monte Carlo sampling. By inspecting the cumulative distribution function cdf of solved  $z_*$  (Figure 2), we can get an idea of the likelihood of  $z_*$  occurring at location z. A more quantitative measure of likelihood can be obtained by calculating the mean location  $\bar{z}_*$ and standard deviation  $\sigma_{z_*}$  of the futures of z. Plots of the cdf of  $\delta$  (Figure 3) can be

δ	$z_*$ with $v = 0.1$	$z_*$ with $v = 0.05$
1e-1	0.72322525	0.86161262
1e-2	0.47492741	0.73746015
1e-3	0.24142361	0.62030957
1e-4	0.05266962	0.50487264
1e-5	0.00550856	0.38970223
0.0	3.689827 e-9	1.489844e-6

Table 1: Location of the transition layer  $z_*$  found by solving Burgers' equation directly with mystic for select v and  $\delta$ . Solving Burger's equation for a given  $\delta$  and v also produces A, where  $A \simeq \pm (1.0 + \delta)$ .

```
### exact_supersensitive.py :: solve Burgers' equation for v and delta ###
from math import tanh
from mystic import reduced
from mystic.solvers import lattice
bounds = [(0,1), (None, None)]
@reduced(lambda x,y: abs(x)+abs(y))
def objective(x, v, delta):
  z, A = x
  return [A * tanh(0.5 * (A/v) * (1. - z)) - 1.,
          A * tanh(0.5 * (A/v) * (1. + z)) - 1. - delta]
def solve(v, delta):
  "solve for (z,A) in analytical solution to burgers equation"
  result = lattice(objective, ndim=2, nbins=4, args=(v, delta),\
                   bounds=bounds, ftol=1e-8, disp=False, full_output=True)
  return delta,result[0],result[1]
if __name__ == '__main__':
  for v in [0.1, 0.05]:
    for delta in [1e-1, 1e-2, 1e-3, 1e-4, 1e-5, 0.]:
      _, result, fit = solve(v, delta)
      print "v, delta:", (v, delta)
      print "z, A:", result.tolist()
      print fit, "\n"
```

Figure 1: Solving Burgers' equation directly with mystic for several v and  $\delta$ . The lattice solver starts nbins Nelder-Mead optimizers at the center-points of a uniform grid instead of requiring a single initial value for (z,A). A lambda function is used to reduce the output of the objective to a single value. Results are summarized in Table 1.

used to validate that our inputs were sampled from a distribution closely resembling the theoretical cdf, and also helps ensure we select an appropriate number of futures N in the calculation of likelihood of success,  $P(z_* > \frac{x\bar{z}_*}{100})$ , where we define "success" as when the transition occurs at a  $z_*$  greater than  $\frac{x\bar{z}_*}{100}$  for a given scaling x.

The code in Figure 4 details how we sample M = 110000 instances of  $\delta$  from  $U(0, \epsilon)$  for each combination of v and  $\epsilon$ . The M samplings of  $\delta$  are passed into solve, and produce N futures of z. An unordered iterative map uimap from pathos.pools.ProcessPool provides embarrassingly-parallel invocations of solve. Although we start with M samplings, solutions of solve with convergence less than  $tol = 1e^{-9}$  are discarded, and results are calculated until we have N solutions of (1) within tolerance tol. The N futures of z, and corresponding  $\delta$ , for each  $(v, \epsilon)$ , are then sorted and saved to a file. Discarding solutions that fail to converge within tol does not appear to bias the results, and solve fails to achieve the desired tolerance tol in very few of the M attempts. For example, with N = 100000, v = 0.05, and  $\epsilon = 0.01$ , only 3 of M = 110000 (~  $2.7e^{-3}$ %) possible invocations of solve fail to achieve the desired convergence tol. In going to much larger N, we find that the normalized cumulative distribution of discarded  $\delta$  approximates the sampling distribution for all combinations of  $(v, \epsilon)$ , thus discarding the poorly converged solutions does not appear have any bias on the results. For the above case, results for Nfutures of z were obtained in 2:09:42.320102 using 8-way parallel on the above-specified Macbook. Timings and number of discarded  $\delta$  were similar for all combinations of v and  $\epsilon$  (as seen in Table 4).

The choice of the sampling distribution  $U(0, \epsilon)$  is somewhat arbitrary. For example, we can instead assume  $\delta$  is a random variable with a truncated Gaussian distribution:

$$\delta \sim G(0, \epsilon, \epsilon/2, \sqrt{\epsilon^2/12}),$$

where  $\epsilon/2$  and  $\sqrt{\epsilon^2/12}$  are, respectively, the theoretical mean and standard deviation of  $\delta$ . As seen in the code in Figure 5, we will choose the range, mean, and standard deviation of the truncated Gaussian distribution to be the same as those of the uniform distribution  $U(0, \epsilon)$ . Additionally, choosing identical moments will better facilitate more direct comparisons of results between the two distributions. We again discard solutions that fail to converge within to1, and again note that the discarded  $\delta$  do not appear to bias the results. Sampling from  $\delta \sim G(0, \epsilon, \epsilon/2, \sqrt{\epsilon^2/12})$ , with N = 100000, v = 0.1, and  $\epsilon =$ 0.01, using the above-specified Macbook, provides results in 2:02:04.456247, where again only 2 of M = 110000 invocations of solve fail to meet the desired convergence. As with  $U(0, \epsilon)$ , timings and the number of discarded  $\delta$  are generally similar for all combinations of v and  $\epsilon$ .

