Abstract. We report measurements of the scale of cosmic homogeneity (r_h) using the recently released quasar sample of the sixteenth data release of the Sloan Digital Sky Survey (SDSS-IV DR16). We perform our analysis in 2 redshift bins lying in the redshift interval $2.2 < z < 3.2$ by means of the fractal dimension D_2 . By adopting the usual assumption that r_h is obtained when $D_2 \sim 2.97$, that is, within 1% of $D_2 = 3$, we find the cosmic homogeneity scale with a decreasing trend with redshift, and in good agreement with the Λ CDM prediction. Our results confirm the presence of a homogeneity scale in the spatial distribution of quasars as predicted by the fundamental assumptions of the standard cosmological model.

1 Introduction

The advent of increasingly larger and high precision observational data sets has enabled us to test the standard model of Cosmology (SMC) with unprecedented precision, as recently done with Cosmic Microwave Background (CMB) observations [1], Type Ia Supernova (SNIa) distances [2], and large-scale clustering (LSS) [3–5]. Given that we are currently able to constrain the SMC parameters with nearly sub-percent precision, we should also be able to perform precise tests of the fundamental hypothesis underlying the SMC as well. One of these hypothesis corresponds to the Cosmological Principle (CP), which states that the Universe is statistically homogeneous and isotropic at large scales and described by the Friedmann-Lemaître-Robertson-Walker (FLRW) metric. Although it is a widely accepted assumption in modern Cosmology, it is yet to be proven through cosmological observations. Hence, it is paramount that we establish the CP as an observationally valid assumption, rather than a mathematical simplification of the actual Universe (see e.g. [6] for a discussion).

Observational tests of cosmological isotropy have been carried out with null results for a significant deviation of such assumptions [7–13]. However, cosmic homogeneity can only be indirectly tested, as we observe down the past lightcone, not on time-constant hypersurfaces [14–16]. Still, we can test consistency between the FLRW hypothesis and cosmological observations, and thus confirm cosmic homogeneity given that we obtain evidence for both FLRW consistency tests and statistical isotropy.

A possible method to probe consistency between observational data and the homogeneity assumption consists in performing counts-in-spheres of cosmic objects e.g. luminous red galaxies and quasars, so that we measure the scale where these counts are statistically similar to those obtained from random - thus homogeneous by construction up to Poisson noise - catalogues. This will be hereafter referred as the *cosmic homogeneity scale* (r_h), which denotes the transition of the locally lumpy Universe to a smoother, statistically homogeneous one. This test has been extensively carried out in the literature, and most authors confirmed the existence of such a scale [17–27]. However, there are still claims of possible absence of such scale, as discussed for instance in [28–30], and also that these measurements could be biased by the survey window function [31].

In this paper we estimate the cosmic homogeneity scale using the spatial distribution of quasar number counts from the recently released quasar sample (DR16Q) of the Sloan

Digital Sky Survey IV (SDSS-IV) [32]. As in previous BOSS data releases, DR16 is divided into two different regions in the sky, named south and north galactic cap and the latter was the region used in this paper. This data-set contains 120,000 quasars within the redshift interval $2.2 < z < 3.2$, so that it is possible to probe the scale of cosmic homogeneity at two redshift bins by means of scaled counts-in-spheres. Our results are used to estimate a possible redshift dependence of quasar bias, and verify whether there is a transition from a lumpy to a homogeneous Universe as well as the scale at which such transition happens. Furthermore, we compare these results with the theoretical prediction of the standard scenario for the matter density perturbations. We find a good agreement with previous results using different types of tracers of large-scale structure.

This paper is organised as follows. In Section 2 we briefly describe the observational data used in our analysis. Section 3 discusses the method and correlation function estimators adopted. The results and discussions are presented in Section 4. Section 5 summarises our main conclusions.

2 Observational Data

We perform our analysis using the latest release of data of the SDSS-IV. The DR16Q is currently the largest catalogue of spectroscopically selected quasars, as it is 99.8% complete with few contamination (0.3 – 1.3%). This catalogue contains 750,414 quasars, including 239,081 Ly α object corresponding a 25% increase over DR12Q. The DR16Q catalogue has also been visually inspected, providing reliable classifications and redshifts [32]. Given the quality and redshift range of this data-set, the DR16Q allows us to expand the homogeneity scale measurements to higher redshifts, and test the redshift evolution of r_h predicted by the SMC.

