(Dated: February 3, 2021)

Beta-delayed neutron emission is important for nuclear structure and astrophysics as well as for reactor applications. Significant advances in nuclear experimental techniques in the past two decades have led to a wealth of new measurements that remain to be incorporated in the databases.

We report on a coordinated effort to compile and evaluate all the available β -delayed neutron emission data. The different measurement techniques have been assessed and the data have been compared with semi-microscopic and microscopic-macroscopic models. The new microscopic database has been tested against aggregate total delayed neutron yields, time-dependent group parameters in 6-and 8-group re-presentation, and aggregate delayed neutron spectra. New recommendations of macroscopic delayed-neutron data for fissile materials of interest to applications are also presented. The new Reference Database for Beta-Delayed Neutron Emission Data is available online at: http://www-nds.iaea.org/beta-delayed-neutron/database.html.

I. INTRODUCTION

Neutron-rich nuclei can emit neutrons after β -decay when their decay Q-value is larger than the (one/two/three...) neutron separation energy: $Q_{\beta} > S_{xn}$. This decay mode is called " β -delayed (β n) neu-

tron emission" and was discovered in 1939 by Roberts *et al.* [1, 2], shortly after the discovery of fission by Meitner, Hahn, and Strassmann in 1938 [3]. Immediately after this, Bohr and Wheeler [4] improved their liquid drop model to describe these new decay mechanisms.

The β -delayed two- and three-neutron emission (β 2n and β 3n) process was discovered 40 years later in ¹¹Li [5, 6], and in 1988 the (so far) only β 4n emitter, ¹⁷B, has been investigated and a tentative branching ratio of $P_{4n} = 0.4(3)$ has been measured [7].

'Delayed' in this context means, that the neutron is emitted with the β -decay half-life of the precursor ${}^{A}Z$, ranging from a few milliseconds for the most neutronrich isotopes up to 80(18) s for ²¹¹Tl, the longestlived β -delayed neutron (β n) precursor observed to date. These delayed neutrons have to be distinguished from the prompt neutrons evaporated immediately (in the order of 10^{-14} s) after a fission event from a neutron-rich nucleus and usually form only a small fraction of the total neutrons emitted from fission ($\approx 1\%$). Nevertheless, they play an important role in controlling the dynamic rate of fission in a chain-reacting assembly and hence in reactor kinetics and the safe operation of a reactor.

This important role of delayed neutrons in determining the reactor kinetics and reactivity was recognized early on and led to several measurements of delayed neutron groups [8–12]. In 1954, an extensive delayed neutron program was initiated at Los Alamos National Laboratory. One major outcome of this program was the 6group fitting parameters by Keepin and co-workers (see Sect. V A 1, [13]). In a least-squares fit of the delayed neutron emission curves of ²³⁵U, they found that by grouping the β n emitters in six groups – according to their halflives – they could reproduce the experimental data.

In 1990, Subgroup 6 was established by the NEA-OECD "Working Party on International Nuclear Data Evaluation Co-operation" (WPEC-SG6) [14] to assess the differences between the calculated and measured values of the reactivity scale obtained from reactor kinetics. The observed discrepancies were largely attributable to the uncertainties in the delayed neutron data used in these calculations. Their effort to address this included international benchmark measurements of the effective delayed neutron fraction, made on fast critical assemblies, which aimed to provide high-quality experimental information for 235 U, 238 U, and 239 Pu.

One of the outcomes of this working group was the refinement of the Keepin parameters by the laboratories in Los Alamos and Obninsk from a 6-group fit to an 8-group fit. This was achieved by separating the three longestlived delayed neutron precursors (⁸⁷Br, ¹³⁷I, and ⁸⁸Br) into single groups.

Independent of the effort to determine integral delayed neutron yields for applications, there have also been several attempts to measure, compile and evaluate β -delayed neutron data of individual precursors. Groups in Sweden [15, 16], USA [17, 18], and Germany [19] became active in measurements of β -delayed neutron probabilities and spectra in the late 1970s. A large number of data was published in the following decades and subsequently compiled and evaluated by Rudstam and collaborators [15, 16, 20, 21] and Pfeiffer et al. [22].

Values from these compilations and evaluations have sometimes been incorporated in ENSDF [23], together with independent recommendations by the respec-Consequently, these values have also tive evaluator. been transferred to evaluated data libraries such as ENDF/B [24, 25], JENDL [26, 27] and JEFF [28, 29] decay-data libraries, as well as in nuclear astrophysics applications. Other independent evaluations have also been performed to address specific needs in applications, such as the highly-specific evaluations of decay data for short- to very short-lived radioisotopes, including β -delayed neutron emitters, which were performed from 1996 to 1998 by Nichols [30] for the UK-based data file. These evaluations were subsequently adopted in the JEFF decay-data libraries [29].

The first comprehensive compilation and evaluation of β -delayed neutron emission spectra was published by Brady [31] in an effort to combine measured spectra with statistical model calculations to complete the experimental data that was sometimes scattered or limited in energy range. The resulting spectra were adopted in the ENDF/B libraries and were further supplemented with model calculations by Kawano et al. [32].

Until 2011 only sporadic efforts have been made to collect data of 'microscopic' quantities related to the β delayed neutron emission, namely half-lives and neutronbranching ratios of very neutron-rich nuclei to reveal nuclear structure properties for nuclei far from stability. This data has also been used directly as nuclear physics input for astrophysical reaction network calculations for the "rapid neutron capture" (r) process in explosive astrophysical scenarios like core collapse supernovae and binary neutron star mergers, or indirectly to benchmark and improve theoretical predictions which are needed for extrapolating models towards the yet inaccessible regions of the nuclide chart ("Terra Incognita").

Recent experimental efforts relied largely on the existing generation of radioactive beam (RIB) facilities but with the next generation of these facilities becoming operational within this decade, a plethora of new nuclides will become accessible. The vast majority of these new nuclides on the neutron-rich side will be β n-emitters.

According to the Atomic Mass Evaluation in 2016 (AME2016) [33], 651 out of the 3435 known nuclei are β n emitters, meaning that their $Q_{\beta 1n}$ is (within mass uncertainties) positive. Theoretical models estimate that about 4000 additional nuclei should exist between the proton- and neutron dripline, most of them are on the neutron-rich side and will be β n emitters.

In 2011, 72 years after the discovery of β -delayed neutrons , only 216 β n emitters had measured neutronbranching ratios: 81 nuclei in the lighter mass region (Z < 28), 134 nuclei in the fission regions between Z = 29 - 57, and a single (unconfirmed) measurement of the P_{1n} value of ²¹⁰Tl [34] in the whole mass region above Z > 57.

Currently (as of August 2020) 653 nuclei between ⁸He and ²³⁷Ac have been identified as potential β -delayed oneneutron emitters ($Q_{\beta 1n} > 0$ keV). However, as of August 2020 only 306 of those nuclei have measured β -delayed one-neutron branching ratios (P_{1n}): 114 in the light mass region Z < 28 [35], 183 in the fission fragment region (Z = 29 - 57), and 9 in the region above Z > 57 [36]. A total of 28 of these measurements provided only an upper limit for the P_{1n} value, and another six provided only lower limits.

As far as delayed multi-neutron emission is concerned, 300 potential β 2n-emitters have been identified, alongside 138 β 3n-emitters, and 58 β 4n-emitters. The number of measured multi-neutron branching ratios is however much smaller: only 31 P_{2n} values have been measured (23 for Z < 28 and eight for Z > 28) and four P_{3n} values (¹¹Li,¹⁷B, ¹⁹B, and ²³N). One single tentative measurement for the P_{4n} value of ¹⁷B has been reported.

One of the largest and most focused recent efforts to fill this large gap between identified and measured β delayed neutron branching ratios is the "Beta-delayed neutrons at RIKEN" (BRIKEN) project [37]. Since 2016 this international collaboration has been measuring halflives and neutron-branching ratios of almost all accessible β n emitters. The collaboration will conclude its experimental campaigns in 2021 and is expected to add in the near future > 250 new β -delayed neutron emitters to the existing list. The data from the experimental runs in 2016–19 is presently being analyzed, and a small fraction has already been published and included in the latest Z > 28 evaluation [36]. An overview of the BRIKEN and future campaigns can be found in Sect. II D.

This rapidly developing landscape of measured β n emitters and respective application-driven needs for reliable β n data necessitates both, a thorough update of the existing β n-data compilations and a review of the recommended group parameters. In response to these urgent data needs, the International Atomic Energy Agency (IAEA) coordinated an international effort to produce a 'Reference Database of Beta-Delayed Neutron Emission Data' [39–42].

The results of this coordinated effort are reported in this paper. The methods for measurement of microscopic β -delayed neutron data are described in Sect. II, followed by the compilation and evaluation efforts (including new recommendations of standards for P_{1n} measurements) and systematic descriptions in Sect. III. Comparisons of the β -delayed neutron data (half-lives, β -delayed neutron -branching ratios and spectra) with global theoretical approaches are presented in Sect. IV.

Macroscopic (integral) delayed neutron yields and spectra have been used to verify and validate the microscopic data. Measurement methods, new data, and compilation efforts are presented in Sect. V. Summation and time-dependent calculations of total delayed neutron yields and spectra based on the evaluated microscopic β - delayed neutron data are described and compared with recommended values in Sect. VI. The impact of the new β -delayed neutron data on integral reactor calculations is discussed in Sect. VII. Finally, the systematics of the measured macroscopic data are discussed in Sect. VIII and new recommendations for 6- and 8-group kinetic parameters for major and minor actinides are given in Sect. IX.

The structure of the reference database is detailed in Sect. X and a summary of the main conclusions of this work is provided in Sect. XI.

All the microscopic and macroscopic data presented herein, are available online at http://www-nds.iaea. org/beta-delayed-neutron/database.html [43].

II. MICROSCOPIC DATA: METHODS AND MEASUREMENTS

A. Delayed neutron emission probabilities

The neutron-branching ratio of a nucleus into the $\beta 1 {\rm n}$ decay channel is defined as

$$P_{1n} = \frac{N_{1n}}{N_{decays}}.$$
(1)

where N_{1n} stands for the number of decays (N_{decays}) that emit one neutron. Similar expressions hold for any other β -delayed multi-neutron decay channel. This quantity can be measured in various ways with different techniques, either directly by counting the number of emitted neutrons, or indirectly by counting γ -rays or other decay products. Special care has to be taken that the number of counted events are free of any contaminations, i.e. that the contributions from background activities are subtracted and the random noise is properly corrected for.

Eight methods for the determination of P_{1n} values were extracted from the previous Rudstam evaluation [21] and were reviewed in the IAEA CRP summary reports [39– 41] for their strengths and weaknesses and, in particular, potential sources of systematic errors and uncertainties. These methods were complemented by newer methods. Note that only a few of these methods are also suited for the measurement of multi-neutron emission probabilities.

Throughout this article the following notation will be used: precursor (^AZ) or mother nucleus stands for the β -decaying nucleus; β -decay daughter or intermediate nucleus is the product from the β decay of the precursor (^AZ+1), and β -delayed neutron daughter stands for the final nucleus with ^{A-1}Z+1 for the case of one-neutron emission, ^{A-2}Z+1 for the case of two-neutron emission, etc.

The majority of P_{xn} values in the literature have been determined using methods that involve neutron counting using moderated neutron detectors. These type of counters combine a medium acting as a neutron energy

FIG. 1. Chart of nuclides with color-coded $Q_{\beta n}$ window (in keV, retrieved from NuDat 2.7 [38]).

moderator with a detector sensitive to thermal neutrons to maximize detection efficiency. Typical moderators are made of dense hydrogenated material, like high-density polyethylene that has replaced the paraffin wax of earlier designs. The first counters used BF₃-filled proportional tubes as a thermal neutron detector, but nowadays the more expensive ³He is preferred because of its advantages [44] (see also Sect. II B). This detector can be considered as an evolution of the neutron long counter [45], where very high detection efficiencies are achieved by arranging several tubes in a 4π geometry around the source. Apart from the large detection efficiency, another distinct advantage of this type of detector is the virtual absence of a low-energy threshold.

Recent examples of this kind of setup applied to the measurement of P_{xn} are NERO (now HABANERO) at the National Superconduction Laboratory (NSCL) at Michigan State University (USA) [46], LOENIE at Lohengrin-Institute Laue Langevin (France) [47], 3Hen at HRIBF-Oak Ridge National Laboratory (USA) [48], BELEN at the GSI Helmholtz Center for Heavy Ion Research in Darmstadt (Germany) and at the heavy ion accelerator laboratory of the University of Jyväskylä (Finland) [49], and TETRA at ALTO - Institute de Physique Nucleaire in Orsay (IPNO, France) [50]. The latest setup is BRIKEN at RIKEN Nishina Center in Wako (Japan) which is a temporary merger of the 3Hen and BELEN counters with some additional 3 He tubes from RIKEN [37, 51].

The detection efficiency of these type of detectors exhibits a dependency on neutron energy which can be a source of systematic uncertainty in the determination of P_{xn} values (see discussion in II A 1). The effect is related to the moderation process and depends on the geometry of the counter (number and spatial distribution of neutron detectors). Thus the detector design can be optimized to minimize the dependency of the efficiency on neutron energy. An example of this is the LOENIE counter [47]: With only 18 ³He tubes a very small (17%) but flat efficiency up to 2 MeV is achieved.

Nowadays the general trend is to minimize the energy dependency of the efficiency curve while still maximizing the overall detection efficiency. This can be achieved by increasing the number of tubes considerably, as has been done for example in the case of the BRIKEN setup which could use up to 166 ³He tubes. The optimization of the geometry incorporating many tubes is a complicated problem that can be solved by combining Monte Carlo simulations with a parametric approach [37]. In this way a configuration with an efficiency in excess of 75% below 1 MeV was obtained that drops (only) to an efficiency of 54% at 5 MeV.