The code in Figure 6 details how  $\bar{z}_*$ ,  $\sigma_{z_*}$ ,  $\bar{\delta}$ ,  $\sigma_{\delta}$ ,  $\mathsf{cdf}(z_*)$ , and  $\mathsf{cdf}(\delta)$  are calculated. First, the results calculated using the Monte Carlo sampling in Figure 4 are loaded from disk. Then, for each N in [100, 1000, 2000, 5000, 100000, 100000], N individual  $z_*$  are randomly selected for calculations of  $\bar{z}_*$ ,  $\sigma_{z_*}$ ,  $\bar{\delta}$ ,  $\sigma_{\delta}$ , and  $\mathsf{cdf}(z_*)$  (if inputs is False) or  $\mathsf{cdf}(\delta)$ (if inputs is True). The use of numpy.random.choice ensures N unique  $z_*$  and  $\delta$  are selected for the calculations of mean, standard deviation, and  $\mathsf{cdf}$ . The strategy used of writing intermediate results to disk is meant to reduce computational cost, as the expensive Monte Carlo sampling of the solve function will not need to be repeated for each new evaluation of  $\bar{z}_*, \sigma_{z_*}, \delta, \sigma_{\delta}, \mathsf{cdf}(z_*)$  and  $\mathsf{cdf}(\delta)$ . The calculated mean locations  $\bar{z}_*$  and corresponding standard deviations  $\sigma_{z_*}$ , due to uniform random perturbations  $\delta \sim U(0,\epsilon)$ on the boundary condition, are presented in Table 2 for v = 0.05,  $\epsilon = 0.1$ , and several values of N. Results for  $\delta \sim G(0, \epsilon, \epsilon/2, \sqrt{\epsilon^2/12})$ , are also presented in the same table. Looking at Table 2, one can infer that roughly N = 10000 or greater should be used to calculate  $\bar{z}_*$  and  $\sigma z_*$ . The quality of the results due to increasing N samplings of  $\delta \sim U(0,\epsilon)$  can be visualized in plots of  $cdf(z_*)$  and  $cdf(\delta)$ , in Figure 2 and Figure 3, respectively. Similarly, plots for  $\delta \sim G(0, \epsilon, \epsilon/2, \sqrt{\epsilon^2/12})$  are shown in Figure 7 and Figure 8. The representative quality of the sampled distribution for large N is seen by  $cdf(\delta)$ closely approximating the theoretical cdf. While Figure 7 shows that the basic shape of the  $cdf(z_*)$  sharpens for smaller v and doesn't change dramatically for any choice of  $\epsilon$ , it is apparent that the location of  $\bar{z}_*$  does change with  $\epsilon$ . A comparison can be more quantitatively made by examining the moments of  $z_*$ , as is presented in Table 3. Results for  $\bar{z}_*, \sigma_{z_*}, \delta$ , and  $\sigma_{\delta}$  for N = 100000 Monte Carlo realizations of  $\delta$ , for all combinations of v and  $\epsilon$  considered, for both  $\delta \sim U(0,\epsilon)$  and  $\delta \sim G(0,\epsilon,\epsilon/2,\sqrt{\epsilon^2/12})$ . It should be noted that the moments  $\delta$ , and  $\sigma_{\delta}$  for both the selected truncated Gaussian and uniform distributions of  $\delta$  are constant with respect to v, and are directly scaled with  $\epsilon$ . Also note that the moments of  $\delta \sim U(0,\epsilon)$  and  $\delta \sim G(0,\epsilon,\epsilon/2,\sqrt{\epsilon^2/12})$  are not a perfect match; the mean of  $\delta$  is roughly identical, however  $\sigma_{\delta}$  for each distribution is only similar. The results show that  $\bar{z_*}$  decreases with decreasing  $\epsilon$ , where the decrease in  $\epsilon$  is more pronounced for larger v. The behavior of  $\sigma_{z_*}$  mirrors that of  $\bar{z_*}$ , but on a smaller scale. Note that small perturbations in  $\epsilon$  (or v) can lead to significant differences in the stochastic response in the output. Looking back at results from Xiu [15], we note that results for  $\bar{z}_*$  with  $\delta \sim U(0,\epsilon)$ are very consistent, while the results for  $\sigma_{z_*}$  are less so.

To get an idea of the dynamics of u(z) in (1), we find stochastic solutions of Burgers' equation with a left boundary wall at  $\delta \sim U(0, \epsilon)$  for a given v and  $\epsilon$ . The code in Figure 9 additionally provides the dynamics at an estimate of where the tails of the distribution for  $z_*$  might be located – it finds the solutions of u(z) at  $\delta(v, \max(\bar{z}_* - 3 * \sigma_{z_*}, 0))$  and  $\delta(v, \min(\bar{z}_* + 3 * \sigma_{z_*}, \epsilon))$ . Results are shown in Figure 10.

δ	N	100	1000	2000	5000	10000	100000

Figure 9: Calculation of u(z) due to direct solution of Burger's equation at the lower and upper limit of  $\delta$  and at  $\delta(v, \bar{z}_*)$ . We also solve for u(z) at  $\delta(v, \max(\bar{z}_* - 3 * \sigma_{z_*}, 0))$  and  $\delta(v, \min(\bar{z}_* + 3 * \sigma_{z_*}, \epsilon))$ . The values of z and std are copied from Table 3.

Figure 10: Stochastic solutions for  $\delta \sim U(0, \epsilon)$  and v. The upper and lower boundaries, zub and zlb, are the deterministic solutions corresponding to the limiting values of the random inputs for  $\delta$  (i.e.  $[0, \epsilon]$ ). Also shown are max and min, calculated using z which are at most three standard deviations away from  $\bar{z}_*$  (i.e. ave).

#### 7 Using Sampling to Estimate Probability of Success

The probability that some condition is true can be determined in a very straightforward way by sampling. By applying sampling on an indicator function that defines the criteria for "success", we can calculate the probability of success P(success). We define

success := 
$$\begin{cases} z_* > \frac{x\bar{z_*}}{100}, \text{ with} \\ x = 100 + dx, dx \in [0, 15] \end{cases}$$
(2)

(i.e. when the shock occurs at a distance  $z_*$  that is greater than the product of average distance  $\bar{z}_*$  and scaling factor  $\frac{x}{100}$ ). The scaling factor is introduced to demonstrate the decrease in probability of success as the target distance for the shock event moves further away from the origin.

