Abstract

During the 2016-17 and 2018-19 running periods, the BESIII experiment collected 7.5 fb^{-1} of e^+e^- collision data at center-of-mass energies ranging from 4.13 to 4.44 GeV. These data samples are primarily used for the study of excited charmonium and charmoniumlike states. By analyzing the di-muon process $e^+e^- \rightarrow (\gamma_{\text{ISR/FSR}})\mu^+\mu^-$, we measure the center-of-mass energies of the data samples with a precision of 0.6 MeV. Through a run-by-run study, we find that the center-of-mass energies were stable throughout most of the data-taking period.

I. INTRODUCTION

The BESIII experiment [1] was designed to study physics in the τ -charm energy region (2.0 – 4.9 GeV) [2] with e^+e^- annihilation produced by the BEPCII storage ring [3]. Since it started running in 2008, a variety of data samples have been collected at different center-of-mass (CM) energies for the study of light hadron spectroscopy, charmonium and charmoniumlike states (also called XYZ states), charm physics, τ physics, various QCD-related studies, and the search for new physics beyond the standard model [4].

The Beam Energy Measurement System (BEMS) [5] was designed to precisely measure BESIII CM energies (E_{cm}) using a method based on Compton back-scattered photons. However, its capability at high energy (E_{cm} above 4 GeV) is degraded by its detection efficiency and limited calibration sources for high-energy gamma rays. Therefore, an alternative algorithm was developed to measure the E_{cm} for data samples above 4 GeV. This method uses the well-understood QED process $e^+e^- \rightarrow (\gamma_{\text{ISR/FSR}})\mu^+\mu^-$ (the di-muon process), where $\gamma_{\text{ISR/FSR}}$ is a radiative photon due to initial state radiation (ISR) and/or final state radiation (FSR). Using this method, a precision of 0.8 MeV was previously achieved for the data taken from 2011 to 2014 [6].

In this paper, we present the E_{cm} measurement for the XYZ data samples taken at BESIII from 2017 to 2019. The method used in Ref. [6] is followed, but the precision of the momentum calibration is improved, and the E_{cm} is measured with an uncertainty of 0.6 MeV.

Using the selected di-muon events, $e^+e^- \rightarrow (\gamma_{\text{ISR/FSR}})\mu^+\mu^-$, we determine E_{cm} with

$$E_{\text{cm}} = (M_{\text{p}}(\mu^+\mu^-) + \Delta M_{\text{ISR/FSR}} + \Delta M_{\text{cal}}) \times c^2, \quad (1)$$

where $M_{\text{p}}(\mu^+\mu^-)$ is the peak position of the $\mu^+\mu^-$ invariant mass of selected di-muon events; $\Delta M_{\text{ISR/FSR}}$ is the mass shift due to the emission of ISR or FSR photons, estimated from Monte Carlo (MC) simulation of the di-muon process by turning on and off the ISR/FSR processes in MC generation; and ΔM_{cal} is the correction introduced by the momentum calibration of the $\mu^+\mu^-$ tracks, obtained from an analysis of the process $e^+e^- \rightarrow \gamma_{\text{ISR}}J/\psi$.

II. THE BESIII DETECTOR AND DATA SETS

The BESIII detector is described in detail in Ref. [1]. The cylindrical core of the detector covers 93% of the full solid angle and consists of a helium-based multilayer drift chamber (MDC), a plastic scintillator time-of-flight system (TOF), and a CsI(Tl) electromagnetic calorimeter (EMC), which are all enclosed in a superconducting solenoidal magnet providing a 1.0 T magnetic field. The solenoid is supported by an octagonal flux-return yoke with resistive plate counter muon identification modules interleaved with steel. The charged-particle momentum resolution at 1 GeV/ c

is 0.5%, and the dE/dx resolution is 6% for electrons from Bhabha scattering. The EMC measures photon energies with a resolution of 2.5% (5%) at 1 GeV in the barrel (end cap) region. The time resolution in the TOF barrel region is 68 ps, while that in the end cap region is 110 ps. The end cap TOF system was upgraded in 2015 using multi-gap resistive plate chamber technology, providing a time resolution of 60 ps [7].