The efficiency calibration of these instruments requires the use of mono-energetic isotropic neutron sources spanning the range of neutron energies of interest to well above 5 MeV for exotic nuclei [52]. Photo-neutron (γ, n) and α induced reaction sources (like ²⁴¹Am/⁹Be or ^{24x}Cm/¹²C), as well as fission sources have been employed [53] but these are difficult to prepare or have a very broad energy spectrum. Beam-induced (p, n) and (α, n) reactions have also been used [46] although it seems difficult to reach the required accuracy.

In experiments at radioactive beam facilities β -delayed neutron emitters with well know P_{1n} values and neutron spectra are used for the efficiency calibration of the setup. For sources with a broad neutron energy distribution the measured neutron detection efficiency is averaged over the respective neutron energy range. However it should be kept in mind that this is an approximation as different neutron spectra – detected with different average efficiencies – can have the same average energy. Thus, for these sources the measurements should be combined with detailed Monte Carlo simulations, although the accuracy of the latter in complex geometries is still under discussion.

The moderation process introduces a delay between neutron emission and detection that reaches few hundreds of μ s. This poses a problem for conventional triggered event-based data acquisition systems. The use of an event gate of this length can lead to a sizable loss of data due to the acquisition dead time. This problem is overcome by modern event-less self-triggered data acquisition systems, as in the case of the most recent neutron detection setups 3Hen, BELEN, TETRA, and BRIKEN.

In the following, the eight different methods for obtaining P_{1n} values as well as their advantages and disadvantages are discussed.

1. Beta-neutron coincidences (" β -n")

In this method β 's and neutrons are counted in coincidence and compared with the number of β counts. Thus the efficiency of the β detector is greatly reduced, while the neutron efficiency in absolute terms is needed. This method was labelled "n/ β " in Ref. [21] and has been renamed here to " β -n" to account for the proper sequence of emissions of the particles.

For measuring the one-neutron emission probability (P_{1n}) , the respective equation is

$$P_{1n} = \frac{1}{\epsilon_{1n}} \, \frac{N_{\beta 1n}}{N_{\beta}},\tag{2}$$

where ϵ_{1n} is the one-neutron detection efficiency, $N_{\beta 1n}$ is the number of time-correlated β -1n events, and N_{β} is the amount of detected β 's. The main assumption in Eq. 2 is that the detector efficiency for β decays is constant for all energies and thus cancels out. However, β detectors have a lower threshold of typically 50–150 keV, and the respective efficiency curve shows a steep drop below $\approx 1-2$ MeV (see Fig. 2).

In contrast, a moderated ³He-neutron detector has an

(almost) constant neutron detection efficiency for energies up to 1 MeV, and then the curve drops slowly. These effects might introduce systematic errors if the calibrating isotopes have very different β - or neutron-energy spectra [49]. Examples of efficiency curves for a typical β - and moderated neutron detector used in experiments at the IGISOL facility in Jyväskylä are shown in Fig. 2 [54]. It can be seen that the highest neutron energies are connected to low-energy β 's with the lowest detection efficiency due to the detector thresholds, and vice versa.

An additional source of uncertainty is that the energy dependence (slope) of the neutron efficiency curve is often ignored. However, if the neutron energy distribution of the calibrant isotope is very different to the one of the isotope to be measured, this will induce systematic effects which need to be corrected for. For moderated neutron detectors the "average detection efficiency" depends on the neutron energy spectra of each isotope. Fig. 3 shows the neutron spectra of the β n emitters ⁸⁷Br (green line), ⁹⁵Rb (blue line), and ¹³⁷I (red line) as an example. For comparison, two simulated neutron detection efficiency curves for two state-of-the-art neutron detectors, BELEN [54] and BRIKEN [37], are plotted as dashed lines.

The correct description for the neutron-branching ratio should therefore include detection efficiencies $\langle \epsilon \rangle$ which are averaged over the respective energy ranges:

$$P_{1n} = \frac{\epsilon_{\beta}}{\langle \epsilon_{\beta}' \cdot \epsilon_n \rangle} \frac{N_{\beta 1n}}{N_{\beta}}$$
(3)

In this equation ϵ_{β} is the mean β efficiency. $\langle \epsilon'_{\beta} \cdot \epsilon_n \rangle$ is the product of the averaged β efficiency above the neutron separation energy weighted by the respective β intensity spectrum and the averaged neutron efficiency weighted by the neutron spectrum [49, 54]. If $\epsilon_{\beta} = \langle \epsilon'_{\beta} \rangle$, then the simplified Eq. 2 is recovered.

Even with this simplification, the method requires the knowledge of the neutron spectra of the respective isotope to be measured (see Sect. IIB). Since these spectra are not available for all isotopes, one can use as a guidance the spectra of calibration isotopes like the ones shown in Fig. 3 and listed in Sections IIIC and IIIE, selected to cover the expected neutron energy range of the isotopes of interest.

When analyzing decay curves the signals from all contributing decays need to be considered. This requires a proper knowledge of the different half-lives of all involved nuclei and possible isomeric states. In turn, if a half-life in a decay chain is not know, this method can also be used to extract the unknown half-lives of β n emitters from β and β n-decay curves.

Extensions of the " β -n" method to include multineutron emission increase the complexity as the neutronemission multiplicity (x) increases. Since the neutrondetection efficiency is < 100%, a β xn decay channel will contribute to the counts $N_{\beta yn}$ with $y \leq x$ [6] which must be taken into account. It is also important to include corrections for accidental coincidences with background neutrons, in particular when the background rate

FIG. 2. Examples of efficiency curves for a β - and a neutron detector [54] in comparison with an example neutron spectra. Note that the highest neutron energies are connected to β 's with the lowest detection efficiency due to the detector thresholds.

FIG. 3. Examples of neutron spectra for ${}^{87}\text{Br}$ (green), ${}^{95}\text{Rb}$ (blue), and ${}^{137}\text{I}$ (red) in comparison with two (simulated) efficiency curves for state-of-the art neutron detectors (dashed and dotted line) used in experiments at the IGISOL facility in Jyväskylä [54] and at RIKEN [37].

is large and the P_{xn} value is small. The importance of a proper background correction has been discussed recently in Refs. [51, 54, 55]. As in the P_{1n} case (Eq. 3), the correct expressions must include variable, isotope- and decay channel-dependent β - and neutron-detection efficiencies.

In summary, the " β -n" method is a generic and widely employed method that is well-suited for the measurement of single- and multi-neutron-branching ratios . It is the method of choice if the rate of neutrons from the respective decay is small compared to the rate of background neutrons, since the coincidence relations will increase the sensitivity to the neutrons of interest. It is a reliable method if all pitfalls as described above are carefully considered and accounted for. The main sources of systematic uncertainty are the β and neutron detection efficiencies that have to be simulated carefully.

2. Neutron and β counting ("n, β ")

In this method the β 's and neutrons are counted simultaneously but separately (not in coincidence). This method was labelled "n- β " in Ref. [21]. The P_{1n} value can be extracted from the ratio of counted events corrected by the ratio of detection efficiencies:

$$P_{1n} = \frac{\epsilon_{\beta}}{\epsilon_n} \, \frac{N_{1n}}{N_{\beta}}.\tag{4}$$

The "n, β " method requires that either both efficiencies are determined separately or that their ratio is obtained from calibration nuclei. All systematic errors on β and neutron detection efficiencies related to the different intensity distributions and the shape of the efficiency curves discussed in the previous method apply also here and have to be included properly. The β detection needs to be checked for potential sources of background, e.g. conversion electrons or changing noise in the detectors. This method is also quite generic and applicable to the measurement of multiple neutron emission. The main practical limitation is the neutron signal-to-background ratio that can be overcome by the use of β -n coincidences (the " β -n" method).

3. Relative neutron counting (" $P_{1n} {}^{A}Z$ ")

This is a neutron-only counting method and requires that in the decay chain either a descendant or the parent ^AZ is a β n-emitter with well known P_{1n} value which becomes the normalization. In addition, all half-lives have to be known including that of the measured precursor which could be determined independently from β activity curves. It is based on the analysis of the measured neutron activity curve to disentangle the different contributions. The method has been applied only in a few cases after chemical or mass separation, thus activity curves must be corrected for contaminants. In its simplest form it assumes that the neutron energy spectrum (and thus the neutron detection efficiency) for parent and descendants are identical but eventually corrections as discussed before should be applied.

4. Neutron counting per fission ("fiss,n")

This method was labelled "fiss" in Ref. [21]. Historically this is the oldest method used to measure neutron emission probabilities of individual precursors [56]. It is based on the determination of the number of β -delayed neutrons per fission of a given precursor $Y_{A,Z}^n$ with a suitable neutron detector. This number is compared then to the fission yield $Y_{A,Z}$ of that precursor to obtain the P_{1n} value:

$$P_{1n} = \frac{Y_{A,Z}^n}{Y_{A,Z}} \tag{5}$$

Typically fission of 235 U at thermal neutron energies has been used in these measurements. The main source of systematic error is the accuracy of the fission yields available at the time of the measurement. For example, in the evaluation of Rudstam [21] the results of earlier studies were updated using the fission yields Y_A from Wahl [57] and the respective charge fraction P_Z . However, new mass- and charge-dependent fission yields $Y_{A,Z}$ are now available, e.g. from evaluated libraries like ENDF/B-VIII.0 and JEFF-3.1.1. Thus, a renormalization of the older data to the new fission yields standards is advisable.

This method was applied mostly to chemically separated samples [21], a procedure that requires a certain processing time (in the order of 1 s) and is not suited for very short-lived β -delayed neutron emitters. It is affected by systematic uncertainties of the chemical separation efficiency as well as the neutron efficiency. For older experimental data, the lack of separation of the different isotopes and the presence of contaminants could have affected the determination of the P_{1n} value. Experience shows that the reliability of this method can be poor and that should be taken into account when comparing with other methods.

5. Neutron and γ counting ("n, γ ")

This method was called " γ ^AZ" in [21] and is renamed to "n, γ " method to account for the separate counting of neutrons from the precursor and γ 's from the daughter ^AZ decay (^AZ+1 in the nomenclature in this paper). It should not be confused with the "n- γ " method in [21] which actually designates a " γ , γ " method (see below). Because of the usually much longer half-live of the daughter it is convenient to measure first the neutron activity of the sample, and then the γ -activity in a separate dedicated setup [58].

The method requires that the absolute γ -intensity I_{γ}^{abs} of one or more transitions in the decay of the daughter is known. Corrections for growth and decay of activities, which require a knowledge of half-lives, must be applied before calculating the P_{1n} :

$$\frac{P_{1n}}{1-P_{1n}} = \frac{\epsilon_{\gamma} \cdot I_{\gamma}^{abs}}{\epsilon_n} \frac{N_n}{N_{\gamma}} \tag{6}$$

The γ -ray detection efficiency ϵ_{γ} is usually well known, thus the main issue is the availability and accuracy of absolute γ intensities per decay. If the daughter decay activity is also co-produced and present in the sample, this needs to be accounted for. The method can be used also with γ -rays from subsequent descendants in the β decay chain.

6. Double γ counting (" γ, γ ")

This method involves counting of γ -rays emitted by descendants in both, the β -decay and the β xn-decay chains. The γ activities can be labeled by their masses, which in the case of β 1n emitters are A and A-1, respectively. The method requires knowledge of the absolute γ -intensities per decay for both transitions used [59]. After correcting the γ counts by the growth and decay of activities, the possible branching-out/branching-in from/to the respective decay chains and the presence of contaminant activities in the sample, the P_{1n} can be deduced from:

$$\frac{P_{1n}}{1 - P_{1n}} = \frac{\epsilon_{\gamma}^A \cdot I_{\gamma}^{abs,A}}{\epsilon_{\gamma}^{A-1} \cdot I_{\gamma}^{abs,A-1}} \frac{N_{\gamma}^{A-1}}{N_{\gamma}^A} \tag{7}$$

The main advantage of this technique lies in the relative simplicity of detecting γ rays as compared to detecting neutrons, but the problem is shifted to the determination or knowledge of the absolute γ intensities per decay. The main drawback can be the low signalto-background ratio requiring that the limited peak efficiency of γ -ray detectors is compensated by high counting statistics. Tagging with β particles can be used to improve the sensitivity but at the cost of introducing a possible dependence on the β detection efficiency. If β -decaying isomers are present with half-lives similar to the ground state, γ rays can provide a uniquely selective tool to discriminate them, and measure correctly the P_{xn} values of isomeric and ground states.

Fragmentation facilities offer new opportunities for this technique, as descendants of the nucleus of interest ^AZ in the β and β xn decay chains can be independently produced and transmitted with the beam. In this case, absolute γ intensities for suitable transitions can be determined in the same experiment using the number of implanted ions for normalization [60]. However, the possible existence of isomers should be investigated, and the activity should be corrected according to the correlation time. Since ions with different Z are implanted at different depths in the respective implantation detector, β efficiency corrections might also be needed.

The " γ, γ " method is suitable for the measurement of multi-neutron emission branches.

7. Ion and neutron counting ("ion,n")

This corresponds to the "ion" method as defined in [21]. It is based on the direct measurement of the number of parent nuclei rather than the β 's emitted. It has been applied at mass separators by counting the number of selected ions. For example, ions can be counted by implantation on an electron multiplier that is surrounded by the neutron detector [61]. In other arrangements two measurements are needed, one for counting the ions, where the beam is deflected to the electron multiplier, and one for counting neutrons where the beam is implanted in a collector in the middle of the neutron detector [62]. In this case, additional systematic uncertainties must be considered. The neutron emission probability is determined as

$$P_{1n} = \frac{\epsilon_{ion}}{\epsilon_n} \, \frac{N_{1n}}{N_{ion}}.\tag{8}$$

Here N_{ion} is the number of ions after correction for contaminants and background and ϵ_{ion} is the ion detection efficiency. The determination of the ion detection efficiency of the electron multiplier can be an issue as shown in [61].