The code in Figure 11 details how the indicator function success is passed the samples generated by the code in Figure 4, and is used to produce P(success). Monte Carlo estimates for P(success) can be found in Figure 16 for both  $\delta \sim U(0, \epsilon)$  and  $\delta \sim G(0, \epsilon, \epsilon/2, \sqrt{\epsilon^2/12})$ . While the code in Figure 11 uses v = 0.1 and eps = 0.1, simply editing those two variables will calculate P(success) for other values of v and  $\epsilon$ . As see in the latter figure, the selection of a different distribution for  $\delta$  does have an effect on the results, with the probability of success for  $\delta \sim U(0, \epsilon)$  found to be slightly greater than for  $\delta \sim G(0, \epsilon, \epsilon/2, \sqrt{\epsilon^2/12})$ . Additional calculation time required, beyond what is

```
listed in Table 4, is negligible.
```

```
### pof_supersensitive.py :: calculate P(success) with Monte Carlo ###
v, eps = 0.1, 0.1
M = 100000 # number of samples
pcnt = range(0, 16)
import numpy as np; import pickle
from mystic.math.measures import mean, std
fname = 'burgers_MC_{}_deltas_v_{}_eps_{}.pkl'.format(M,v,eps)
with open(fname, 'rb') as f:
  z = pickle.load(f)
z = z['z']
z_{, s_z = mean(z), std(z)
print "v, eps, N:", (v, eps, M)
print "mean, std:", z_{,s_z} # sampled mean and std of z_{\{ast\}}
success = lambda z,zave: z > zave # define "success" indicator function
for p in pcnt:
  dz = round(1 + 0.01*p, 2)
  prob = success(z, z_{\ast}dz).sum()/float(len(z)) # probability of success
  print "P(z > %r*bar\{z\}) = %r" % (dz,prob)
```

Figure 11: Monte Carlo estimate for probability of success  $P(z_* > \frac{x\bar{z}_*}{100})$  at  $\delta \sim U(0, \epsilon)$  (or  $\delta \sim G(0, \epsilon, \epsilon/2, \sqrt{\epsilon^2/12})$ ) for  $\epsilon = 0.1$  and v = 0.1. We define success as where  $z_* > \frac{x\bar{z}_*}{100}$ , with x = 100 + dx,  $dx \in [0, 15]$  as in (2). See Figure 18(b) for the resulting distribution when the sampling of  $\delta$  and subsequent calculation of P(success) is repeated 100000 times.

# 8 Calculating Bounds on Probability of Success

The value of P(success) is dependent on sampling  $\delta \sim U(0, \epsilon)$  (or  $\sim G(0, \epsilon, \epsilon/2, \sqrt{\epsilon^2/12})$ ); thus, any new sampling of  $\delta$  will likely yield slightly different results for P(success). A natural question is: How different? This question can be directly addressed if the distribution of calculated P(success) is known. The most common way of resolving the output distribution for a given function, given random variable inputs, is (maybe unsurprisingly) Monte Carlo sampling. Thus, by running the code in Figures 4 and 11 repeatedly, we can begin to resolve what the output distribution of P(success) looks like for different samplings of  $\delta$  (Figure 18(b)). A simple way to identify lower and upper bounds on P(success) is to use the minimum and maximum values found in the sampled distribution of P(success). In Figure 16, we see the sampled bounds obtained thusly for 100000 independent calculations of P(success), each with N = 100000 independent samplings of  $\delta$ . The results show an obvious trend of decreasing P(success) for increasing  $\epsilon$ . It also appears that P(success) decreases with decreasing v, to the point where P(success) is 0. Additionally, when one compares sampling of  $\delta \sim U(0, \epsilon)$  versus  $\delta \sim G(0, \epsilon, \epsilon/2, \sqrt{\epsilon^2/12})$ , sampling from the uniform distribution yields slightly larger P(success).

In engineering, finance, and many fields of science, there is a goal of minimizing risk or optimizing design for a given system under uncertainty. Minimization of risk, or optimization of design, can be performed without full knowledge of the output distribution of the system, if the most likely and extremal output values of the system are known. Thus, in addition to the most likely value (as found in the previous section), we are also interested in determining the greatest upper bound and the least lower bound, with certainty. Knowing the greatest upper bound and least lower bound for probability of success enables us to make guaranteed decisions about the system. If we don't know the extrema, then we fall into the realm of having some measure of confidence in our predictions (as opposed to being able to guarantee with certainty). With respect to the system defined by (1), have we thus far found the *optimal* lower and upper bounds for P(success)? No, likely not. Given more time, and more samplings of  $\delta$ , it is likely that eventually a more extremal value of P(success) will be found. Given the current computational cost of 2  $hr \times 100000$  (22.8 years, without hierarchical parallel computing – or alternately, roughly 35 days on 256 compute nodes with 8 cores each), it's unlikely that better bounds will be found in a reasonable time and reasonable use of computing resources. Ultimately, to find the optimal lower and upper bounds, we need a change in approach.

#### 9 An OUQ Refresher

Rigorous quantification of the effects of epistemic and aleatoric uncertainty is an increasingly important component of research studies and policy decisions in science, engineering, and finance. In the presence of incomplete imperfect knowledge (sometimes called *epistemic uncertainty*) about the objects involved, and especially in a high-consequence decision-making context, it makes sense to adopt a posture of *healthy conservatism*, i.e. to determine the best and worst outcomes consistent with all available knowledge. This posture naturally leads to uncertainty quantification (UQ) being posed as an optimization problem. Such optimization problems are typically high dimensional, and hence can be difficult and expensive to solve computationally (depending on the nature of the constraining information).

In [11, 13], a theoretical framework is outlined for *optimal uncertainty quantification* (OUQ), namely the calculation of optimal lower and upper bounds on probabilistic output quantities of interest, given quantitative information about (underdetermined) input probability distributions and response functions. In their computational formulation [8, 9], whose derivation we outline below, OUQ problems require optimization over discrete (finite support) probability distributions of the form

$$\mu = \sum_{i=0}^{M} w_i \delta_{x_i},\tag{3}$$

where i = 0, ..., M is a finite range of indices, the  $w_i$  are non-negative weights that sum to 1, and the  $x_i$  are points in some input parameter space  $\mathcal{X}$ ;  $\delta_a$  denotes the Dirac measure (unit point mass) located at a point  $a \in \mathcal{X}$ , i.e., for  $E \subseteq \mathcal{X}$ ,

$$\delta_a(E) := \begin{cases} 1, & \text{if } a \in E, \\ 0, & \text{if } a \notin E. \end{cases}$$

Note that  $\delta_{x_i}$  signifies a unit point mass, and not  $\delta$  the position of the left boundary wall; however, in the next section, we will see for the example in this paper that  $\delta_{x_i} = \delta$ .