We assume two redshift bins from DR16Q to provide two new homogeneity scales measurements considering quasars at $2.2 < z < 3.2$. The choice of the bins is based on the widest possible redshift bin that comprises the largest number of data points, and that provides the smallest possible relative error for the homogeneity scale as we increase the number of data points. Following this procedure, we end up with $\sim 19,000$ quasars in each redshift bin, which ranges from $2.2 < z < 2.4$, and from $2.5 < z < 3.2$ (see table 1). Moreover, we stress that there is no overlap between redshift bins to avoid any correlation that affects the two independently homogeneity scale estimates.

z interval	\bar{z}	N_q
2.20-2.40	2.30	19026
2.50-3.20	2.85	19093

Table 1. The two redshift bins used in the analysis and their properties: redshift range, mean redshift value, and number of quasars.

3 Method

3.1 Fractal Correlation Dimension

From the data described in the previous section, we identify the spatial three-dimension position of each quasar. This is carried out using the right ascension (α), declination (δ) and redshift (z) of each object. As we are exploring the three-dimensional approach to the

homogeneity scale, we must convert the angles and redshifts into physical separation (r) between each pair of quasars $\{Q_i, Q_j\}$ according to

$$r = \sqrt{d(z_{Q,1})^2 + d(z_{Q,2})^2 - 2d(z_{Q,1})d(z_{Q,2}) \cos \theta}; \quad (3.1)$$

$$\cos \theta = \cos [\sin \delta_{Q,1} \sin \delta_{Q,2} + \cos \delta_{Q,1} \cos \delta_{Q,2} \cos (\alpha_{Q,1} - \alpha_{Q,2})], \quad (3.2)$$

where the radial comoving distance of each quasar $d(z_Q)$ reads

$$d(z_Q) = \int_0^z \frac{cdz'}{H(z')}; \quad H(z) = H_0 \sqrt{\Omega_m(1+z)^3 + \Omega_\Lambda}. \quad (3.3)$$

We assume a Λ CDM fiducial model with $\Omega_m = 0.313$, $\Omega_\Lambda = 0.687$, $H_0 = 67.48$ km/s/Mpc, which is consistent with the latest Planck release [1].

From these quantities, we can obtain the so-called scaled counts-in-sphere (\mathcal{N}), as well as the fractal dimension D_2 [20]. We obtain these quantities by comparing the observational data with random catalogues, and thus determine the scale where the former tends to the latter. To do so, we use the Peebles-Hauser (PH) correlation function, defining the PH estimator as [23].

$$\mathcal{N}(<r) \equiv \frac{\sum_{\rho=0}^r DD(\rho)}{\sum_{\rho=0}^r RR(\rho)}, \quad (3.4)$$

where $DD(r)$ is the pair of observed quasars counts within a separation radius r normalised by the the total number of pairs, $N^{\text{obs}}(N^{\text{obs}} - 1)/2$. On the other hand $RR(r)$ is the equivalent counting for the random catalogues. Note that the estimator based on Landy-Szalay correlation function [23] could be used, but previous results found similar results with the PH estimator [24, 26], hence we will just deploy the PH estimator this time around.

Note also that the estimators, \mathcal{N} and D_2 , are given in terms of the two-point correlation function (following previous works [23, 24, 26]), instead of the number of points inside spheres with different radii, which would affect the results due to possible overlapping between spheres [34, 35].

From \mathcal{N} , we can compute the fractal correlation dimension D_2 , which are related by

$$D_2^q(r) \equiv \frac{d \ln \mathcal{N}(<r)}{d \ln r} + 3. \quad (3.5)$$

As the distribution approaches the homogeneity scale, the scaled counts-in-sphere $\mathcal{N} \rightarrow 1$, and hence the fractal correlation dimension $D_2 \rightarrow 3$. In our analysis, we adopt the latter definition. The advantage of using it rather than \mathcal{N} is that D_2 is not strongly correlated as \mathcal{N} (see e.g. [24] for a discussion). We define the the scale where $D_2^q(r)$ reaches 1% of the homogeneous definition, i.e., $D_2^q(r) = 2.97$, as the cosmic homogeneity scale r_h^q . As commonly accepted in the literature, this definition of threshold for the correlation dimension is due to the survey geometry and incompleteness [20, 23, 24].