The data samples analyzed in this work are listed in Table I. They include 16 different CM energies from 4.13 to 4.44 GeV and were collected in two running years: from December 2016 to May 2017 (labelled as “2017XYZ” hereafter, the integrated luminosities are measured in Ref. [8]); and from February 2019 to June 2019 (labelled as “2019XYZ” hereafter, the integrated luminosities are estimated by using online monitoring information). The column “Sample” shows the nominal CM energy in MeV used during online data taking. The true CM energy is usually within a few MeV of the nominal value. Run numbers are used to divide the data into subsamples. Other columns, such as $\mathcal{L}$ (pb^{-1}), will be illustrated below.

TABLE I. Summary of the data samples, including run numbers, integrated luminosity $\mathcal{L}$ [8], the measured J/ψ mass after FSR correction $M^{\text{cor}}(J/\psi)$ (in MeV/c^2), $M_p(\mu^+\mu^-)$ (in MeV/c^2), and E_{cm} . Superscripts represent data from different periods: “1” stands for 2017XYZ data, and “2” stands for 2019XYZ data. The first uncertainties are statistical, and the second systematic.

A GEANT4 [9] based detector simulation package is developed to model the detector response for MC events. In our analysis, the di-muon sample is generated with BABAYAGA3.5 [10], and the $e^+e^- \rightarrow \gamma_{\text{ISR}} J/\psi$ sample is generated with KKMC [11]. One million events are generated for each process at each CM energy.

III. EVENT SELECTION AND MEASUREMENT OF $M_p(\mu^+\mu^-)$

The di-muon process $e^+e^- \rightarrow (\gamma_{\text{ISR/FSR}})\mu^+\mu^-$ is selected by requiring two oppositely charged tracks in the detector, each positively identified as a muon. Both charged tracks are reconstructed

from hits in the MDC within the polar angle range $|\cos \theta| < 0.8$ and are required to pass interaction point (IP) within 10 cm along the beam direction and within 1 cm in the plane perpendicular to the beam. The energy deposition in the EMC for each charged track is required to be less than 0.4 GeV to suppress backgrounds from radiative Bhabha events.

The sample after these selections includes di-muon events with no photon emission or with very low-energy radiative photons, ISR J/ψ with $J/\psi \rightarrow \mu^+\mu^-$, and ISR $\mu^+\mu^-$ events with a smooth $\mu^+\mu^-$ invariant mass ($M(\mu^+\mu^-)$) distribution. The events in the J/ψ mass region are used for track momentum calibration and those with high invariant mass are used to measure the E_{cm} after the additional selections shown below.

To suppress di-muon events with high energy radiative photons, a requirement on the cosine of the opening angle between the two tracks, $\cos \theta_{\mu^+\mu^-} < -0.9997$. To further remove cosmic ray events, the TOF time difference between the two tracks is required to be $|\Delta t| < 2$ ns. The background contribution after the above selection criteria is less than 0.1% compared with signal and is therefore neglected in the following analysis.

The $M(\mu^+\mu^-)$ distribution for the 4190 data sample is shown in Fig. 1 as an example. The distributions of the other samples are very similar. The distribution is a Gaussian due to the momentum resolution of the $\mu^+\mu^-$ but is distorted by ISR and FSR effects which produce a tail on the left side of the peak. The central part of the distribution can be approximated with a Gaussian function. We measure the peak position of the distribution ($M_p(\mu^+\mu^-)$) by fitting it with a Gaussian function in a range of $(-1\sigma, +1.5\sigma)$ around the peak, where σ is the standard deviation of the Gaussian. If the goodness of the fit, $\chi^2/ndf > 2.0$ (ndf is the number of degrees of freedom of the fit), we slightly reduce the fit range until $\chi^2/ndf < 2.0$ to guarantee a good fit quality. The fit result for the 4190 data sample is shown in Fig. 1. The values of $M_p(\mu^+\mu^-)$ for the other data samples are obtained in a similar way and are shown in Table I.

FIG. 1. The $\mu^+\mu^-$ invariant mass distribution and the fit result of the 4190 sample. Dots with error bars are data, and the red solid curve is the fit.

To examine the stability of the E_{cm} over the data-taking period for each data sample, the fit procedure is repeated for each run of the data sample. The measured peak values of the $\mu^+\mu^-$ invariant mass distribution versus run number for all 16 samples are shown in Fig. 2. There are small jumps of less than 1 MeV in the 4200, 4210, 4246, 4380, and 4400 samples. Before and after

the jumps, the energy is stable. We fit each stable part of the distribution with a linear function and Table II summarizes the average, $M^{\text{ave}}(\mu^+\mu^-)$, for each period of time. The deviation of $M^{\text{ave}}(\mu^+\mu^-)$ from the peak position obtained in the full data sample is taken as one source of systematic uncertainty.