More recently (see [63] as an example), non-destructive ion counting with microchannel plates before implantation has been applied to post-accelerated mass-separated ion beams. In this example however, γ counting of descendant decays was used instead of neutron counting to obtain the P_{1n} value (" γ ,ion" method).

8. Double ion counting ("ion,ion")

The "ion, ion" method is possibly the only new method for the measurement of β -delayed neutron emission probabilities that was developed in recent years, thanks to advances in instrumentation. It is based on counting directly the number of parent nuclei and the number of daughter nuclei produced after neutron emission, circumventing the direct neutron detection.

The method includes several different techniques like detecting recoils in a Beta-decay Paul trap (BPT) [64], observing recoil tracks with an optical time-projection chamber (OTPC) [65], or separating and counting ions with a heavy-ion storage ring [66] or a Multi-Reflection Time-Of-Flight (MR-TOF) spectrometer [67]. With the first two methods it is also possible to extract neutron energy spectra for the one-neutron emitters via the energy of the recoil, but not in the case of multi-neutron emitters. More details can be found in Sect. II C.

B. Delayed neutron spectra

Most of the available data on the spectra of β -delayed neutrons have been obtained using three different techniques: ³He spectrometers, gaseous proton recoil spectrometers, and time-of-flight spectrometers. In the following the principles, instruments, and analysis methods of the three techniques are described.

1. ³He spectrometers

This method is based on the detection of fast neutrons through the reaction $n + {}^{3} He \rightarrow p + {}^{3} H$, which has a positive Q-value of 764 keV. In a 3 He filled proportional detector the reaction leads to the appearance of a peak in the spectrum for mono-energetic neutrons. The neutron energy E_n can be determined from the displacement of the observed peak with respect to the thermal neutron peak. For a continuum neutron energy distribution, the measured spectrum must be deconvoluted using the energy-dependent neutron detector response.

Following the introduction of high-pressure gridded ionization chambers [68] with good energy resolution (10-20 keV) and efficiency, this method has been used to measure β -delayed neutron spectra of several fission systems and individual precursors [31]. One disadvantage of this type of detector is the fast drop in efficiency with neutron energy: whereas at thermal energies the reaction cross section is as large as 5316 b it drops to 0.8 b at 1 MeV. This imposes a practical limit in the maximum measurable energy of about 3 MeV. In addition, the large peak due to the thermal-epithermal neutron background limits the minimum measurable energy to about 100 keV or more.

The accurate determination of the detector response is an essential step in this method. This is typically achieved using mono-energetic neutrons from reactions like ${}^{7}\text{Li}(p,n){}^{7}\text{Be}$. The shape of the measured response departs from that of a simple peak due to several effects. Apart from electronic and microphonic noise, the response includes the effect of γ -ray interactions (including pulse pile-up), a peak due to thermal neutron background, the effect of neutron-induced recoils in the gas, the detector-wall effect, and ballistic effects (incomplete charge integration, see [69] for a detailed discussion). Information on signal risetime can be used to eliminate some of these artifacts [70], at the cost of lowering the efficiency.

Nowadays, digital electronics allow a more detailed pulse shape analysis [71]or the use of the full response function [72]. After parametrization of the detector response as a function of E_n , several suitable algorithms can be used to unfold the response from the measured spectrum [20, 69]. The evaluation of systematic uncertainties in this method is not a simple task. Information about their magnitude can be obtained by comparison of results obtained by different groups and detector systems [20, 73]. This issue is discussed in Sect. III E.

2. Gaseous proton recoil spectrometers

This method is based on the detection of protons that are elastically scattered by neutrons. The detectors used are either methane- or hydrogen-filled proportional counters at high pressure in which the gas acts at the same time as the target for the reaction and as detecting media. These detectors are insensitive to thermal neutrons and compared to ³He spectrometers have a better energy resolution below ~ 200 keV. Because of this they are considered to be superior in this energy range [31]. They have, however, a lower efficiency which limits the practical measurable energy range up to about 1 MeV.

At typical β n energies, struck protons are scattered isotropically and the ideal detector response is a step function. Thus the neutron energy distribution is obtained by spectrum differentiation [74] rather than by deconvolution [75]. Fourier filtering can be applied to reduce the fluctuations of the extracted distribution [76].

However the true detector response departs from the ideal response and a number of corrections must be applied [17]. These type of detectors are sensitive to γ rays that contaminate the low-energy part of the spectrum (< 100 keV), but γ signals are efficiently eliminated using pulse shape discrimination. Different discrimination methods have been applied [17, 77] and the energy-dependent impact on neutron counting must be evaluated. In addition, the response is altered by the recoils of heavier nuclei present in the gas mixture, by walland end effects and by position-dependent variations of the signal amplitude. The PSNS code [78] allows the inclusion of all these corrections and is commonly employed to analyze the data. In general the corrections are found to be small and sometimes instead of correcting the data they are used to evaluate the size of the related systematic uncertainties [17]. A comparison of the results obtained with this technique and with ³He spectrometers is presented in Sect. III E.

3. Neutron energy spectroscopy with time-of-flight spectrometers

The time-of-flight (TOF) methods involve detection of neutrons using the β -neutron delayed coincidence method. In radioactive beam experiments, the start signal for the neutron time-of-flight measurement is given by a β detector trigger, and the stop signal is provided by a neutron detector, which is typically a fast plastic or liquid scintillator. The required time resolution for the TOF measurements is in the nanosecond range. The TOF distance and timing resolution determine the total resolution [79].

The key advantages of TOF arrays are the relatively high intrinsic efficiency for high-energy neutrons, the ability to measure neutrons without recording their full energy, and the relatively well-understood interaction crosssections with the scintillator which enables reliable simulations. The disadvantage of the TOF technique is the limitation of the achievable resolution for high-energy neutrons (> 3 MeV) due to the $E \sim 1/TOF^2$ dependence in the typical geometry and susceptibility of the detector response to neutron scattering. Neutron- γ discrimination can be achieved by using liquid scintillators. The high cost of the detector material prevented the use of solid organic crystals such as stilbene and para-terphenyl for making large TOF arrays. Recently developed plastic scintillators with neutron- γ discrimination capability [80] are now available.

Until recently the most successful TOF arrays used for β -delayed neutron spectroscopy were TONNERRE [81], which was used in experiments at CERN and at GANIL (France), and the TOF array developed at the NSCL (USA) [82]. Both were used to measure light-mass nuclei with distinct neutron transitions [83–85]. The heaviest studied isotopes were ${}^{51-53}$ K [86]. Both TOF arrays share a similar design with about 1 m flight path, and long and curved plastic scintillator bars.

The currently operational TOF arrays for decay studies are VANDLE [87, 88] (used at various facilities in the USA, at CERN, and at RIKEN), DESCANT [89, 90] at TRIUMF/ISAC in Vancouver (Canada), and MON-STER which has been built for FAIR and already used at ISOLDE and at the IGISOL facility in Jyväskyä [91].

VANDLE is a TOF array using a fully digital data acquisition system [92]. The focus is on a high detection efficiency with the use of straight bars made of EJ200 plastic scintillators (Eljen Technology, USA). A digital distributed trigger enables a low-energy neutron threshold down to 100 keV.

MONSTER is a TOF array based on BC501A (St. Gobain) and EJ301 (Eljen Technology) cylindrical liquid scintillators. Both BC501 and EJ301 offer excellent neutron/ γ -ray pulse shape discrimination capabilities, which allow to strongly suppress the competing γ ray background and β -neutron detector coincidences due to cosmic rays. MONSTER is operated with a fully digital data acquisition system based on 14 bits resolution and 1 Gsample/s digitisers.

DESCANT is a 70-element array of deuterated liquidscintillator detectors (BC-537, St. Gobain) that can be used with both the TIGRESS and GRIFFIN γ -ray spectrometers at TRIUMF-ISAC for reaction studies and the investigation of β -delayed neutron emitters [89, 90]. DES-CANT forms a close-packed array that replaces the forward "lampshade" of 4 HPGe clover detectors in each of the GRIFFIN and TIGRESS γ -ray spectrometers, providing high detection efficiency for neutrons in the range of ≈ 100 keV to 10 MeV.

The decay of ¹⁷N, a well-defined standard for neutronbranching ratio measurements (see Table I), can be used for energy- and detector-response calibrations in TOF experiments. The energy of the three main neutron lines are well-known from ³He ion chamber measurements [93–97] and appear fully resolved in TOF measurements [81, 98].

Alternatively, if a calibration with neutron transitions of energies higher than 2 MeV is desired, the use of ¹⁵B or ⁴⁹K is possible. However, there are no high-resolution ³He-detector measurements for the decay of ¹⁵B, and only one measurement for ⁴⁹K [99]. Several measurements of the delayed neutron emission of ¹⁵B [81, 82, 98] and ⁴⁹K [86, 99] have been published using TOF arrays and show deviations up to 10% in the reported neutron energies.

Monte Carlo simulations are a complementary tool to calibrations since they offer a large flexibility and can reach a high level of accuracy in the simulation of neutron interactions and detector properties [100, 101]. They are used for extending the overall efficiency calibration of a TOF spectrometer to a broader neutron energy range than available with mono-energetic neutron sources. Moreover, Monte Carlo simulations can also be applied for determining the time-energy relation of the neutron detectors, quantifying the cross-talk and estimating the time-correlated neutron and γ -ray background due to elastic, inelastic and (n, γ) reactions. Many new measurements have been performed in the past few years and the results are presently being analyzed.

C. New methods (for P_n values and energy spectra)

1. Total absorption γ -ray spectroscopy

Total absorption γ -ray spectroscopy (TAGS) was first applied to β -decay studies at ISOLDE-CERN in the 1970's [102] as a tool to measure accurately β -decay intensity distributions. It has been used since then to tackle a variety of problems, including the investigation of reactor decay heat evolution [103], the nuclear level densities and γ -ray strength functions far from stability [104], and the spectrum of reactor anti-neutrinos [105]. Recently it was proposed to use this technique to measure P_{1n} values and delayed neutron spectra [106]. This is indeed an exciting possibility, the current status of the method is summarized here. A total absorption spectrometer is a γ -ray calorimeter made with a large volume of inorganic scintillation material surrounding the source with a $\sim 4\pi$ solid-angle coverage. Such a detector is capable of absorbing the full energy of the γ -cascade following the decay, thus identifying the excitation energy of the populated state. However, due to detector inefficiency and β penetration, this is not true for all events, and a spectrum deconvolution procedure is needed to recover the information.

Due to the large detector size, neutrons emitted after β decay have a large probability to interact with the scintillation material through elastic collisions, inelastic scattering, and radiative capture. The latter two processes generate γ -rays that are easily detected. In principle, this is a source of contamination of the spectrum that needs to be determined and subtracted [107].

The neutron reaction cross sections, specific to the scintillation material, determine the amount of background signals. Large differences are observed in (n, γ) cross sections between scintillators, which is the reason for the choice of BaF₂ in the spectrometer of Ref. [107] since the neutron-induced background is minimized.

On the other hand, Ref. [106] proposes to turn the large capture cross section of NaI(Tl) into an advantage, allowing the measurement of neutron-emission probabilities and spectra. Beta-delayed neutrons captured in the scintillator produce a bump in the energy spectrum above ~ 6.8 MeV, whose shape depends on the neutron-energy distribution and the height is proportional to the P_{1n} value.

The difficulty of the method is that it relies on the Monte Carlo simulation of the transport and generation of radiation by neutrons in the detector to extract the desired information [108]. Contrary to the simulation of photon transport, the accuracy of such simulations is not guaranteed a priori and should be investigated by comparison between different codes and nuclear data libraries [100] and, if possible, by dedicated measurements [109].

Alternatively, a collection of neutron emitters with well-known P_{1n} values and neutron spectra can be measured with TAGS and compared with the results of the standard methods. This was done in Ref. [106] for the case of ¹³⁷I, and a good agreement was found with the P_{1n} value recommended in this CRP [36] (see Table I).

However, in a similar work reported in Ref. [108], the P_{1n} value obtained for ¹³⁷I was 11% smaller, while the value for ⁹⁵Rb was found to be 22% larger than the evaluation [36]. It is clear from this that further work is needed, both experimentally and from the point of view of simulations, to clarify the situation and establish the systematic uncertainties of the method. This is worth the effort – given the sizable number of β n emitters that have been measured recently and will be measured in the near future with the TAGS technique.

2. Ion-recoil methods

The Beta-decay Paul Trap (BPT) [110], an opengeometry linear radiofrequency quadrupole (RFQ) ion trap designed for precision β -decay studies, has been used to determine β -delayed neutron (β n) branching ratios and energy spectra from the recoil energy imparted to the daughter ions following β decay. This novel way to perform β n spectroscopy circumvents the challenges associated with direct neutron detection.

The BPT collects and suspends radioactive ions in vacuum at the center of a radiation-detector array consisting of ΔE -E plastic scintillator telescopes, microchannel plate (MCP) detectors, and high-purity germanium (HPGe) detectors, used to detect the β particles, recoiling daughter ions, and γ rays, respectively, emitted following the decay. Following β decay, the recoil ions emerge from the trap volume essentially unperturbed by scattering and the TOF of the recoiling ion to the MCP detectors is determined. The β n decays can be identified because the higher-energy recoil ions characteristic of neutron emission (with kinetic energies up to tens of keV) have shorter TOFs than the other recoiling daughter ions (which have kinetic energies typically less than 500 eV).

The β n branching ratios can be deduced by comparing the number of β -ion coincidences with TOFs characteristic of neutron emission to the total number of β decays from trapped ions obtained from the number of detected: (1) β particles emitted from the trapped precursor, (2) β -ion coincidences with longer TOFs characteristic of β decay to bound states, and (3) β -delayed γ rays.