3.2 Theoretical predictions and bias

We find the theoretical expectation for the cosmic homogeneity scale in a given range by means of the two-point correlation function from the matter density power spectrum

$$\xi(s, \bar{z}) = \frac{1}{2\pi^2} \int P_m(\kappa, \bar{z}) \frac{\sin(\kappa s)}{\kappa s} \kappa^2 d\kappa, \quad (3.6)$$

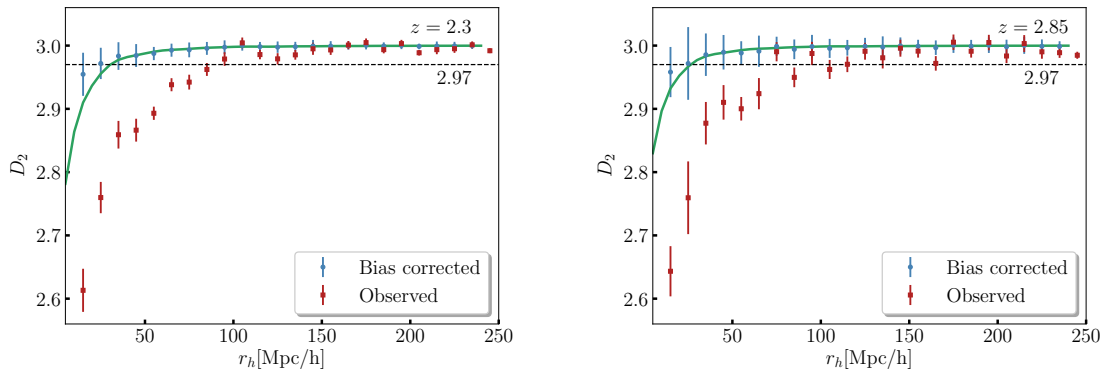

Figure 1. Fractal correlation dimension in each redshift bin. Blue points stand for observational values adjusted by the correspondent bias, green lines correspond to the theoretical prediction of the fiducial cosmological model, whereas the dotted blue line gives our homogeneity scale threshold, that is, $D_2^m = 2.97$.

where the matter power spectrum is obtained from the CAMB code [33] assuming the fiducial model previously described. Then we calculate the theoretical scaled count-in-spheres as

$$\mathcal{N}_{\text{th}}(< r, \bar{z}) = \frac{3}{4\pi r^3} \int_0^r (1 + \xi(s, \bar{z})) 4\pi s^2 ds, \quad (3.7)$$

and the correspondent theoretical fractal correlation dimension according to

$$D_2^m(r) \equiv \frac{d \ln \mathcal{N}_{\text{th}}(< r)}{d \ln r} + 3. \quad (3.8)$$

In order to compare the theoretically predicted homogeneity scale with the observed counterpart, we need to obtain how the quasars trace the underlying matter distribution, i.e., the quasar bias. This quantity can be computed directly from the correlation dimension, as given by [23, 24]

$$D_2^m(r) = \frac{D_2^q(r) - 3}{b^2} + 3, \quad (3.9)$$

where b represents the quasar bias, which is fitted according to a specific model.

4 Analysis and Results

In order to estimate the homogeneity scale in each redshift bin with the DR16Q data, firstly we obtain the correlation dimension as described in Eq. 3.5. We use twenty random catalogues for this purpose, which implies that we have this number of D_2^q . We fit a polynomial expression to describe the evolution of each D_2^q , and then we find the corresponding homogeneity scale (r_h^q) where $D_2^q = 2.97$ for each realisation. Finally, we perform a bootstrap analysis over these twenty r_h^q values, obtaining their corresponding mean and standard deviation in each redshift bin. These results are shown in the second column in Table 2. It is worth mentioning that in our analysis we follow [26, 36] and adopt bootstrap instead of mock catalogues, as the former method seems to provide more conservative error estimates (see [36] for more details).

\bar{z}	r_h^q	r_h^m	r_h^{th}
2.30	89.80 ± 5.05	29.66 ± 2.22	31.59
2.85	71.35 ± 3.13	24.13 ± 3.49	27.56

Table 2. Homogeneity scale obtained from the estimator PH in each redshift slice. The first column provides the r_h values obtained from the real data, the second column corresponds to the homogeneity scale after accounting for the bias as described in the text, r_h^m , and the third column is the r_h^{th} estimated from the fiducial model following Eq. 3.8. All values are given in units of Mpc/h.