Many UQ problems such as certification, prediction, reliability estimation, and risk analysis can be posed as the calculation or estimation of an expected value, i.e. an integral, although this expectation (integral) may depend in intricate ways upon various probability measures, parameters, and models. This point of view on UQ is similar to that of [1], in which formulations of many problem objectives in reliability are represented in a unified framework, and the decision-theoretic point of view of [12]. In the presentation below, an important distinction is made between the "real" values of objects of interest, which are decorated with daggers (e.g.  $g^{\dagger}$  and  $\mu^{\dagger}$ ), versus possible models or other representatives for those objects, which are not so decorated.

The system of interest is a measurable response function  $g^{\dagger} \colon \mathcal{X} \to \mathcal{Y}$  that maps a measurable space  $\mathcal{X}$  of *inputs* into a measurable space  $\mathcal{Y}$  of outputs. The inputs of this response function are distributed according to a probability measure  $\mu^{\dagger}$  on  $\mathcal{X}$ ;  $\mathcal{P}(\mathcal{X})$ denotes the set of all probability measures on  $\mathcal{X}$ . The UQ objective is to determine or estimate the expected value under  $\mu^{\dagger}$  of some measurable quantity of interest  $q \colon \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$ , i.e.

$$\mathbb{E}_{X \sim \mu^{\dagger}}[q(X, g^{\dagger}(X))]. \tag{4}$$

The probability measure  $\mu^{\dagger}$  can be interpreted in either a frequentist or subjectivist (Bayesian) manner, or even just as an abstract probability measure. A typical example is that the event  $[g^{\dagger}(X) \in E]$ , for some measurable set  $E \subseteq \mathcal{Y}$ , constitutes some undesirable "failure" outcome, and it is desired to know the  $\mu^{\dagger}$  probability of failure, in which case q is the indicator function

$$q(x,y) := \begin{cases} 1, & \text{if } y \in E, \\ 0, & \text{if } y \notin E. \end{cases}$$

In practice, the real response function and input distribution pair  $(g^{\dagger}, \mu^{\dagger})$  are not known precisely. In such a situation, it is not possible to calculate (4) even by approximate methods such as Monte Carlo or other sampling techniques for the simple reason that one does not know *which* probability distribution to sample, and it may be inappropriate to simply assume that a chosen model pair  $(g^{\mathrm{m}}, \mu^{\mathrm{m}})$  is  $(g^{\dagger}, \mu^{\dagger})$ . However, it may be known (perhaps with some degree of statistical confidence) that  $(g^{\dagger}, \mu^{\dagger}) \in \mathcal{A}$  for some collection  $\mathcal{A}$  of pairs of functions  $g: \mathcal{X} \to \mathcal{Y}$  and probability measures  $\mu \in \mathcal{P}(\mathcal{X})$ . If knowledge about which pairs  $(g, \mu) \in \mathcal{A}$  are more likely than others to be  $(g^{\dagger}, \mu^{\dagger})$  can be encapsulated in a probability measure  $\pi \in \mathcal{P}(\mathcal{A})$  — what a Bayesian probabilist would call a *prior* — then, instead of (4), it makes sense to calculate or estimate

$$\mathbb{E}_{(g,\mu)\sim\pi}\Big[\mathbb{E}_{X\sim\mu}[q(X,g(X))]\Big].$$
(5)

(A Bayesian probabilist would also incorporate additional data by conditioning to obtain the *posterior* expected value of q.)

However, in many situations, either due to lack of knowledge or being in a highconsequence regime, it may be either impossible or undesirable to specify such a  $\pi$ . In such situations, it makes sense to adopt a posture of *healthy conservatism*, i.e. to determine the best and worst outcomes consistent with the available knowledge. Hence, instead of (4) or (5), it makes sense to calculate or estimate

$$\underline{Q}(\mathcal{A}) := \inf_{(g,\mu)\in\mathcal{A}} \mathbb{E}_{X\sim\mu}[q(X,g(X))] \quad \text{and}$$
(6a)

$$\overline{Q}(\mathcal{A}) := \sup_{(g,\mu)\in\mathcal{A}} \mathbb{E}_{X\sim\mu}[q(X,g(X))].$$
(6b)

If the probability distributions  $\mu$  are interpreted in a Bayesian sense, then this point of view is essentially that of the robust Bayesian paradigm [2] with the addition of uncertainty about the forward model(s) g. Within the operations research and decision theory communities, similar questions have been considered under the name of distributionally robust optimization [4, 5, 12]. Distributional robustness for polynomial chaos methods has been considered in [10]. Our interest lies in providing a UQ analysis for (4) by the efficient calculation of the extreme values (6).

In order to compute the extreme values of the optimization problems (6), an essential step is finding finite-dimensional problems that are equivalent to (i.e. have the same extreme values as) the problems (6). This will be achieved by reducing the search over all measures to a search over discrete measures of the form (3). A strong analogy can be made here with finite-dimensional linear programming: to find the extreme value of a linear functional on a polytope, it is sufficient to search over the extreme points of the polytope; the extremal scenarios of  $\mathcal{A}$  turn out to consist of discrete functions and probability measures that are themselves far more singular than would "typically" be encountered "in reality" but nonetheless encode the full range of possible outcomes in much the same way as a polytope is the convex hull of its "atypical" extreme points.