The agreement obtained for the β n branching ratios when using these three approaches provides additional confidence in the results. This approach was first demonstrated in Ref. [64] and has subsequently been used to study mass-separated ion beams of ^{137,138,140}I, ^{135,136}Sb, and ^{144,145}Cs [111, 112] delivered by the CARIBU facility at Argonne National Laboratory.

Additional upgrades to the experimental setup can be implemented to increase the solid angle of the detector array and to improve the ion collection and cooling while minimizing the effect of the electric fields on the recoil ions. Future experiments will also benefit from increases in the intensity and purity of the low-energy beams delivered by the CARIBU facility [113, 114].

The recoil-ion approach is well suited to reconstruct the kinematics of a single undetected particle through conservation of momentum and energy. The studies of β delayed multi-neutron emission will need to incorporate auxiliary neutron detectors.

3. Optical Time Projection Chamber

The potential of using an optical Time Projection Chamber (OTPC) to measure the neutron branching ratio via ion counting has been shown in [65]. The principle is the same as for the discovery of the two-proton radioactivity: a gas-filled TPC is used to produce ionization tracks of the incoming β n-precursor and the recoiling β n-daughter products which are then made visible via a CCD camera. Fig. 4 shows two different decay events of the β n emitter ⁸He. The picture shows only the incoming ⁸He nucleus and the recoiling ⁷Li, the β -delayed neutron is not visible. In the bottom of Fig. 4 the second decay possibility of ⁸He into an α , a triton, and a neutron is shown.

In principle one can reconstruct the energy of the emitted neutron from the length of the recoil tracks. This has been done for the β -delayed triton decay of ⁸He via measurement of the momenta of the recoiling charged particles (α and triton) [115].

The main limitation comes from the generally low recoil energy and the finite resolution (diffusion effects) of the OTPC. So the technique is limited to low-mass precursors and reasonably high neutron energies. In the present setup with a gas mixture of 95% He and 5% N₂ at atmospheric pressure, a lower threshold for neutrons of ≈ 1.4 MeV corresponding to a minimal track length of 10 mm [115] is required for the recoil identification.

The OTPC method is not suitable for measuring P_{2n} values (and higher) since the energy reconstruction is not possible with two outgoing (undetectable) neutrons.

FIG. 4. (Top) β -delayed neutron decay of ⁸He into ⁷Li and a neutron (not visible) in the OTPC. (Bottom) β -delayed triton decay of ⁸He into an α , a triton, and a neutron (not visible) in the OTPC. Pictures courtesy of Janas Zenon, University of Warzaw/ Poland.

4. Measurement in a storage ring

The P_n value could also be measured via ion counting in a heavy-ion storage ring. This complementary method has been proposed for radioactive beams produced at the Fragment Separator (FRS) at the GSI Helmholtz Center for Heavy Ion Research in Darmstadt/ Germany which are injected into the Experimental Storage Ring (ESR). Similarly, at the future Facility for Antiproton and Ion Research (FAIR) the β n-emitter will be produced at the Super-FRS and injected into the Collector Ring (CR). While the β n-emitter is circulating in the ring and decays, the measurement of the neutron-branching ratio could then be carried out via the ion counting method (see Sect. II A 8). This method has been described in Ref. [66] but no proof-of-principle measurement has been carried out yet.

The advantage of this method is that symbiotically the mass and/or half-life of the stored ion could be measured non-destructively by time-resolved Schottky mass spectrometry [116]. However, Schottky mass spectrometry requires "cooling" to reduce the momentum spread of the beam. These beam cooling procedures take several seconds and thus reduce the range of accessible β n precursors.

Capacitive Schottky pick-up plates provide the revolution frequencies of the ions in the storage ring and allow their identification. When these ions decay, the change in mass and charge state leads to a change in the respective revolution frequencies. With Schottky spectrometry it is only possible to study the daughter nuclei that remain within the acceptance of the ring. This restricts the method in the ESR to parent-daughter pairs within an A/q change of $\pm 1.5\%$, but it can be complemented by particle detectors in pockets behind the dipole magnets to detect also β^-/β n-daughter nuclei.

Like all described ion-counting methods this method is independent of the energy of the emitted neutron and the respective neutron detection efficiency. However, different loss mechanisms during the storage in the ring need to be carefully addressed and investigated.

The decay of the ions can occur anywhere on the ring orbit (which is ≈ 108 m for the ESR at GSI Darmstadt) but only those decays that occur in the long straight sections can be detected by a particle detector behind the respective dipole section. All other decays outside this section will lead to a loss of the ions. For the ESR, a multi-purpose particle detector (CsISiPHOS) has been installed and tested [117], which allows a geometrical efficiency of $\approx 20\%$. For experiments in the CR at FAIR two particle detectors will be installed and operated by the ILIMA collaboration [118].

5. Ion counting using a MR-TOF

Multi-Reflection Time-Of-Flight (MR-TOF) spectrometers are becoming more and more popular as devices to measure precisely masses, determine the beam composition, or to manipulate and clean ion beams. This versatility has also led to the proposal to measure neutron-branching ratios (including multi-neutron emission branches) with a MR-TOF, parallel to the determination of masses and half-lives [67, 119]. The setup at the Fragment Separator (FRS) at GSI Darmstadt/ Germany, the so-called FRS Ion Catcher [120], consists of a Cryogenic Stopping Cell (CSC) and a MR-TOF spectrometer.

The composition of the fast (E > 500 MeV/u) beam is identified with the standard set of detectors at the FRS. A beam containing only the isotopes of interest is stopped and stored in the CSC. After some decay time the ions are then extracted from the CSC into the MR-TOF for further identification and measurement. The relative intensities of β n precursors and respective decay daughters will then allow to extract the neutron-branching ratios.

Fig. 5 gives a schematic view of the setup and a simulated MR-TOF mass spectrum for the yet unmeasured β 2n decay of ¹³⁷Sb. Within the next years this promising method will be tested with radioactive beams at the GSI Helmholtz Center in Darmstadt/ Germany.

FIG. 5. Schematic view of the MR-TOF technique using a Fragment Separator (FRS), a Cryogenic Stopping Cell (CSC) and a MR-TOF device to count the ions. At the bottom a simulated MR-TOF mass spectrum is shown. Picture reprinted with permission from [67] (https://creativecommons.org/licenses/by/4.0/).

D. Outlook for future measurements

There has been a lot of progress in measuring β n emitters in the last decade, especially with precision better than 5%. The earlier measurement campaigns were mainly driven by fission reactor studies and thus focused around the two – low mass and high mass – fission fragment groups. The reactor community still strives for more precise measurements of important fission fragments that are the main contributors to the delayed neutron yield ν_d (see priority list on p. 15 in Ref. [40]) but the general scientific focus has now shifted.

The nuclear astrophysics community is interested in measurements of the most neutron-rich, heavy (Z > 26)nuclei that can be accessed with the new generation of radioactive beam facilities, especially those around the N = 50, 82, and 126 shell closures which are the progenitor nuclei that are responsible for the creation of the solar *r*-process abundance peaks at $A \approx 80, 130$, and 195. Masses, decay half-lives, neutron-capture cross sections, and neutron-branching ratios of these neutron-rich nuclides are important nuclear physics input parameters for astrophysical network calculations, and in turn also help to improve theoretical nuclear models that are required for the prediction of even more exotic nuclei.

A detailed review of the *r*-process nucleosynthesis, the astrophysical scenarios, the required nuclear data, how they can be measured at radioactive beam facilities and with what accuracy, is provided in Ref. [121]. Figs. 6 and 7 give an overview of the status quo of β n-emitter as of August 2020. These pictures include the vast amount of measurements that were performed during the course of the evaluation work that has been published in Refs. [35, 36] (see following Sect. III), as well as the majority of the (yet unpublished) data from the BRIKEN project [37, 51] which will conclude its campaign in 2021.

This decade will see the transition to the new generation of radioactive ion beam (RIB) facilities that are still under construction. Two of the main competitors for the study of the most neutron-rich β n-emitter will be the Facility for Rare Isotope Beams (FRIB) at Michigan State University/ USA, which is planning to be operational by the end of 2021, and the Facility for Antiproton and Ion Research (FAIR) in Darmstadt/ Germany which is aiming at producing the first beams in ≈ 2027 . Until then, the "FAIR Phase-0" program will be operating at the existing GSI facilities, using many of the newly designed detector setups and upgrades of the accelerator facilities.

These new facilities will push the limits on what can be measured on the neutron-rich side of the chart of nuclides closer towards the driplines. Two of the key regions for future r-process experiments at these new facilities are the so-called "Rare Earth Region" (A = 160 - 170) and the nuclei with Z < 75 along the N = 126 shell closure. As can be seen in Fig. 7 and in the recently published evaluation [36], only a small number of β -delayed neutron emitters has been measured so far for Z > 57. Experiments in the next decade will allow us to access these neutron-rich nuclei for the first time and achieve a better understanding of the formation of these two abundance peaks in the solar r-process abundance distribution.

III. COMPILATION AND EVALUATION

A. Compilation and evaluation methodology

Standard procedures were followed for the evaluation of nuclear spectroscopic data as defined for the Evaluated Nuclear Structure Data File (ENSDF) and discussed at three Research Coordination meetings of the CRP [39, 40, 42], with the addition of guidelines for half-life evaluations as formulated by A.L. Nichols and B. Singh (see p. 31–40 in Ref. [122]). Emphasis has been placed on making sure that the P_n value and half-life data have been compiled thoroughly, together with the method used for each measurement, from all the available measurements published in peer-reviewed journals as well as in certain selected secondary references. This was followed by a selection of the most reliable set of data for a nuclide which could be averaged to obtain recommended values.

Details of the procedures and policies of evaluations for this CRP are described in two publications. A detailed paper on the compilation and evaluation of data in the Z = 2 - 28 region (cut-off date December 2014) was published by M. Birch *et al.* [35] in 2015. The newly evaluated data for Z = 29 - 83 (cut-off date August 2020) can be found in J. Liang *et al.* [36].

B. New evaluated $(T_{1/2}, P_n)$ data

In total, as of August 2020 data for nuclide identification, half-lives and P_n values have been extracted and evaluated for 653 neutron-rich known or potential β -delayed neutron emitters from more than 750 publications, mostly in main-stream peer-reviewed journals.

The evaluations in Refs. [35, 36] included only the very first batch of data from the aforementioned BRIKEN measuring campaign at RIKEN. The upcoming publications will be included in evaluations of these mass ranges in the near future. The cut-off date for the data used for the calculations of macroscopic data in this CRP paper (see Secs. VI and VII) was March 2020. The data used in these calculations can be found in the reference database [43].

Some data that was published in the months between March 2020 and the cut-off date of the Z > 28 evaluation was included in the published version [36]. This data was not used for the calculation of macroscopic parameters in Secs. VI and VII as already mentioned, however, the differences are minute and have a negligible impact on the calculated parameters.

The most noteworthy addition is the inclusion of data published by the EURICA collaboration at RIKEN [123], measuring half-lives of 55 neutron-rich nuclei between ¹³⁴Sn and ¹⁵⁵La. In addition, for 13 neutron-rich nuclei the β -decay half-life was measured for the first time: ^{140–142}Sb, ^{139–144}Te, ^{144–146}I, and ¹⁴⁸Xe. This led, for example, to tiny changes in the recommended half-lives for the P_{1n} standards ^{144,145,146}Cs:

- ¹⁴⁴Cs: 581(6) ms \longrightarrow 582(6) ms
- ¹⁴⁵Cs: $321.7(11) \text{ ms} \longrightarrow 321.7(10) \text{ ms}$
- ¹⁴⁶Cs: 229.7(10) ms \longrightarrow 229.5(10) ms
 - 1. Z = 2 28 region

Based on Q values deduced from the Atomic Mass Evaluation (AME) 2016 for neutron-rich nuclides [33, 124], a total of 221 experimentally observed nuclides were identified as known or potential β -delayed neutron emitters

FIG. 6. Chart of nuclides for Z = 0 - 14 (top), Z = 15 - 28 (middle) and Z = 29 - 43 (bottom) with status for half-life and neutron-branching ratio measurements. Boxes show previously measured neutron-branching ratios, whereas circles indicate isotopes that have recently measured but have not yet been published or included in the latest evaluations [35, 36]. Crosses indicate isotopes for which half-lives have been measured for the first time recently.

FIG. 7. Chart of nuclides for Z = 44 - 57 (top) and Z = 58 - 86 (bottom) with status for half-life and neutron-branching ratio measurements. Boxes show previously measured neutron-branching ratios, whereas circles indicate isotopes that have recently measured but have not yet been published or included in the latest evaluations [35, 36]. Crosses indicate isotopes for which half-lives have been measured for the first time recently.

in Ref. [35]. Of these nuclei, half-lives had been measured for 180 nuclides, P_{1n} values for 114, P_{2n} values for 21, and P_{3n} values for only three nuclides. There is only one nucleus, ¹⁷B, where a tentative P_{4n} value has been reported [7]. In addition there were 9 isomeric values for P_{1n} values reported. For about 50% of the cases, P_{xn} values are available from only one measurement.

Since the cut-off date for this part of the evaluation was in 2015, work on an update to include recent publications has started by the Canadian community. So far, four new nuclides have been identified as β n-emitter, and two decay half-lives and three new P_{2n} values were measured.

2. Z = 29 - 57 region

The latest evaluation comprised the heavier mass region and was recently published [36] with a cut-off date of August 2020. A total of 318 nuclei were identified as β -delayed neutron emitters, based on Q values deduced from the AME2016 [33, 124]. This region is of utmost importance due to the production of most of these nuclides in the fission of uranium and other actinides, and therefore of relevance in nuclear power reactors. Out of these 318 nuclei, half-lives have been measured for 284 nuclides, P_{1n} values for 183 nuclides, and P_{2n} values for only eight nuclides. So far no P_{3n} or P_{4n} values have been determined in this mass region.