FIG. 2. Measured run-by-run values for the $M_p(\mu^+\mu^-)$ of di-muon events in each data sample. The red solid lines show the fit results for the data samples of each stable period of time. The green dotted lines are the fit results of the entire sample when there is an energy jump.

IV. MOMENTUM CALIBRATION WITH ISR J/ψ SIGNAL

The momentum measurement of the muon tracks is validated with $J/\psi \rightarrow \mu^+\mu^-$ candidates produced via the process $e^+e^- \rightarrow \gamma_{\text{ISR}}J/\psi$ selected in the previous section. The distribution of $M(\mu^+\mu^-)$ of each sample is fitted with a crystal-ball function [12] for the J/ψ signal and a linear function to model the background from continuum production of $e^+e^- \rightarrow \gamma\mu^+\mu^-$. Figure 3(a) shows the fit result for the 4190 data sample as an example. The peak position of the J/ψ signal, $M^{\text{obs}}(J/\psi)$, is used to calibrate the momentum measurement of the muon tracks.

Due to FSR, $J/\psi \rightarrow \mu^+\mu^-\gamma_{\text{FSR}}$, the measured $M^{\text{obs}}(J/\psi)$ is slightly lower than the world average J/ψ mass ($m_{J/\psi}$) given by the PDG [13]. The mass shift due to the FSR photon(s) $\Delta M_{\text{FSR}}^{\gamma J/\psi}$ of the process $e^+e^- \rightarrow \gamma_{\text{ISR}}J/\psi$ at each E_{cm} is obtained by using the generator PHOTOS [14] with FSR turned on or off. The shift is around $0.3 \text{ MeV}/c^2$ with little dependence on the CM energy of the data sample.

TABLE II. Average value of $M^{\text{ave}}(\mu^+\mu^-)$ (in MeV/c^2) for each stable data-taking period within each data sample.

Sample	Run Number	$M^{\text{ave}}(\mu^+\mu^-)$	Run Number	$M^{\text{ave}}(\mu^+\mu^-)$

FIG. 3. (a) Fit to the $M(\mu^+\mu^-)$ distribution in the J/ψ signal region for the 4190 data sample. Black dots with error bars are data, the red curve shows the fit result, the blue curve is for signal, and the green dashed line is for background. (b) The difference between $M^{\text{cor}}(J/\psi)$ and the world average mass of J/ψ [13], $\Delta M^{\text{cor}}(J/\psi)$ for each data sample.

Comparing the $M^{\text{cor}}(J/\psi) = M^{\text{obs}}(J/\psi) + \Delta M_{\text{FSR}}^{\gamma J/\psi}$ (as shown in Table I) with J/ψ nominal mass value $m_{J/\psi}$ in Particle Data Book (PDG), we measure the bias in the J/ψ mass measurement ($\Delta M^{\text{cor}}(J/\psi)$) due to the muon track momentum calibration, as shown in Fig. 3(b). It can be seen that the bias in J/ψ invariant mass is stable throughout one running year, but is quite different in the 2017XYZ and 2019XYZ samples. This may indicate that the calibrations in these two periods of time have significant differences.

Through MC simulation we find that the bias in $M(\mu^+\mu^-)$ measurement depends on $(M(\mu^+\mu^-) -$

$m_{J/\psi}$) linearly (see Fig. 4), so the correction to the $M(\mu^+\mu^-)$ due to calibration is expressed as

$$\Delta M_{\text{cal}} = -(k \times (E_{\text{cm}} - m_{J/\psi}) + \Delta M^{\text{cor}}(J/\psi)), \quad (2)$$

where the slopes $k = (7.11 \pm 0.50) \times 10^{-4}$ and $(7.04 \pm 0.57) \times 10^{-4}$ are for the 2017XYZ and 2019XYZ samples, respectively. They agree within the statistical uncertainties in the MC samples, which indicates that the momentum dependence of the calibration constants is very similar in the 2017XYZ and 2019XYZ samples.

FIG. 4. The dependence of the bias in $M_p(\mu^+\mu^-)$ due to the bias in track momentum calibration with di-muon events and it should be the same for data and MC (slope k). The $(E_{\text{cm}}^{\text{out}} - E_{\text{cm}}^{\text{in}})$ are the difference between output and input E_{cm} (the output E_{cm} is equal to the $M_p(\mu^+\mu^-)$ if the events without radiation.) at different CM energies and simulated by di-muon events without radiation.