One general setting in which a finite-dimensional reduction can be effected is that in which, for each candidate response function  $g: \mathcal{X} \to \mathcal{Y}$ , the set of input probability distributions  $\mu \in \mathcal{P}(\mathcal{X})$  that are admissible in the sense that  $(g, \mu) \in \mathcal{A}$  is a (possibly empty) generalized moment class. More precisely, assume that it is known that the  $\mu^{\dagger}$ -distributed input random variable X has K independent components  $(X_0, \ldots, X_{K-1})$ , with each  $X_k$  taking values in a Radon space<sup>1</sup>  $\mathcal{X}_k$ ; this is the same as saying that  $\mu^{\dagger}$  is a product of marginal probability measures  $\mu_k^{\dagger}$  on each  $\mathcal{X}_k$ . By a "generalized moment class", we mean that interval bounds are given for the expected values of finitely many<sup>2</sup> test functions  $\varphi$  against either the joint distribution  $\mu$  or the marginal distributions  $\mu_k$ . This setting encompasses a wide spectrum of possible dependence structures for the components of X, all the way from independence, through partial correlation (an inequality constraint on  $\mathbb{E}_{\mu}[X_iX_j]$ ), to complete dependence ( $X_i$  and  $X_j$  are treated as a single random variable ( $X_i, X_j$ ) with arbitrary joint distribution). This setting also allows for coupling of the constraints on g and those on  $\mu$  (e.g. by a constraint on  $\mathbb{E}_{\mu}[g]$ ).

To express the previous paragraph more mathematically, we assume that our information about reality  $(g^{\dagger}, \mu^{\dagger})$  is that it lies in the set  $\mathcal{A}$  defined by

$$\mathcal{A} := \left\{ (g,\mu) \middle| \begin{array}{l} g \colon \mathcal{X} = \mathcal{X}_0 \times \dots \times \mathcal{X}_{K-1} \to \mathcal{Y} \text{ is measurable,} \\ \mu = \mu_0 \otimes \dots \otimes \mu_{K-1} \text{ is a product measure on } \mathcal{X}, \\ \langle \text{conditions that constrain } g \text{ pointwise} \rangle \\ \mathbb{E}_{\mu}[\varphi_j] \leq 0 \text{ for } j = 1, \dots, N, \\ \mathbb{E}_{\mu_k}[\varphi_{k,j_k}] \leq 0 \text{ for } k = 0, \dots, K-1, j_k = 1, \dots, N_k \end{array} \right\}$$
(7)

for some known measurable functions  $\varphi_j \colon \mathcal{X} \to \mathbb{R}$  and  $\varphi_{k,j_k} \colon \mathcal{X}_k \to \mathbb{R}$ . In this case, the following reduction theorem holds:

**Theorem 9.1** ([11, §4]). Suppose that  $\mathcal{A}$  is of the form (7). Then

$$\underline{Q}(\mathcal{A}) = \underline{Q}(\mathcal{A}_{\Delta}) \quad and \quad \overline{Q}(\mathcal{A}) = \overline{Q}(\mathcal{A}_{\Delta}), \tag{8}$$

where

$$A_{\Delta} := \left\{ (g,\mu) \in \mathcal{A} \middle| \begin{array}{c} for \ k = 0, \dots, K-1, \\ \mu_k = \sum_{i_k=0}^{N+N_k} w_{k,i_k} \delta_{x_{k,i_k}} \\ for \ some \ x_{k,1}, x_{k,2}, \dots, x_{k_{N+N_k}} \in \mathcal{X}_k \\ and \ w_{k,1}, w_{k,2}, \dots, w_{k_{N+N_k}} \ge 0 \\ with \ w_{k,1} + w_{k,2} + \dots + w_{k_{N+N_k}} = 1 \end{array} \right\}.$$
(9)

Informally, Theorem 9.1 says that if all one knows about the random variable  $X = (X_0, \ldots, X_{K-1})$  is that its components are independent, together with inequalities on N generalized moments of X and  $N_k$  generalized moments of each  $X_k$ , then for the purposes of solving (6) it is legitimate to consider each  $X_k$  to be a *discrete* random variable that takes at most  $N + N_k + 1$  distinct values  $x_{k,0}, x_{k,1}, \ldots, x_{k,N+N_k}$ ; those values  $x_{k,i_k} \in \mathcal{X}_k$  and their corresponding probabilities  $w_{k,i_k} \geq 0$  are the optimization variables.

<sup>&</sup>lt;sup>1</sup>This technical requirement is not a serious restriction in practice, since it is satisfied by most common parameter and function spaces. A *Radon space* is a topological space on which every Borel probability measure  $\mu$  is *inner regular* in the sense that, for every measurable set E,  $\mu(E) = \sup\{\mu(K) \mid K \subseteq E \text{ is compact}\}$ . A simple example of a non-Radon space is the unit interval [0, 1] with the lower limit topology.

<sup>&</sup>lt;sup>2</sup>This is a "philosophically reasonable" position to take, since one can verify finitely many such inequalities in finite time.

For the sake of conciseness and to reduce the number of subscripts required, multiindex notation will be used in what follows to express the product probability measures  $\mu$  of the form

$$\mu = \bigotimes_{k=0}^{K-1} \sum_{i_k=0}^{N+N_k} w_{k,i_k} \delta_{x_{k,i_k}}$$

that arise in the finite-dimensional reduced feasible set  $\mathcal{A}_{\Delta}$  of equation (9). Write  $\mathbf{i} := (i_0, \ldots, i_{K-1}) \in \mathbb{N}_0^K$  for a multi-index, let  $\mathbf{0} := (0, \ldots, 0)$ , and let

$$\boldsymbol{M} := (M_0, \dots, M_{K-1}) := (N + N_0, \dots, N + N_{K-1}).$$

Let  $\#\boldsymbol{M} := \prod_{k=1}^{K} (M_k + 1)$ . With this notation, the  $\#\boldsymbol{M}$  support points of the measure  $\mu$ , indexed by  $\boldsymbol{i} = \boldsymbol{0}, \ldots, \boldsymbol{M}$ , will be written as

$$\boldsymbol{x_i} := (x_{1,i_1}, x_{2,i_2}, \dots, x_{K,i_K}) \in \mathcal{X}$$

and the corresponding weights as

$$w_{i} := w_{1,i_1} w_{2,i_2} \dots w_{K,i_K} \ge 0,$$

so that

$$\mu = \bigotimes_{k=0}^{K-1} \sum_{j_k=0}^{N+N_k} w_{k,j_k} \delta_{x_{k,j_k}} = \sum_{i=0}^{M} w_i \delta_{x_i}.$$
 (10)

It follows from (10) that, for any integrand  $f: \mathcal{X} \to \mathbb{R}$ , the expected value of f under such a discrete measure  $\mu$  is the finite sum

$$\mathbb{E}_{\mu}[f] = \sum_{i=0}^{M} w_i f(\boldsymbol{x}_i) \tag{11}$$

(It is worth noting in passing that conversion from product to sum representation and back as in (10) is an essential task in the numerical implementation of these UQ problems, because the product representation captures the independence structure of the problem, whereas the sum representation is best suited to integration (expectation) as in (11).)