The data for isomers are generally poorly determined and often the half-lives and P_n values are mixed with the data for ground states. For a large number of cases P_{1n} values are available from only one measurement, and for several others only upper limits are reported. However the data for the main isotopes contributing to fission yields seem to be in good order.

3. Z = 58 - 87 region

In this mass region 110 experimentally known nuclides were identified as β -delayed neutron emitters based on Q values from the AME2016 [33, 124]. Half-lives are known for only 54 of these, and P_{1n} values for only 9 nuclides. Measurements for six Tl isotopes (^{211–216}Tl) and two Hg isotopes (^{210,211}Hg) were reported only recently [125, 126], while a tentative value of P_{1n} for ²¹⁰Tl was reported in a secondary publication in 1961 [34].

C. P_{1n} Standards

The selection of certain radionuclides as standards for P_{1n} follows criteria which are given in Refs. [35, 36]. The main criteria for "good" standards are:

• Easy production at various facilities (large quantities, clean beams, no isomers).

- Measured using reliable methods outlined in Sect. II A in four or more independent experiments.
- Consistent results with overall uncertainty of less than 5%.

Exceptions are 49 K, 82 Ga, and 146,147 Cs, where the overall uncertainty is 5–10%. 147 Cs has only three independent measurements, but these measurements are very robust and consistent.

In summary, the following nuclides are recommended as P_{1n} standards, covering different Z regions up to Z=55: ⁹Li, ¹⁶C, ¹⁷N, ⁴⁹K, ⁸²Ga, ⁸⁷Br, ⁸⁸Br, ⁹⁴Rb, ⁹⁵Rb, ¹³⁷I, ¹⁴⁵Cs, ¹⁴⁶Cs, and ¹⁴⁷Cs. The recommended half-lives and P_{1n} values for these standards can be found in Table I.

TABLE I. Table with P_{1n} standards and their corresponding half-lives as recommended from this CRP [35, 36].

Nuclide	Half-life (s)	P_{1n} (%)	Ref.
⁹ Li	0.1782(4)	50.5(10)	[35]
^{16}C	0.7546(80)	99.28(12)	[35]
^{17}N	4.171(4)	95.1(7)	[35]
^{49}K	1.263(50)	86(9)	[35]
82 Ga	0.601(2)	22.7(20)	[36]
$^{87}\mathrm{Br}$	55.64(15)	2.53(10)	[36]
$^{88}\mathrm{Br}$	16.29(8)	6.72(27)	[36]
$^{94}\mathrm{Rb}$	2.704(15)	10.39(22)	[36]
$^{95}\mathrm{Rb}$	0.378(2)	8.8(4)	[36]
^{137}I	24.59(10)	7.63(14)	[36]
^{145}Cs	0.582(6)	13.5(6)	[36]
^{146}Cs	0.3217(10)	14.3(8)	[36]
$^{147}\mathrm{Cs}$	0.2295(10)	28.5(20)	[36]

D. Systematics for P_{1n} values

In several studies [127–130] correlations between known values of P_{1n} and other β decay gross properties $(T_{1/2}, Q_{\beta}, S_n)$ have been described to estimate unknown P_{1n} values. The basic correlation between P_{1n} and β -decay properties is:

$$P_{n} = \frac{\int_{S_{n}}^{Q_{\beta}} S_{\beta}(E) f(Z, Q_{\beta} - E) \ dE}{\int_{0}^{Q_{\beta}} S_{\beta}(E) f(Z, Q_{\beta} - E) \ dE},$$
(9)

where $S_{\beta}(E)$ is the β -decay strength function and $f(Z, Q_{\beta} - E)$ is the Fermi integral. The integrations is performed over the available β energy window, $Q_{\beta} - E$.

One of the earliest semi-empirical expressions originates from Amiel *et al.* in 1970 [127]. Already then it was known that the neutron emission probability depends on the available $Q_{\beta n}$ energy window, the level density, and the competition of neutron and γ emission. A plot of the log P_{1n} vs. log $Q_{\beta n}$ resulted in a linear dependence with slope *m*. This led to the conclusion that the dependency of the P_{1n} value on the $Q_{\beta n}$ window is dominant over any influence from the level density.

The evaluated half-lives and P_{1n} values in this CRP were analyzed by the three empirical approaches proposed by K.L. Kratz and G. Herrmann [128] (Kratz-Herrmann formula, KHF), an improved KHF systematics developed by E.A. McCutchan *et al.* [129], and a level-density dependent systematics by K. Miernik [130]. These estimates can be used as guidance for future experiments close to the known region, as well as to cross-check if outliers in existing data appear. They are however of limited use for *r*-process abundance calculations since they do not reach out far enough in *A*.

For Z = 2 - 28 region, global fits with the Kratz-Herrmann and McCutchan *et al.* systematics were presented in Ref. [35]. More detailed systematic plots using all the three approaches are presented for the Z = 28 -57 region in Ref. [36], where a new approach of fitting the McCutchan *et al.* systematics by individual Z has also been presented for most of the elements in this region. It appears that this approach has better potential for predicting unknown P_{1n} values. Unfortunately, there is not enough data in the Z = 58 - 87 region to attempt fits with the systematics.

1. Kratz-Herrmann formula

In the Kratz-Herrmann formula (KHF) [128] the β strength function is assumed to be constant above a certain cut-off energy C, and to be zero below that energy. It also assumes that the Fermi integral might evolve as a function of the $Q_{\beta n}$ value. This leads to the following description:

$$P_{1n} \sim a \left(\frac{Q_{\beta n}}{Q_{\beta} - C}\right)^b,\tag{10}$$

where a and b are free parameters (fitted to the respective data range), and C is the cut-off parameter. The values for the cut-off parameter depend on the proton/neutron number:

- C = 0 for even-even nuclei.
- $C = 13/\sqrt{A}$ for even-odd/odd-even nuclei.
- $C = 26/\sqrt{A}$ for odd-odd nuclei.

For the latest fit parameters and a log-log plot of P_n as a function of $\left(\frac{Q_{\beta n}}{Q_{\beta}-C}\right)^b$, the reader is referred to Ref. [36].

2. McCutchan systematics

The considerable scatter and large reduced χ^2 in the plots of the KHF systematics questions the reliability of predictions made employing this systematics. Thus, an improved systematics was developed by McCutchan *et. al.* [129] which considers both, the β -delayed neutron emission probability as well as the half-life. As the halflife is inversely proportional to the decay Q value, the ratio $P_{1n}/T_{1/2}$ is considered as a function of the $Q_{\beta n}$ value:

$$\frac{P_{1n}}{T_{1/2}} \sim c \ Q^d_{\beta n},\tag{11}$$

where c and d are fitted parameters.

3. Improved systematics along Z chains

While the $P_{1n}/T_{1/2}$ systematics from McCutchan show an improvement over the KHF, there is still considerable scatter. "Isotopic" systematics along a given Z can provide a much better picture for unknown P_{1n} values. In Ref. [36] this method was used for nuclides in the region Z = 29 - 57 which had three or more isotopes with a measured value for their P_{1n} and $T_{1/2}$, respectively.

The improved systematics along a given Z shows linear behavior when plotted in a log-log scale. Despite some scatter in this presentation, extreme outliers can indicate isotopes that require further investigation, e.g. the isotopic chains of As, Pd, and Ba [36].

4. Systematics based on the Effective Density Model

The phenomenological effective level density function model by Miernik [130] assumes that the β = strength function is proportional to the level density $\rho(E)$ fed by β -decay:

$$S_{\beta}(E) \propto \rho(E) = \frac{\exp(a_d \sqrt{E})}{E^{2/3}}$$
(12)

The parameter a_d is fitted to existing data, so that the derived formula can be used across an entire mass surface.

In order to calculate P_n using this systematics, one needs to first find the a_d for the nuclides of interest. Then the β -decay energy Q_{β} of the parent and the neutron separation energy S_n can be used within the integration of Eq. 9. The Fermi integral can be calculated precisely with available tables, and the integration of Eq. 9 can be carried out numerically.

An attempt to extend this model to multi-neutron emission (up to P_{3n}) can be found in [131]. The assumption is that the neutrons are emitted sequentially, and that the many-body channels are negligible. The limitation of this description is also that only Gamow-Teller transitions are considered and that the neutron- γ competition is approximated with a "threshold method".

Numerical values for the fit parameters and more details are given in Refs. [36, 130].

E. Delayed neutron spectra for individual precursors

Delayed neutron spectra have been measured for less than 50 β n emitters. These include 34 fission products for which good quality data exists which was obtained using ³He and gaseous proton recoil spectrometers and measured by several groups at different installations. As it was pointed out in the late 1970's [19] discrepancies were observed between the different sets of data in particular at low neutron energies. This lead to an attempt to benchmark the different methods at different laboratories [70] and triggered new measurements at other facilities [17, 73].

An evaluation of the available neutron spectra for the 34 individual fission products was carried out during the thorough and comprehensive work presented in the PhD Thesis of M. C. Brady in 1989 [31]. The list of isotopes included in the evaluation is given in Appendix D of that work. Most of the experimental data was coming from ³He spectrometer measurements carried out by the Studsvik group (G. Rudstam *et al.*), the Mainz group (K.-L. Kratz *et al.*) and the Pacific Northwest Laboratory (PNL) group (P. Reeder *et al.*). Proton recoil data from the Idaho National Engineering Laboratory (INEL) group (R. C. Greenwood *et al.*) was also included. Additional data was published by this group in 1997 [18] and thus was not included in the Brady evaluation.

The data from the Studsvik group was provided with uncertainties. The uncertainty for the other data sets was inferred from generic assessments by the respective authors. Brady [31] stated that the Mainz and Studsvik data are in "fair agreement" above few hundred keV, and are considered to be of better quality than PNL data. Probably because of this she gave preference to a single data set instead of averaging different data sets, when available.

In general, due to the smaller uncertainties and broader energy range, preference was given to ³He data from the Mainz group. If available, the proton recoil data from INEL replaced the ³He data below 200 keV. The selected data were extended by theoretical model calculations to cover the full $Q_{\beta n}$ window. This procedure lead to a renormalization of the experimental data. The recommended data is presented in graphical form (figures 12 to 45 in Ref. [31]).

The originally evaluated data from Brady was incorporated into the ENDF/B-VI decay data sub-library [132]. Uncertainties are not included explicitly in the recommended data of [31] neither can they be retrieved from ENDF/B. In addition an evaluation of possible systematic errors from the comparison of different data sets was not carried out in Brady's work. The lack of realistic uncertainties for individual precursor spectra diminishes its helpfulness. For example, it does not allow for an evaluation of uncertainties on aggregate spectra calculated by the summation method. In addition it is difficult to define reference β -delayed neutron spectra for calibration or inter-comparison purposes. This issue is further discussed below.

1. Digitization of delayed neutron (DN) energy spectra

Digitization of several β -delayed neutron spectra has been done using the GSYS2.4.3 code and its later version 2.4.7 [133]. This code is routinely and extensively used for the digitization of cross section plots for the EX-FOR database [134]. The quality of the digitization was checked by plotting the extracted data and comparing the plot with the corresponding figure in the paper.

The extracted datasets of all the figures were sent to the IAEA Nuclear Data Section for further checking by an expert staff scientist. All the data files were finally prepared for inclusion into the Reference Database for delayed neutrons [43].

a. Z = 2 - 28 region: Beta-delayed neutron spectra from ⁸He [135], ⁹Li [136, 137], ¹¹Li [5, 83, 138, 139], ¹⁴Be [138], ¹⁵B [81, 98], ¹⁶C [140], ¹⁷B [141], ¹⁷N [81, 98, 140], ¹⁸N [142], ²¹N [143, 144], and ^{27,28}Na [145] were digitized. Note that some of these are time-of-flight spectra, e.g. for ⁹Li from Ref. [136].

b. Z = 29 - 57 region: Spectra are available from different groups:

- R.C. Greenwood and A.J. Caffrey [17]: Spectra of delayed neutrons for the isotope-separated, fission product precursors $^{93-97}$ Rb and $^{143-145}$ Cs were digitized independently by two groups over an energy region of $\approx 10 1300$ keV. The data was transformed to an equidistant scale with an energy bin of 1 keV for use in the summation method.
- P.L. Reeder *et al.* [73]: Measured energy spectra of delayed neutrons from ⁹³⁻⁹⁵Rb and ¹⁴³Cs were digitized.
- M.C. Brady [31]: Several measured delayed neutron spectra obtained from different experimental groups (mainly Mainz, Studsvik, and groups at the TRISTAN online separator) were analyzed in this work as raw and adjusted spectra. This work includes ⁷⁹⁻⁸¹Ga, ⁸⁵As, ⁸⁷⁻⁹⁸Rb, ^{129,130}In, ¹³⁴Sn, ¹³⁵Sb, ¹³⁶Te, ¹³⁷⁻¹⁴¹I, and ¹⁴¹⁻¹⁴⁷Cs. Both the raw as well as the adjusted spectra from this work were digitized.
- R.C. Greenwood and K.D. Watts [18]: Delayed neutron spectra of ^{87,88,90}Br, ^{137–139}I, and ¹³⁶Te were presented in this paper. All were digitized, and were subsequently transformed to equidistant scale with an energy bin of 1 keV for use in the summation method.

2. Assessment of spectra as a reference for calibration purposes

Defining β -delayed neutron reference spectra would be an important asset in practical work. These could serve to benchmark new setups and methods for the measurement of β -delayed neutron spectra. It will also serve to study the neutron energy dependency of the efficiency in devices aiming to determine neutron emission probabilities. The lack of an evaluation of uncertainties, in particular systematic uncertainties, introduces ambiguities in the results.

An attempt was made within the CRP to asses the size of systematic uncertainties by comparison of spectral data obtained by different groups and different methods. However, it was realized that with the available information it is not possible to make a quantitative assessment. To illustrate the difficulty of the task, the cases of 94 Rb and 95 Rb are shown in Fig. 8, which have reasonably large P_{1n} values and are easily produced in fission reactions.