V. THE MASS SHIFT $\Delta M_{\text{ISR/FSR}}$

The E_{cm} of the initial e^+e^- pair is measured via the di-muon process $e^+e^- \rightarrow (\gamma_{\text{ISR/FSR}})\mu^+\mu^-$. However, due to the emission of radiative photons, the invariant mass of the $\mu^+\mu^-$ pair is smaller than E_{cm} by $\Delta M_{\text{ISR/FSR}}$. This correction is estimated with MC simulation using BABAYAGA3.5 [10].

We generate one million di-muon events for each sample with ISR/FSR turned on or off, apply the same event selection criteria to the di-muon events in data (as described in Sec. III), and fit the distributions of $M(\mu^+\mu^-)$ from the samples with ISR/FSR on and off with a Gaussian function in a range around the peak (same as for data in Sec. III). The difference in $M_p(\mu^+\mu^-)$ is taken as the mass shift $\Delta M_{\text{ISR/FSR}}$ caused by ISR or FSR. The $\Delta M_{\text{ISR/FSR}}$ versus E_{cm} shown in Fig. 5 indicates that the ISR/FSR effect depends on E_{cm} linearly. The data are fitted with a linear function to have an improved precision measurement of the correction. The fit gives

$$\Delta M_{\text{ISR/FSR}} = (1.17 \pm 0.05) \times 10^{-3} \times E_{\text{cm}} + (-1.91 \pm 0.20) \quad (3)$$

with a correlation factor of -0.99 between the slope and the intercept, and the goodness of the fit is $\chi^2/\text{ndf} = 6.2/12$.

FIG. 5. The mass shift $\Delta M_{\text{ISR/FSR}}$ versus CM energy for $e^+e^- \rightarrow (\gamma_{\text{ISR/FSR}})\mu^+\mu^-$ MC samples. The red solid line is the fit with a linear function.

VI. SYSTEMATIC UNCERTAINTIES

The systematic uncertainty in E_{cm} is from the momentum calibration of $\mu^\pm$, the estimation of the mass shift $\Delta M_{\text{ISR/FSR}}$ due to ISR/FSR, the open angle cut of $\cos \theta_{\mu^+\mu^-}$, the corresponding fit procedure, and the generator. The bias of the momentum measurement of $\mu^\pm$ and the estimation of the mass shift $\Delta M_{\text{ISR/FSR}}$ due to ISR/FSR both have a linear relationship with E_{cm} , and the uncertainty caused by the uncertainty of the parameters is regarded as the systematic uncertainties.

In order to reduce the influence of the events with large radiation, we have required $\cos \theta_{\mu^+\mu^-} < -0.9997$. Different cut values will give different $M_p(\mu^+\mu^-)$ and corresponding radiation correction values $\Delta M_{\text{ISR/FSR}}$. The changes in these two parts cancel each other out. The biggest difference comes from the data between -0.9997 and -0.99975 , and is 0.12 ± 0.02 MeV. We take 0.14 MeV as the uncertainty due to this requirement.

The $M_p(\mu^+\mu^-)$ is measured by fitting with a Gaussian function in the range of $(-1\sigma, +1.5\sigma)$ around the peak with fit quality $\chi^2/\text{ndf} < 2.0$. If the fit range is smaller than the standard range, the difference in fit results is less than 0.1 MeV. We take this as the uncertainty due to the fit method.

The contribution to the systematic uncertainty of the ISR/FSR correction from the generator is negligibly small, as claimed in Ref. [10]. The uncertainties from other sources, such as background and other event selection criteria, are negligible.

Assuming all the sources of systematic uncertainty are independent, the total systematic uncertainty is obtained by adding all the items in quadrature, which is listed in Table I. The uncertainty is smaller than 0.6 MeV for all the data samples.

VII. SUMMARY

The center-of-mass energies, E_{cm} , of the data samples are obtained by using Eq. (1), with the correction factors in Eqs. (2) and (3). The final results are listed in Table I including the

statistical and systematic uncertainties. The corresponding statistical uncertainty is very small, and the systematic uncertainty is found to be less than 0.6 MeV. The stability of E_{cm} over time for the data samples is also examined.

The results presented in this work are essential for the discovery of new states and the investigation of the transitions of charmonium and charmoniumlike states [15] using the BESIII data. Some of the analyses have been presented in Refs. [16–21].