Furthermore, not only is the search over  $\mu$  effectively finite-dimensional, as guaranteed by Theorem 9.1, but so too is the search over g: since integration against a measure requires knowledge of the integrand *only* at the support points of the measure, only the #M values  $y_i := g(x_i)$  of g at the support points  $\{x_i \mid i = 0, \ldots, M\}$  of  $\mu$  need to be known. So, for example, if  $g^{\dagger}$  is known, then it is only necessary to evaluate it on the finite support of  $\mu$ . Another interesting situation of this type is considered in [13], in which  $g^{\dagger}$  is not known exactly, but is known via legacy data at some points of  $\mathcal{X}$  and is also known to satisfy a Lipschitz condition — in which case the space of admissible g is infinite-dimensional before reduction to the support of  $\mu$ , but the finite-dimensional collection of admissible values  $(y_0, \ldots, y_M)$  has a polytope-like structure. Theorem 9.1, formulae (10)–(11), and the remarks of the previous paragraph imply that  $\overline{Q}(\mathcal{A})$  is found by solving the following finite-dimensional maximization problem (and  $Q(\mathcal{A})$  by the corresponding minimization problem):

maximize: 
$$\sum_{i=0}^{M} w_{i}q(\boldsymbol{x}_{i}, y_{i});$$
(12)  
among:  $y_{i} \in \mathcal{Y}$  for  $\boldsymbol{i} = \boldsymbol{0}, \dots, \boldsymbol{M},$   
 $w_{k,i_{k}} \in [0, 1]$  for  $k = 0, \dots, K - 1$  and  $i_{k} = 0, \dots, M_{k},$   
 $x_{k,i_{k}} \in \mathcal{X}_{k}$  for  $k = 0, \dots, K - 1$  and  $i_{k} = 0, \dots, M_{k};$   
subject to:  $y_{i} = g(\boldsymbol{x}_{i})$  for some  $\mathcal{A}$ -admissible  $g: \mathcal{X} \to \mathcal{Y},$   
$$\sum_{i=0}^{M} w_{i}\varphi_{j}(\boldsymbol{x}_{i}) \leq 0 \text{ for } j = 1, \dots, N,$$
$$\sum_{i_{k}=0}^{M_{k}} w_{k,i_{k}}\varphi_{k,j_{k}}(x_{k,i_{k}}) \leq 0 \text{ for } k = 0, \dots, K - 1 \text{ and } j_{k} = 1, \dots, N_{k},$$
$$\sum_{i_{k}=0}^{M_{k}} w_{k,i_{k}} = 1 \text{ for } k = 0, \dots, K - 1.$$

Generically, the reduced OUQ problem (12) is non-convex, although there are special cases that can be treated using the tools of convex optimization and duality [3, 4, 12, 14]. Therefore, numerical methods for global optimization must be employed to solve (12). Unsurprisingly, the numerical solution of (12) is much more computationally intensive when #M is large — the so-called *curse of dimension*.

#### 10 Rigorous Upper Bounds on Probability of Success

The OUQ problem at hand is to find the global maximum of the probability function P(success), where success is the success/failure criterion on solutions of (1) defined in (2). Substituting into (6), we have q(x, y) = success, g(X) = model,

$$\underline{Q}(\mathcal{A}) := \inf_{\mu \in \mathcal{A}} \mathbb{P}_{\mu}[\texttt{success}], \quad \text{and}$$
(13a)

$$\overline{Q}(\mathcal{A}) := \sup_{\mu \in \mathcal{A}} \mathbb{P}_{\mu}[\texttt{success}].$$
(13b)

Unlike sampling methods, OUQ doesn't require the distribution of the input random variables to be specified; we instead represent the unknown probability distribution by a product measure (composed of discrete support points, each with an accompanying weight), and any constraining information is specified in the set  $\mathcal{A}$ . Specifically, we will

define  $\mathcal{A}$  as constraints on the feasible set of solutions, where:

$$\mathcal{A} = \left\{ (g, \mu) \middle| \begin{array}{l} g = \texttt{model} : \mu \in [\texttt{lb}, \texttt{ub}] \to \mathbb{R}, \\ \mu = \sum_{i=0}^{3} w_i \delta_i, \\ \sum_{i=0}^{3} w_i = 0, \\ \mathbb{E}_{\mu}[g] = \texttt{z\_mean}, \\ \bar{\mu} = \texttt{d\_mean} \end{array} \right\}$$
(14)

This imposes a mean constraint on  $\delta$ , a mean constraint on  $z_*$ , and normalizes the weights. We will use three support points to represent the product measure in the problem. To solve this OUQ problem, we will need to write the code for the bounds, constraints, and objective function -- then we will plug the code into a global optimizer.

The optimization is performed by leveraging the product\_measure class in the mystic software. The code in Figures 12, 13, 14, and 15 detail how to use mystic to find the upper bound on P(success) at  $\delta \sim U(0, \epsilon)$  with v = 0.1 and  $\epsilon = 0.1$  under the constraints defined in  $\mathcal{A}$ . While the code in Figure 12 is specifically for v = 0.1 and eps = 0.1, editing those two variables – and looking up the corresponding  $\bar{z}_*, \sigma_{z_*}, \bar{\delta}$ , and  $\sigma_{\delta}$  in Table 3 – will enable calculations of the upper bound of P(success) for other values of v and  $\epsilon$ . Similarly, making the modification MINMAX = 1 will produce the lower bound instead of the upper bound. In general, the code in Figure 14 imposes the constraints,  $\mathcal{A}$ , on the product measure used in the optimization problem. Specifically \_constrain imposes a mean constraint for  $\delta$  on the product measure c, and constrain imposes a mean constraint for  $z_*$  on c and additionally normalizes the measure's weights. These constraints are used by solver (in Figure 15) to specify the feasible set of solutions that the optimizer can search. In terms of implementation, simple constraints on input parameter ranges are imposed with the SetStrictRanges method, and all other constraints are imposed with the SetConstraints method. If we add or subtract new constraints in  $\mathcal{A}$ , we then will have to modify the corresponding code in Figure 14.