In the evaluation work of Brady [31], ³He spectrometer data was available for both nuclei, provided directly by the Mainz group and the Studsvik group. Data was available also from the PNL group [73], but was disregarded because it had lower statistics and a smaller energy range. Preference was given to Mainz data over Studsvik data for both isotopes, but no information is given about the differences between both data sets. Below 200 keV the Mainz data was replaced by proton-recoil data from INEL [17].

Figure 8 displays the resulting evaluated spectra as retrieved from the ENDF/B-VII.1 library [24] (same spectra are available in ENDF/B-VIII.0 [25]). It is compared with the full INEL spectrum obtained by digitization of the graphical representation in [17]. The data from PNL is also included in the figure, and was obtained by digitization of figures in [73]. The three data sets are histogramed with a 10 keV bin width and are normalized to the counts in the region from 0.2 to 1.2 MeV. As can be seen there are notable differences. When comparing values integrated over a range of 100 keV, to minimize the effect of different energy resolution and statistics, the discrepancies reach up to 30-50%. The drop observed in the PNL data at around 0.5 MeV is likely due to a sudden rise of their efficiency that the authors quote as of uncertain origin but was also observed by other groups. Later this rise of efficiency has been identified as a spurious effect of neutron resonances excited in iron which is generally present in the experimental setup [146].

It is not easy to arrive to a conclusion regarding the size of systematic errors from this information alone. In particular the loss of the primary information handled by Brady is unfortunate. In addition, it seems that the systematic errors of the different techniques are not fully understood. A proper evaluation work will require new well-controlled measurements that should profit from the advances in radioisotope production methods and instrumentation made in recent years.

FIG. 8. Comparison of measured β -delayed neutron spectra for ⁹⁴Rb (top panel) and ⁹⁵Rb (bottom panel). Red line: Data retrieved from ENDF/B-VII.1 database. Blue line: Data from Greenwood *et al.* (INEL) [17]. Green line: Data from Reeder *et al.* (PNL) [73]

For practical applications the interested user should be warned about possible large uncertainties in the shape of β -delayed neutron spectra retrieved from the ENDF/B-VIII.0 [25] and ENDF/B-VII.1 [24] libraries. Whenever possible the effect of spectra obtained from different measurements should be studied. It should be noted also that the experimental spectra in the ENDF/B data base are augmented with model calculations to cover the full $Q_{\beta n}$ energy window. These calculations use FRDM+QRPA β -strength distributions [147] and Hauser-Feshbach neutron branching ratios [32] to obtain the neutron spectra as described in the following sections. The model spectra additions are easily identified due to the smooth character of their distribution.

IV. THEORY OF MICROSCOPIC DATA

In this section we compare the new evaluated CRP $(T_{1/2}, P_n)$ data described in Sect. III with "state-of-theart" microscopic models. The comparisons are limited to global self-consistent β -decay models that take into account both the allowed Gamow-Teller (GT) and first forbidden (FF) decays on equal footing and can be used to calculate both half-lives and β -delayed neutron emission probabilities. Self-consistent models have the advantage of being founded on first principles. Their parameters are determined from a limited set of sample nuclei and are then kept unchanged for the whole nuclear chart. Thus, they are considered more reliable for extrapolations to extreme N/Z ratios. However, before they are used for predicting nuclear properties in unexplored mass regions, their accuracy has to be tested against existing experimental data. The aim of this section is to ascertain whether these global models are robust in the description of the evaluated CRP data which include new results from ongoing large-scale experiments at RIB facilities worldwide. This will then mean they can be used in extrapolations to mass regions where experimental data are either unavailable or inaccessible.

Beta-decay properties are influenced by various different factors. First of all, the competition between the GT and high-energy FF transitions accelerates the β decay, while in the region of the ground-state spin inversion such concurrence may produce isotopic irregularities in the half-lives and P_n values. Second, the effects of many particle-many hole (np-nh) configurations substantially enriches and softens the β -decay strength distribution. Third, a local fragmentation of the β -strength due to deformation may change nuclear β -decay characteristics. In transitional nuclei a co-existence of spherical and deformed shapes may also be of importance.

In the comparisons, we use two self-consistent global models which treat GT and FF transitions consistently, but do not take into account complex npnh configurations or deformation effects. For completeness we also include the results of the recently updated microscopic-macroscopic model of Ref. [148] which are taken from the publicly available supplementary tables (https://t2.lanl.gov/nis/molleretal/ publications/ADNDT-BETA-2018.html).

The three models are listed below:

- Fayans Energy Density Functional (EDF) [149] combined with continuum quasiparticle randomphase approximation (CQRPA). A common abbreviation DF+CQRPA is used below for different versions of the density functional, namely DF3 from [150–152] as well as the extended DF3a which was developed within the CRP to compare with the new evaluated data.
- Relativistic Hartree–Bogoliubov+QRPA [153] based on the D3C* functional (RHB+RQRPA) [154]. This model was also extended within the CRP to perform global calculations.
- Microscopic-macroscopic model of Ref. [148] based on the latest version of the finite-range droplet model FRDM12 published in Ref. [155] combined with the BCS+RPA '(Q)RPA' description for the GT decays and a phenomenological approach based on the 'Gross theory' for first forbidden (FF) decays. The β -delayed neutron emission properties

are estimated by considering the competition between neutron and γ emission in the daughter nucleus using the Hauser-Feshbach statistical model (HF). This approach 'FRDM12+(Q)RPA+HF' is different from the sharp cut-off model used in the previous calculations [147] whereby multi- β -delayed neutron emission emission was assumed to occur at energies above the corresponding neutron separation.

In addition to the above models, which are used in isotopic chains and global comparisons of both $T_{1/2}$ and P_{xn} values, we include the results from the finite amplitude method (FAM) [156] in selected comparisons of half-lives. The FAM is a mean-field model used up to now solely for calculations of half-lives, however, it provides a breakthrough approach for treating deformed nuclei [157–159] with the Skyrme functional SkO' [160], therefore is worth comparing with the CRP data for deformed nuclei.

A few attempts have been made to include complex np-nh configurations within the self-consistent approach in the study of the fine structure of the β -decay strength functions and integral β -decay properties. The preferred models are the latest versions of the interacting shellmodel (SM) [161, 162] which include the allowed GT and FF decays. Also "beyond the QRPA approximation" models based on the EDF approach have been developed and applied to selected nuclei near the closed shells. Practical schemes of this kind of models are the phonon-phonon coupling model (PPC) within the FRSA approximation [163–165] and particle-vibration coupling models (PVC) [166–168] of the β -decay strength function. However, these models are still limited to the allowed GT approximation. Among the models with complex configurations, β -delayed neutron emission branching ratios have been tackled so far only in the SM frameworks [161, 162] and FRSA [164, 165]. We have included published results from the SM [161, 162], FRSA [163–165], and PVC models [166–168] in the comparison of halflives of ⁷⁸Ni in this report.

Finally, we mention the self-consistent models for spherical and deformed nuclei in the GT approximation [169–174] which have been used in selected isotopic regions. Ref. [170] in particular is dedicated to the next generation of JENDL evaluated decay data, including β -decay half-lives, β -delayed neutron branching ratios, as well as neutron energy spectra. A detailed review of the self-consistent models of β decay can be found in Refs. [175–177].

Sect. IV A discusses the extensions to the two selfconsistent models that were performed within the CRP. Comparisons of the models with the evaluated CRP $(T_{1/2}, P_n)$ data are shown in Sect. IV B for: (i) isotopic chains of nuclides in the fission mass region, (ii) isotopic chains of nuclides relevant to nuclear astrophysics and (iii) global comparisons with respect to the $(T_{1/2}, P_n)$ data and mass number A. Finally, theoretical DN spectra are compared with experimental spectra from Brady's thesis [31] in Sect. IV E.

A. Self-consistent QRPA-based models

The DF+CQRPA and RHB+QRPA models have been extended to perform large-scale calculations of β -decay half-lives and delayed multi-neutron emission probabilities within the CRP. These extensions are briefly described in the following.

1. DF+CQRPA

The β -decay strength function is calculated in the extended finite Fermi systems theory (FFST) [178] based on the energy density functional (EDF) theory which allows for fully self-consistent description of the ground state properties of nuclei with pairing. Treating the effects of momentum and energy dependence of the functional and effective forces on an equal footing leads one to the Fayans EDF [149] with the fractional-linear dependence on normal density. The surface and pairing components of the EDF contain the gradient of the density. Such an ansatz is more general than the standard density dependence of the Skyrme functional that is a result of effective 3N correlations. Within the present CRP the ground-state and β -decay characteristics for more than 200 (quasi-) spherical nuclei were re-calculated with the DF3a functional [179] which differs from the previous version DF3 by stronger effective tensor-like components. It gives the same quality of description of the ground-state properties as the DF3 functional and a better description of β -decay of heavy nuclei [180].

Based on such an approach a framework that allows for large-scale continuum QRPA calculations of the GT and FF β -decay properties (DF3a+CQRPA) was developed in Refs. [151, 152]. For large-scale β -decay calculations the effective approximation is used for the spin-isospin effective NN interaction. In the one-particle-one-hole (ph) channel it consists of the Landau- Migdal interaction and one- π and ρ -meson exchange terms (modified for nuclear medium effects). For nuclei with pairing correlations, the density-dependent, A-dependent, zero-range T = 1ground-state pairing is used. For the spin-isospin effective NN interaction in the particle-particle (pp) channel (isoscalar T = 0 effective interaction or dynamic pairing) a mass-independent zero-range interaction with constant strength is assumed.

Allowed and first-forbidden transitions are treated on equal footing in terms of the full set of multipole operators that depend on the space and spin variables. The relativistic vector operator α and axial charge operators γ_5 are reduced to their non-relativistic space-dependent counter parts via the relations for conservation of vector current (CVC) and partial conservation of axial current (PCAC). An advantage of such a scheme is that it is convenient to use in the full ph-basis continuum pnQRPA framework [151, 152].

The correlations beyond the QRPA are included by re-scaling the spin-dependent multipole responses by the same energy-independent quenching factor $Q = (g_A/G_A)^2$. The one-pion component of the residual interaction is quenched by the same factor Q. The axial-vector coupling constant $|g_A/G_A| = 1.0$ is used both for GT and FF decays, and the amplification of the γ_5 component of the spin-dipole operator is accounted for as in Ref. [181]. The energy-dependent effect of np-nh configurations can be included via the spreading width Γ_{\downarrow} [182].

In the case of odd-A and odd-odd nuclei (hereafter called "odd" nuclei), their degenerate ground states are treated through averaging the corresponding multiplet components via equal filling approximation. The interaction of the odd nucleon with a "core" and rearrangement effects are properly taken into account [150].

In 2016, the DF+CQRPA framework was extended by fixing the odd nucleon in a given state. In this way, the DF3a+CQRPA model can account for possible groundstate spin inversion effects which have been shown to impact the β -decay observables [177, 183]. Though the present version of the model is basically limited by the spherical approximation, it should be noted that the deformation caused by the unpaired nucleon is properly taken into account in the FFST equations for the oddodd and odd-A nuclei.

2. Relativistic Density Functional+QRPA

Large-scale calculations of β -decay half-lives and β delayed neutron-emission probabilities were performed in Ref. [153] with the main goal of applying the results in heavy-element nucleosynthesis and comparing them with the new CRP $(T_{1/2}, P_n)$ database. The model was based on the relativistic nuclear energy density functional (RNEDF), which constructs the nuclear ground state from the nucleon mean-field and a minimal set of exchange mesons together with the electromagnetic field. The ground-state properties were obtained from the relativistic Hartree-Bogoliubov model which correctly describes the pairing in open-shell nuclei. In the calculation, the D3C* density functional, which includes momentumdependent terms [154], was used together with the pairing part of the Gogny D1S interaction for the description of the pairing correlations. For the isoscalar proton-neutron (pairing-like) NN-interaction, a two-Gaussian form was used following its introduction in Ref. [184]. Unlike the DF+CQRPA approach, which is free from fitting the parameters to the 'output' half-lives, the strength of the interaction was adjusted to reproduce the experimental half-lives available at the time.

The FF transitions were treated at the same level as the allowed GT transitions. The same value of the axialvector coupling constant $|g_A/G_A| = 1.0$ was used for all transitions, both allowed and first-forbidden, while the amplification of the γ_5 operator was not included. For odd-A and odd-odd nuclei, the ground state energy was computed by constraining the average number of particles to be odd which resulted in an *even* RHB state. Its energy differs from the *true* RHB state by the energy of the odd quasi-particle (or both in the case of odd-odd nuclei). This approach was tested on Q_{β} -values for even-Z and odd-Z isotopic chains and was found to be in satisfactory agreement with the data.

The limitations of the model are: (i) the model considers nuclei to be spherical, disregarding the possible effects of deformation on the transition spectra, and (ii) the model determines the ground state and excitations at zero temperature which has implications for applications to the r-process nucleosynthesis since the latter takes place at finite temperatures. Both approximations are necessary to reduce the total computational cost of the large-scale calculations.

B. Comparison with new evaluated $(T_{1/2}, P_n)$ data for important β -delayed neutron emitters

The evaluated CRP $(T_{1/2}, P_n)$ data described in Sect. III are compared with the previously listed selfconsistent global models [151, 153] and microscopicmacroscopic results [148] for light and heavy fission products. The CRP data can be downloaded from the IAEA online database [43]. The selected isotopic chains contain the most important β n-emitter associated with the highest fission yields, as recommended by the evaluated libraries ENDF/B-VIII.0 [25], JEFF-3.1.1 [28] and JENDL/DDF-2015 [27]. In order to assess the quality of the description of the β -decay characteristics, we analyze both the T_{1/2} and P_{xn} values.