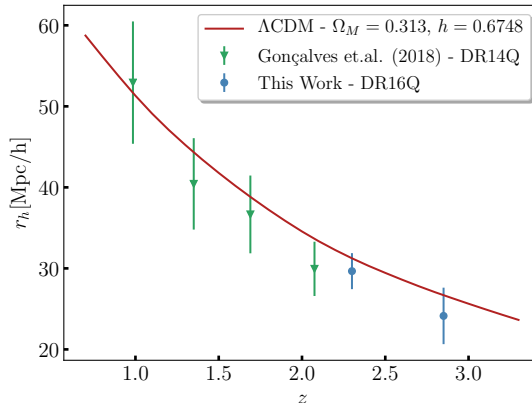

Figure 2. Homogeneity scale obtained in the present paper (blue points) and in [26]. The red line stands for the theoretical prediction for a Λ CDM fiducial model ($\Omega_m = 0.313$, $\Omega_\Lambda = 0.687$, $H_0 = 67.48$ km/s/Mpc), the fiducial model used in the present paper.

We obtain the bias as described in Sec. 3.2. We assume a constant bias along each redshift bin ($b(r) = b_0$), and then we perform a χ^2 analysis in Eq. 3.9, whose best fit values for each redshift bin are $b(z = 2.3) = 2.53 \pm 0.03$ and $b(z = 2.85) = 2.92 \pm 0.08$, accordingly. Given these values, we obtain the correlation dimension for the matter distribution (blue points and bars in Figure 1), and hence the bias corrected values for the homogeneity scale r_h^m - third column in Table 2.

It is worth mentioning that we explored the impact of different parameterisations of the bias on the radial comoving distance $d(z_Q)$, finding very similar results. In addition, we verified the possibility of a redshift evolution for the bias, finding a best-fitted parameterisation of $b(z) = b_1 + b_2(1 + z)$, with $b_1 = 0.22$ and $b_2 = 0.7$ (see also [26]). Still, our results are robust with respect to different bias choices. Moreover, we note that these results are in good agreement with previous estimates in the literature. For instance, $b(z = 0.53) = 1.38 \pm 0.10$ [37], $b(z = 1) = 1.61 \pm 0.22$ [38], $b(z = 1.41) = 1.92 \pm 0.50$ [39], which shows that our results are compatible with the previous results within 2σ confidence level (CL).

We also compare the results measured from the real data, r_h^m with the theoretically predicted scale of homogeneity from Eq. 3.8, which is presented in the fourth column of 2. We find that they are in excellent agreement with each other, showing that the observed homogeneity scale is consistent with the standard model.

For the sake of comparison, in Fig. 2 (blue points) we plot the homogeneity scale for the matter distribution, as well as the values obtained in the previous work at the corresponding redshift bins [26]. We also display the theoretical predictions from the fiducial model in this

plot (red line), showing great agreement with our measurements - 1σ confidence level. These results confirm the decreasing trend of the homogeneity scale according to the redshift range, as obtained in previous analyses.

5 Conclusions

In this paper, we estimated the homogeneity scale using the latest quasar sample of the Sloan Digital Sky Survey, namely the SSS-IV DR16 data-set. To our knowledge, this is the first time that the transition to statistical homogeneity is assessed in such high redshift range ($2.2 < z < 3.2$). We split the original data set in two redshift slices, and verify whether there is indeed such characteristic scale, and also the presence of a possible evolution of r_h^m with respect to the redshift. Our analyses were performed using the scaled counts-in-spheres approach, $\mathcal{N}(< r)$, as well as the fractal correlation dimension D_2 . We follow the usual definition that the cosmic homogeneity is attained where $D_2 \rightarrow 2.97$. We find that there is indeed evidence for such characteristic scale, i.e., $r_h^q = 89.80 \pm 5.05$ Mpc/h ($\bar{z} = 2.30$) and $r_h^q = 71.35 \pm 3.13$ Mpc/h ($\bar{z} = 2.85$) at 1σ level.

In order to test consistency between data and the SMC, we fitted a constant bias in each redshift range, and thus obtained the scale of homogeneity of the matter distribution r_h^m . We found that this scale indeed presents a decreasing trend with respect to the redshift, following previous results using the previous SDSS-IV DR14 quasar data. Moreover, we found that these results are in great agreement with the homogeneity scale predicted by the theoretical matter power spectrum, r_h^{th} , in both redshift bins, showing consistency between our measurements and the standard model.

Our results showed that there is a clear scale of cosmic homogeneity in the latest SDSS-IV quasar data, as predicted by the fundamental assumptions underlying the Λ CDM model. We plan to explore the interplay between the clustering bias and the homogeneity scale, in addition to other representations of the homogeneity scale rather than the fractal dimension D_2 , in future works. We expect to improve our results, and thus establish the Cosmological Principle as a observationally valid hypothesis of the observed Universe, with the advent of next-generation surveys such as J-PAS [40, 41], DESI [42], Euclid [44], and SKA [43]