Results are plotted in Figure 17 for:

$$\mathcal{A} = \left\{ (g, \mu) \middle| \begin{array}{l} g = \texttt{model} : \mu \in [\texttt{lb}, \texttt{ub}] \to \mathbb{R}, \\ \mu = \sum_{i=0}^{3} w_i \delta_i, \\ \sum_{i=0}^{3} w_i = 0, \\ \sigma_g = \texttt{d\_std}, \\ \bar{\mu} = \texttt{d\_mean} \end{array} \right\}$$
(15)

and:

$$\mathcal{A} = \left\{ (g, \mu) \middle| \begin{array}{l} g = \texttt{model} : \mu \in [\texttt{lb}, \texttt{ub}] \to \mathbb{R}, \\ \mu = \sum_{i=0}^{3} w_i \delta_i, \\ \sum_{i=0}^{3} w_i = 0, \\ \bar{\mu} = \texttt{d\_mean} \end{array} \right\}$$
(16)

for  $\epsilon \in 0.1, 0.01, 0.001$  and  $v \in 0.05, 0.1$ . From the figure, we can see that increasing  $\epsilon$  tightens the bounds. This is in part due to the selection of **d\_mean** and **d\_std** from Table 3, where the values for each  $\epsilon$  and v are different. Perhaps a better, or just an alternate,

comparison would be to use a fixed d\_mean and d\_std for all optimizations on the set of  $\epsilon$  and v above. It's also notable that when comparing the constraints defined in (15) versus (16), we see that the presence of new information (the variance constraint) causes a tightening of the bounds.

In Figure 18(a), we further explore the notion that adding new constraining information to  $\mathcal{A}$  tightens the bounds. We examine the OUQ bounds calculated in four cases: (14), (15), (16), and

$$\mathcal{A} = \left\{ (g, \mu) \middle| \begin{array}{l} g = \texttt{model} : \mu \in [\texttt{lb}, \texttt{ub}] \to \mathbb{R}, \\ \mu = \sum_{i=0}^{3} w_i \delta_i, \\ \sum_{i=0}^{3} w_i = 0, \\ \mathbb{E}_{\mu}[g] = \texttt{z\_mean}, \end{array} \right\}$$
(17)

and also compare to the bounds calculated with Monte Carlo sampling. We see very clearly when comparing results for (14) and (17) that the presence of a new constraint tightens the bounds. Similarly for (15) and (16). Additionally, the difference in the bounds calculated with OUQ compared to the bounds found using Monte Carlo sampling is striking. The Monte Carlo bounds are much tighter – however, are not the *optimal* upper and lower bounds on P(success) – they are merely estimates. The bounds calculated from OUQ are rigorous *optimal* upper and lower bounds. Upon reflection, this should be expected, as the OUQ optimization drives the solver to the extrema of P(success), while Monte Carlo sampling will struggle to select values at the tails of the distribution.

The computational cost of OUQ versus Monte Carlo should also be noted. Not only does OUQ provide better bounds, but it does so at a greatly reduced computational cost. The cost of an OUQ calculation is strongly dependent on the form of constrain (see Table 5). If an equation exists that maps the space to the feasible set, then the optimization typically is faster than without the constraint; however, for numerically imposed constraints (e.g. a nested optimization), the cost tends to be much larger. Constraints on the output of q(X) also tend to be expensive, as imposing a constraint on the output will require several evaluations of q(X) each iteration, in addition to the required number of evaluations by the optimization algorithm itself. The timings in Table 5 are for the DifferentialEvolution2 solver, which is a robust global optimizer, but can be quite slow to converge. Time to solution could be improved by judicious tuning of the optimization settings (e.g. npop, ngen, crossover, etc), or use of an ensemble (e.g. lattice) of fast solvers as used in Figure 1. Timings are presented for a 2.7 GHz Macbook with an Intel Core i7 processor and 16 GB 1600 MHz DDR3 memory, running python 2.7.14 and mystic 0.3.2. Notably, the OUQ calculations can be performed in a reasonable time on a relatively good laptop, while the estimation of upper and lower bounds using Monte Carlo sampling requires institutional computing resources.

One will notice that the OUQ section did not specify whether  $\delta \sim U(0, \epsilon)$  or  $\delta \sim G(0, \epsilon, \epsilon/2, \sqrt{\epsilon^2/12})$  was used. This is because definitions of  $\mathcal{A}$  specified constraints on the moments of  $\delta$  and  $z_*$ , and did not specify a particular input or output distribution. While it is possible to specify the distribution of the input (or output) random variables in  $\mathcal{A}$ , it is in reality unlikely that this information is actually known – more commonly, only the

moment information is known about the input and output variables due to measurements taken on the system. OUQ is built to handle these kinds of physical constraints explicitly, while Monte Carlo cannot.

Figure 15: Define an objective function, then configure the optimizer and solve for lower and upper bounds of the probability of success  $P(z_* > \frac{x\bar{z}_*}{100})$  at  $\delta \sim U(0, 0.1)$  and v = 0.1. objective essentially constructs a product measure from the parameter vector, and then calculates the probability of failure. objective also includes two safety checks that throw out any solutions in the unlikely case that the constraints solver constraints fails to impose the constraints. The solver uses a Differential Evolution algorithm to find the minimum of objective with respect to bounds 1b and ub and constraints constraints. Custom termination conditions are used to signal when solver should stop, while SaveSolver preserves the final state of solver to a file. Results are shown in Figures 17 and 18(a).