1. Light fission products

a. Arsenic isotopes The β -decay characteristics of the As isotopic chain (Z = 33) are compared with the calculations from the new DF3a functional within the DF3a+CQRPA model, as well as with the RHB+QRPA [153] and FRDM12+(Q)RPA+HF [148] models in Fig. 9. As can be seen in the figure, the DF3a+CQRPA calculation in the GT approximation overestimates the evaluated half-lives by up to a factor of 10. Inclusion of the FF decays and the experimental ground-state spin $(J^{\pi} = 5/2^{-})$ leads to a slight underestimation (by up to 19%) of the evaluated half-lives, while the RHB+QRPA and FRDM12+(Q)RPA result in an underestimation by up to a factor of 8. The deformation of As isotopes is rather moderate and the quadrupole moments are estimated to be $\beta_2 \approx 0.1 - 0.15$ [185]. The difference in the results of spherical and deformed calculations of the half-lives is not significant.

A sudden decrease of the P_{1n} value when crossing N = 50 is correlated with the onset of the FF transitions. At N = 52, 53 a qualitative agreement is observed between DF3a+CQRPA and FRDM12+(Q)RPA+HF, though the experimental P_{1n} values are up to a factor of 3 higher. However, the experimental data do not support a sharp

increase of the P_{1n} value at N = 54 as seen in the FRDM12+(Q)RPA+HF and RHB+RQRPA models.

b. Bromine isotopes The CRP half-lives and P_{1n} values for Br isotopes (Z = 35, Fig. 9) are compared with results obtained from the DF3a+CQRPA and RHB+RQRPA models. Both frameworks show a behavior that is typical of the dominance of the GT decays. The deformation in the Br isotopes is estimated to be higher than in As isotopes $(|\beta_2| \approx 0.15 - 0.2)$ [185]. However it is observed that the $T_{1/2}$ given by the spherical DF3a+CQRPA and RHB+RQRPA are closer to the experimental data than those from the deformed FRDM12+(Q)RPA model. The latter underestimates the $T_{1/2}$ by up to a factor of 25 at A < 93 and shows a sudden increase of $T_{1/2}$ at A = 94. At the same time, the N dependence of P_{1n} values in FRDM12+(Q)RPA+HF is in better agreement with the evaluated data, while the DF3a+CQRPA calculation describes the general trend of experimental half-lives and P_{1n} values.

In Table II, the evaluated half-lives and P_{1n} values for Br isotopes are compared with those obtained from the DF3a+CQRPA (spherical option) and RHB+RQRPA models, as well as with the results from the FRDM+RPA model of Ref. [22] that uses the spherical GT approximation ("QRPA-2"). The latter model (based on FRDM of Ref. [186]) was used to estimate the total (integral) DN yields in the evaluation of Wilson and England [187]. Finally, the deformed FRDM12+(Q)RPA calculations that include the FF decays within the Gross theory [148] are also displayed.

As can be seen in the table, DF3a+CQRPA describes the general trend of the isotopic distribution of the halflives and P_{1n} values for N < 58. It can be used for estimating the total (integral) DN yield, as the cumulative fission yields of the DN emitters amplify the contribution of this region (see Sect. VIB 1).

c. Molybdenum isotopes The influence of deformation on the β -decay properties is illustrated for the Mo isotopes (Z = 42) in Fig. 9. Here, β_2 is ≈ -0.3 for 110 < A < 118 while for $A \approx 126$ it is $\beta_2 \approx 0$, as estimated from the quadrupole moments [185].

As can be seen from Fig. 9, the $T_{1/2}$ in Mo isotopes obtained from the spherical DF3a+CQRPA and RHB+RQRPA model are in agreement with the CRP data. They are also close to the results from the deformed FRDM12+(Q)RPA and FAM models in the N = 72 - 82region. However, the FRDM12+(Q)RPA shows some irregularities in the left wing of the isotopic chain corresponding to stronger deformation ($\beta_2 \approx -0.35$) for N < 72, as well as in the (quasi-)spherical region N > 82. At the same time, the A-dependence of the half-lives in the spherical models is quite smooth at N > 82. It should be noted that a detailed study in Ref. [188] has shown some sensitivity of the Mo half-lives due to the oblate, prolate or spherical shape.

d. Rubidium isotopes For the strongly deformed Rb isotopes (Z = 37) with $\beta_2 \approx 0.35$ [185], the spherical RHB+RQRPA describes the experimental half-lives ex-

cept for $^{92-94}$ Rb but does not explain the P_{1n} values for the important β -delayed neutron emitters 95,96 Rb (Fig. 9). The deformed FRDM12+(Q)RPA model tends to underestimate the half-lives in the region of strong deformation for $^{92-98}$ Rb, nevertheless it provides a good description of the P_{1n} data.

2. Heavy fission products

a. Iodine isotopes In Fig. 9, the half-lives and P_{1n} values for the iodine chain (Z = 53) are shown, including the important β -delayed neutron emitters $^{137-139}$ I which are the main contributors to the total (integral) DN yields for thermal neutron-induced fission of 235 U. The spherical DF3a+CQRPA and the deformed FRDM12+(Q)RPA describe the half-lives reasonably for these moderately deformed nuclei with $\beta_2 \approx 0.10 - 0.15$ [185].

As the FRDM+BCS+RPA framework adopted in Ref. [148] does not retain the SO(8)-symmetry of the QRPA, it infers a notable spurious odd-even staggering in half-lives and P_n values. The RHB+RQRPA produces a very smooth N dependence and systematically underestimates the half-lives but interestingly agrees best with the experimental P_{1n} values.

In the DF3a+CQRPA calculation two effects are important: a ground-state spin inversion and contribution of the FF decays. The first one leads to a stabilization of the half-lives at N = 88 - 90 (¹⁴¹⁻¹⁴³I) and the second induces a reduction in the P_{1n} values. Notice that a stabilization of the half-lives of ¹⁴⁴⁻¹⁴⁶I was observed in the recently published RIKEN data [189] (shown in Fig. 9 and in Table II).

b. Cesium isotopes For the isotopic chain of the Cs β -delayed neutron emitters (Z = 55, Fig. 9), the deformation is $\beta_2 \approx 0.15 - 0.2$ [185]. Both, deformed FRDM12+(Q)RPA and spherical self-consistent models, underestimate the $T_{1/2}$ at the beginning of the chain (A = 141) where nuclei have a lower deformation.

The evaluated half-lives at $A \approx 150$ indicate a kind of plateau like the one observed in the iodine isotopes and in self-consistent calculations. The evaluated P_{1n} values at A > 146 also show a stabilization effect. This could be related to the ground-state spin inversion at N > 90 [190].

As in the iodine case discussed before, the RHB+RQRPA seems to reproduce the experimental P_{1n} values the best yet underestimates the half-lives. On the other hand, the DF3a+CQRPA and FRDM12+(Q)RPA show a behavior that reflects the competition of GT and FF decays in the region up to N = 92. For N > 92 (A > 147), the DF3a+CQRPA and RHB+RQRPA describe the experimental P_{1n} values due to increasing contribution from the FF decays. Thus, for the I and Cs isotopic chains, deformation is still not a decisive factor for the mass dependence of the P_{1n} values. It can be seen that for these isotopes the spherical approaches, namely DF3a+CQRPA and RHB+RQRPA, provide a level of ac-

curacy comparable to the highly parametrized deformed FRDM12+(Q)RPA framework.

In Table II, the DF3a+CQRPA half-lives and P_{1n} values for iodine isotopes are compared with the spherical option of the FRDM+RPA model ("QRPA-2") [22] and the recent deformed option of the FRDM12+(Q)RPA [148]. As can be seen, the FRDM+RPA, which was used in the evaluation of Wilson and England [187] for estimating the total (integral) DN yields, often overestimates the experimental P_{1n} values. As it does not reproduce the experimental half-lives, the corresponding isotopes are not correctly assigned to the I-VI group of the 6-group model that is used to describe the total (integral) DN activity (see Sect. IX for more on group constants).

It can be concluded that for fission products a complex interplay of many factors influences the β -decay properties. The local fragmentation of the β strengths due to deformation is not necessarily the main driving force. What is important is an appropriate description of the ground-state properties: total energy release and single-particle energies. The competition of the GT and high-energy FF transitions, effects of complex np-nh configurations and possible ground-state spin inversion also have a strong impact on the results. In transitional nuclei, a co-existence of spherical and deformed shapes may also play an important role.

Summarizing, the self-consistent models give a robust description of the β -decay properties of fission products. The quality of description is comparable to that of the highly-parametrized microscopic-macroscopic FRDM12+(Q)RPA+HF model. As it will be shown in the next section, the self-consistent models are preferable due to their predictive power.

C. Comparison for isotopes relevant to nuclear astrophysics

In this section, the global models are compared with the CRP $(T_{1/2}, P_n)$ data for very neutron-rich isotopes which are at the edge of the current possibilities of ongoing RIB experiments and yet are indispensable for the modeling of the *r*-process nucleosynthesis in nuclear astrophysics.

We focus on two reference semi-magic isotopic chains: Ni $(Z = 28, \pi 1 f_{7/2} \text{ orbital is filled})$ near the crossing of the neutron major shell N = 50 and Sn $(Z = 50, \pi 1 g_{9/2} \text{ orbital is filled})$ around N = 82. The reason for choosing these isotopic chains is that β -decay properties of isotopes before and after the major neutron shell crossings offer a sensitive test for nuclear structure models. The theoretical results are compared with the available CRP data and the half-lives from the latest RIKEN experiment [189].

Throughout the comparisons we show that the mass dependence of total half-lives and P_{xn} is sensitive to a structural indicator % FF that represents the ratio of the FF (or GT) decays over the total rate:

$$\% FF = \lambda_{\rm FF} / \lambda = (T_{\rm GT} - T) / T_{\rm GT}.$$
(13)

FIG. 9. (Left panels) Predictions for half-lives from various theoretical models for As, Br, Rb, Mo, I, and Cs isotopes compared with the evaluated CRP data. For ^{143–146}I also the latest RIKEN data from Ref. [189] is shown. (Right panels) Predictions for P_{1n} values for the same isotopes from various theoretical models compared with the evaluated CRP data. For more information, see text.

Here, λ and $\lambda_{\rm FF}$ are the total rate and rate of the FF transitions only, respectively, T and $T_{\rm GT}$ are the total half-life and the half-life of the GT transitions only, respectively. Naturally, % FF reflects selection rules and, in particular, a reduction of the unique FF compared to the non-unique FF.

1. β -decay properties in the ⁷⁸Ni region

For the reference doubly-magic nucleus ⁷⁸Ni (N=50, Z=28) and the isotopes in the region (both with Z < 28 and $Z \ge 28$), the high-energy (low E_x) GT transitions mostly define the total half-lives at N < 50, while the FF decays give less-important contribution to the total β -decay rates. Eventually, for nuclei with occupied proton $1f_{7/2}$ orbital beyond the N = 50 neutron shell, the high transition-energy FF decays start to compete with the GT decays, although the former continue to make a substantial contribution to the total half-life as their transition energies increase with N - Z.

The total half-lives for the Ni chain obtained from DF3a+CQRPA [151, 177], RHB+RQRPA [153], FRDM12+(Q)RPA [148], and FAM [157] are compared with evaluated data in Fig. 10. The FRDM12+(Q)RPA and DF3a+CQRPA results are close to the experimental data, though an odd-even staggering is observed in the FRDM12+(Q)RPA.

For the spherical RHB+RQRPA as well as for the deformed FAM, the deviation from the evaluated half-lives at N < 50 is quite pronounced. For the doubly-magic nucleus ⁷⁸Ni, they predict 258 ms and 605 ms, respectively, compared to the experimental value of $T_{1/2}$ =122.2(51) ms [35, 191].

In order to understand the origin of these deviations, it is necessary to analyze the contribution of the FF (or GT) decays to the total rate (%*FF* value, Fig. 10). For Ni isotopes with neutron numbers $N \leq 50$, as the $\pi 1f_{7/2}$ orbital is filled, the GT decays ($\nu 1f_{5/2}, \pi 1f_{5/2}$), ($\nu 1p_{1/2,3/2}, \pi 1p_{1/2,3/2}$) overwhelm the hindered FF-unique decay ($\nu 1g_{9/2}, \pi 1f_{5/2}$). Naturally, the %*FF* values obtained from the DF3a+CQRPA for A < 78 are low and the drop of the %*FF* values at A = 78 is mostly related to the competition with the GT transitions. For the FAM and RHB+QRPA models, the calculated %*FF* values for $A \leq 78$ are higher by 30 and 50%, respectively. However, high %*FF* values for A < 78 are not supported by the selection rules and the available decay schemes.

Thus, an overestimation of the half-lives for A < 78 by RHB+RQRPA and FAM may stem from the predicted balance between the GT and FF strengths. For N >50, the non-unique decays $(2d_{5/2}, 2s_{1/2} \rightarrow 2p_{1/2,3/2}, 1f_{5/2})$ contribute to the decay process, yet the %*FF* values calculated from DF3a+CQRPA reach only 25% for A = 86, which is quite close to the FAM prediction. For A >78, all calculations give similar half-lives although the RHB+QRPA gives different %*FF* values.

It turns out that the differences in the total Q_{β} values,

FIG. 10. a) (Upper panel) Half-lives for the Ni isotopes (Z=28) calculated from DF3a+CQRPA (present work), RHB+RQRPA [153], FAM (even-even only) [157], and FRDM12+(Q)RPA [148] compared with the evaluated half-life data [35]; b) (Lower panel) Contributions of the first-forbidden transitions to the total decay rate (% FF value).

multi-neutron emission thresholds, and quasi-particle levels predicted by the different models are very important. The different phase-(sub)-spaces defined by these quantities are reflected in the β -strength distributions and are translated into the half-lives and delayed multi-neutron emission probabilities.