Figure 16: Monte Carlo estimate for probability of success  $P(z_* > \frac{x\bar{z_*}}{100})$ , with bounds also calculated by Monte Carlo sampling. Plots are shown in each subfigure for three values of  $\epsilon$ , where  $\delta \sim U(0, \epsilon)$  or  $\delta \sim G(0, \epsilon, \epsilon/2, \sqrt{\epsilon^2/12})$ . The Monte Carlo bounds are estimated by repeatedly (100000 times) performing N = 100000 independent samplings of  $\delta$  and calculating P(success) for each iteration – then selecting the minimum and maximum from the resulting distribution of P(success). The average P(success) for  $\delta \sim U(0, \epsilon)$  are shown in all plots, for ease of comparison between results using the two different distributions of  $\delta$ .

Figure 17: Monte Carlo estimate for probability of success  $P(z_* > \frac{x\bar{z}_*}{100})$ , with bounds calculated by OUQ. Plots are shown in each subfigure for three values of  $\epsilon$ , where  $\delta \sim U(0, \epsilon)$ . OUQ bounds are calculated with a mean constraint on  $\delta$  (dotted lines), and with a mean constraint and a variance constraint on  $\delta$  (dashed lines). The presence of new information (i.e. the variance constraint) can be seen to tighten the bounds. As expected, P(success) decreases with increasing x.

	$\overline{\delta}$	$ar{\delta}\sigma_{\delta}$	$ar{z_*}$	$ar{\delta}ar{z_*}$
upper	0:03:02	0:20:08	1 day, 22:47:18	18:41:05
lower	0:00:03	0:01:39	0:00:00	1 day, 09:54:17

Table 5: Sample timings for OUQ optimizations defined by (13 - 17), where the name of the column is an indication of the unique constraint applied (e.g.  $\bar{\delta}$  is a mean constraint on  $\delta$ ). The vast difference in timing is due to both the topological nature of the P(success) for the chosen values of v and  $\epsilon$ , and the nature of the constraints in  $\mathcal{A}$ . Note that the optimizations leverage 100000 Monte Carlo realizations of  $\delta$  from Figure 4. The values in the table correspond to a single point on Figure 17.

Figure 18: Monte Carlo estimate for probability of success  $P(z_* > \frac{x\bar{z}_*}{100})$  at  $\delta \sim U(0, 0.1)$ and v = 0.1, with bounds calculated by OUQ. OUQ bounds are calculated with a mean constraint on  $\delta$ , a mean constraint and a variance constraint on  $\delta$ , a mean constraint on z, and a mean constraint on  $\delta$  and a mean constraint on z. The effect of having different information constraints can be seen on the calculated lower and upper bounds. More specifically, the presence of additional information can be seen to generally tighten the bounds. Notice the striking difference between the bounds calculated with OUQ and Monte Carlo sampling. The plot of the distribution of 100000 Monte Carlo sampled values of  $P(z_* > \frac{x\bar{z}_*}{100})$  emphasize how much more capable OUQ is at describing behavior governed by rare events.

#### 11 Discussion and Future Work

In this manuscript, we demonstrate utility of the OUQ approach to understanding the behavior of a system that is governed by partial differential equations (more specifically, by Burgers' equation). In particular, we solve the problem of predicting shock location when we know only bounds on viscosity and on the initial conditions. We calculate bounds on P(success) given the uncertainty in  $\delta$ , using both a standard Monte Carlo sampling approach, and OUQ. The results highlight the stark contrast in the ability of each approach to elucidate the rare-event behavior that occurs at the tails of the unknown distribution of  $\delta$ . OUQ uses numerical optimization to discover the governing behavior at the tails of the distribution for input random variables. In contrast, using Monte Carlo sampling to find accurate extremal behavior in many cases is computationally infeasible. OUQ finds optimal upper and lower bounds on the quantity of interest with regard to the constraining information  $\mathcal{A}$  in the system, while Monte Carlo can only provide an estimate of the upper and lower bounds – and as mentioned above, requires assumptions on the form of the distribution for the input random variables. In short, OUQ provides more accurate bounds at a lower computational cost, and additionally can take advantage of solution-constraining information that Monte Carlo cannot. Since OUQ requires fewer assumptions on the form of the inputs, the predicted bounds are more rigorous than those obtained with Monte Carlo.

OUQ is a very capable but relatively new approach, and has not yet been applied in many fields of science and engineering. This manuscript is the first application of OUQ (that we know of) to a complex system governed by partial differential equations. In our example, we had moment constraints on the input and output variables; however, OUQ is a general formalism, and has been shown to handle other types of constraining physical and statistical information (e.g. legacy data and associated uncertainties, uniqueness, further moments) [11, 13, 6]. Adding further constraining information often has the drawback of making an OUQ calculation more expensive (as complex nested numerical optimizations may be needed to produce the space of feasible solutions). The cost of the optimization is roughly due to the most expensive inner optimization times the number of iterations. Hence, there is a trade-off of adding information and the potential computational cost/complexity [8].

In this manuscript, we used OUQ to solve for the optimal probability of success. We direct the reader to earlier work (especially [11]) to see how to use OUQ for model certification and validation, design of experiments, and calculations of optimal model, model error, and other quantities relevant to risk and statistics under uncertainty. We will close by summarizing a few of the aforementioned applications of OUQ. For example, finding the optimal model in OUQ is essentially finding the functional form that minimizes the worst upper and lower bounds on the model error for all possible models. Experiment design with OUQ starts by selecting a quantity of interest to maximize or minimize, such as P(success) or model error, and a base set  $\mathcal{A}$  of assumptions, measurements, and data; then, as new information is added to  $\mathcal{A}$ , the change in bounds for the quantity of interest is calculated. The piece of information that most dramatically tightens the bounds indicates the best next experiment to perform. The addition of new information

to  $\mathcal{A}$  can be manual, or optimizer-driven, with a OUQ calculation of bounds performed for each new  $\mathcal{A}$ . It should be noted that many OUQ problem formulations require one or more outer optimization loops, and one or more inner optimization loops, to be able to impose the constraints in  $\mathcal{A}$  – thus OUQ can be significantly more computationally expensive than other methods that leverage strong approximations. Since this manuscript is one of the first applications of OUQ to a complex physical system, we intend to follow this study with other examples of using OUQ for complex systems – including examples of experiment design, and in the calculation of the optimal model, for a complex physical system.