The P_{xn} for the Ni chain obtained from DF3a+CQRPA, RHB+RQRPA, the and FRDM12+(Q)RPA+HF models are compared in Fig. 11. It can be seen that in the RHB+RQRPA calculations, the peak of the one-neutron emission probability occurs at ⁷⁸Ni, two mass units earlier compared to the other two model calculations, and that the two-neutron emission probability mass behavior also differs. However, the three experimental P_{1n} data points for $^{75-77}$ Ni are very nicely reproduced by the FRDM12+(Q)RPA+HF and the RHB+RQRPA model, whereas the DF3a+CQRPA model seems to underpredict these isotopes.

Finally, in Fig. 12 we compare the half-lives for the Ni chain with the recently developed "beyond the pn-QRPA" models, such as the FRSA+PPC [163] which takes into account the phonon-phonon coupling, the PVA models with the particle-vibration coupling (PVC) [166, 167, 192], and the "quasi-particle time blocking approximation" (QTBA) [168]. Hybrid shell-model results from [193] are also included in the figure.

The calculations in Fig. 12 have been performed within the GT approximation which is more justified for A <78. In the pnQRPA+PVC developed in the recent paper [167], the experimental half-lives for the Ni isotopes

FIG. 11. Delayed multi-neutron emission probabilities $(P_{1n}-P_{4n})$ for Ni (Z = 28) isotopes calculated with FRDM12+(Q)RPA+HF [148], DF3a+CQRPA (present work), and RHB+RQRPA [153]. These models are compared to the evaluated P_{1n} data for ⁷⁵⁻⁷⁷Ni as published in Ref. [35].

are reasonably well described assuming a rather strong T = 0 pairing (except for A = 80). The corresponding 1p-1h QRPA calculation in the same framework has given a factor of about 10-15 longer half-lives [167]. Thus the renormalization due to the PVC turns out to be very strong leading to QRPA+PVC half-lives that are only by a factor 1.5 shorter for ⁷²Ni and by a factor 1.5 longer for ⁷⁸Ni.

A similar strong renormalization due to the PVC effect is obtained in the QTBA approach [168]. Again, the pure pnQRPA half-lives obtained without assuming phonon-phonon coupling in the QTBA are much higher than the corresponding quantities obtained from the FRSA [165] which includes phonon-phonon coupling. Thus, the renormalization factor due to the effective interactions in these approaches differs significantly (by about 1–2 orders of magnitude). Most probably this difference is due to the fact that the QTBA model uses experimental Q_{β} values instead of self-consistently derived ones.

The above discussion is important if one considers the potential of these models: once the contribution of FF decays is included, they could be implemented in global calculations of β -decay half-lives and β -delayed neutron branching ratios. It has already been shown that "hy-

FIG. 12. Half-lives for Ni isotopes calculated from QTBA [168], FRSA+QRPA+PPC [165] and HFB+QRPA+PVC [167] in comparison with with the evaluated data from Ref. [35]. Also shown are calculations from the SM [161], NuShellX [193] and DF3a+CQRPA with spreading [177].

brid" models, i.e. DF3a+CQRPA including the complex configurations through the spreading width [177] and the shell-model NuShellX with the FF decays added from the DF3a+CQRPA [193], can give an overall reasonable description of the experimental half-lives in Ni for A > 78.

Only a simultaneous account of the FF decays and npnh configurations in these models allows one to describe the "sudden shortening" of the half-lives after crossing the N = 50 shell that was observed in the RIKEN data [191]. It is therefore reasonable to expect that the self-consistent 'beyond pnQRPA' models have the potential to describe all these effects. In this respect, it is important to include the contribution of the firstforbidden decays in the present (spherical) 'beyond pn-QRPA' schemes.

On the other hand, an effort to include the contribution of the complex configurations into the deformed Finite Amplitude Method (pnFAM) [157] would result in a universal approach that could be applied to the whole nuclear chart.

2. β -decay properties in the ¹³²Sn region

For the isotopes beyond the major neutron shell N = 82 in the ¹³²Sn region, the concurrence of GT and FF decays has much in common with the ⁷⁸Ni region. We show that the contribution of GT and FF transitions to the β -decay rates differs for the Z < 50 and $Z \ge 50$ isotopes. The intensive GT decays in the Z < 50 nuclei mostly correspond to the $(\nu 1g_{7/2}, \pi 1g_{9/2})$ configuration. The high-energy GT decays contribute strongly to the total half-lives of the nuclei with Z < 50, N < 82. After

crossing the N = 82 neutron shell, the high-energy FF decays which are mainly related to the $(\nu 1h_{11/2}, \pi 1g_{9/2})$ configuration are active. In contrast to what is observed in nuclei in the $Z \ge 28$ region, the high-energy GT transitions for Z > 50 nuclei are hindered, as the $p1g_{9/2}$ orbital is blocked. At the same time, the high energy FF transitions $(\nu 2f_{7/2}, \pi 1g_{7/2}), (\nu 1f_{7/2}, \pi 2d_{5/2})$ come into effect and mostly define the total half-life.

Fig. 13 shows the comparison of the half-lives obtained from DF3a+CQRPA, RHB+RQRPA, FRDM12+(Q)RPA, and FAM with the evaluated CRP data. For completeness, we include ¹³²Sn in the plot even though it is not a β n-emitter. Within the GT-only approximation, the DF3a half-lives are up to a factor 5 longer than the data. Taking into account the FF decays sets the balance between the GT and FF strengths as shown in Fig. 14 and allows for an excellent description of the experimental half-lives for the Sn isotopic chain.

A rather high percentage of FF decays of 60–75% calculated from the RHB+RQRPA may be the reason for the strong underestimation of the half-lives of ^{133–140}Sn by a factor of 4–5. On the other hand the FRDM12+(Q)RPA half-lives overestimate the experimental data by a factor of ≈ 2 while the DF3a+CQRPA (GT+FF) calculations are quite close to the experimental values.

FIG. 13. Half-lives (upper panel) and P_{1n} values (lower panel) for Sn isotopes (Z = 50). Calculated values from DF3a+CQRPA [177], RHB+RQRPA [153], FAM [157], and FRDM12+(Q)RPA [148] are compared with the evaluated ($T_{1/2}, P_{1n}$) data. The half-life for ¹³²Sn (no β n emitter, 39.7(8) s) was taken from ENSDF.

Note that for the reference doubly-magic nucleus 132 Sn the very low %*FF* value predicted by DF3a+CQRPA calculations (Fig. 14) is consistent with the decay scheme

FIG. 14. Contributions of the FF transitions to the total decay rate (% FF values) for Sn isotopes obtained from DF3a+CQRPA (present work), RHB+RQRPA [153], and FAM [157].

observing 99% intensity for the decay to the GT state at 1.325 MeV with a $\log(ft) = 4.2$. Accordingly, the DF3a calculates a half-life of 35.7 s, compared to the evaluated value of 39.7(5) s from ENSDF. In contrast, the RHB+ RQRPA predicts 610 s and the FAM a value of 820 s.

The corresponding P_{1n} values (Fig. 13) obtained with RHB+RQRPA and DF3a+CQRPA agree in general with the mass dependence of the %*FF* values predicted by these models, however they underestimate the CRP data for A > 133. The FRDM12+(Q)RPA+HF [148] overestimates the P_{1n} values considerably which is consistent with a gradually increasing share of the FF decays at N > 82 due to the increasing contribution of the $\Delta J = 0$ g.s.-to-g.s. transitions at N = 83 - 86. The stabilization of the P_{1n} values at N > 86 predicted by RHB+RQRPA and DF3a+CQRPA reflects a decrease of the %*FF* values for N = 87 - 90 ($^{137-140}$ Sn) due to the competition from the open high-transition energy GT decays.

As was already mentioned, the β -decay characteristics of the semi-magic Ni and Sn isotopic chains are highly sensitive to the details of the nuclear structure aspects of the models, in particular the energy-density functional used. As we move further away from the closed shells, these characteristics become less sensitive to the details of the models. For example in the Pd and Cd isotopes that have pairing in both neutron and proton sectors there is good agreement between the selfconsistent DF3a+CQRPA and RHB+RQRPA calculations [153, 176, 177].

To summarize, from the comparison of theory and evaluated data for a fairly broad range of nuclei shown in this section, the recommended theoretical approach is the quasiparticle random phase approximation (pnQRPA) based on the energy density functional (EDF) approach. Recently developed self-consistent models have been successfully used in this CRP to calculate the half-lives and β -delayed neutron rates of fission products and nuclei near the major closed shells that are important for r-process modeling. Compared to the old semi-empirical models ("Gross theory" versions) and the semi-microscopic FRDM-based (Q)RPA framework for the GT decays that is augmented by a statistical model for the FF decays, the self-consistent β -decay models have the obvious advantage of being well-founded on first principles. By definition, the parameters of the self-consistent global models should be kept the same when extrapolating to different mass regions across the nuclear chart.

Global models based on the energy density functional approach are not only used in β -decay studies but also for a consistent description of a range of nuclear properties in a broad mass region, such as binding energies, radii, magnetic moments, fission barriers as well as nuclear responses to different probes. Consequently, there is a wide variety of data available to constrain the EDF parameters and one can avoid using the "output" half-lives and P_n values for such a purpose. Self-consistent global models are thus a reliable and universal instrument for the description of the middle-heavy, heavy and superheavy nuclei which are in the scope of the present paper.

Finally, it is worth mentioning the rapidly developing "beyond the pnQRPA" models such as FRSA+phononphonon coupling [163, 164], the PVA models with particle-vibration coupling [192] and the "quasi-particle time blocking approximation" (QTBA) [168]. These approaches can potentially describe the β -decay strength function over a wide range of masses across the nuclear chart with a quality comparable to the multiconfigurational shell-model. For example, the "sudden acceleration" of the β -decay after crossing the N = 50shell, that was recently discovered in the Ni isotopic chain at RIKEN [191], has been described by assuming np-nh configurations within the DF3a+CQRPA approach using quasi-particle spreading. This confirms that such a phenomenon can only be explained by considering FF decays and complex configurations simultaneously.

D. Global comparisons of theoretical results

Global comparisons between the CRP evaluated data and the self-consistent models DF3a+CQRPA, RHB+QRPA, as well as the microscopic-macroscopic model FRDM12+(Q)RPA(+HF) are presented in this section. Large-scale calculations of the β -decay energy releases ($Q_{\beta}, Q_{\beta n}$), half-lives ($T_{1/2}$) and delayed neutron (DN) emission probabilities (P_n) for hundreds or even thousands of spherical, near-spherical and deformed nuclei have been performed so far within several models. Nowadays these models provide a reliable data input for the modeling of abundances in the astrophysical r process. They have also been used as predictions for the ongoing large-scale experimental campaigns at RIB facilities worldwide (see, e.g. Refs. [125, 189, 191, 194]).

In Fig. 15, the ratio of half-lives and P_{1n} values from FRDM12+(Q)RPA [148] and the evaluated data are plotted with respect to the evaluated values. It is obvious that the half-lives and neutron-emission probabilities of almost all β n-emitter considered here are reproduced within one order of magnitude.

In the case of half-lives, the majority is reproduced within a factor of two or better, denoted by the black dashed lines. It is also noticeable that the scatter around the ratio of 1 decreases with decreasing experimental halflife, which is a common pattern. Shorter half-lives are characterized by larger Q-values, and a larger portion of the decay strength is included within the Q_{β} window. As a result the half-lives of shorter-lived nuclei are less sensitive to the deviations of the model from the true strength function.

In the case of the comparison with experimental P_{1n} values in the bottom part of Fig. 15 several nuclei can be found aligned on diagonal lines. This surprising feature is due to theoretical P_{1n} values that appear only as integer values in the FRDM12+(Q)RPA+HF model. Lines for $P_{1n}=1,2,3,4$, and 5% are shown in red to guide the eye. For cases where the experimental values are very small, e.g. lower than 1%, any deviation of the model predictions from the true energies and strengths of the transitions will, as a consequence, result in relatively large deviations of the total emission probabilities from the observed values.

Figure 16 shows the same as Fig. 15, but for theoretical results obtained using the RHB+RQRPA model [153] which was extended for nucleosynthesis calculations and for use in comparisons in this CRP. The general behaviour of the model is quite similar to the FRDM12+(Q)RPA+HF shown above, but with some notable differences. In the case of half-lives, the relativistic approach manages to provide, on average, a somewhat better description for half-lives <200 ms as indicated by the smaller scatter of ratios around the value of 1. However, for longer half-lives >10 s the model seems to systematically underestimate the experimental half-lives. In the case of neutron emission probabilities, the same diagonal trend as for the FRDM12+(Q)RPA+HF model in Fig. 15 can be seen, due to the fact that many nuclei have similar theoretical P_{1n} values around 1–2%.

Figures 17 and 18 present the same results as in the previous two figures, but now the ratios are plotted versus the atomic mass number A, in order to explore the impact of shells on the results. The FRDM12+(Q)RPA+HF formalism provides a very robust description of the data, without showing any visible strong dependence of the model predictions on the atomic mass number (except for a notable dip in the deformed $A \approx 90 - 95$ region). This is true both for the half-lives and for the one-neutron emission probabilities.

However, the results obtained with the relativistic RHB+RQRPA model (Fig. 18) show significant effects

FIG. 15. Ratios of theoretical and experimental results for the half-lives (upper panel) and P_{1n} values (lower panel) calculated using the FRDM12+(Q)RPA+HF formalism [148], plotted versus the corresponding experimental values. Diagonally aligned nuclei in the lower plot are nuclei that have the same theoretical P_{1n} value. Lines for $P_{1n} = 1, 2, 3, 4$, and 5% are shown to guide the eye.

of the nuclear shell structure on the quality of the results in the description of the β -decay half-lives. These results display a clear arch between two mass regions, from $A \approx 90$ to $A \approx 140$, which is consistent with the fact that the model does not take nuclear deformations into account. Therefore, the model produces deviations in the regions of the nuclear chart between closed shells where nuclei have non-negligible ground-state deformations. However, the β -decay half-lives are well reproduced within a factor of 2 (although longer than measured) for the mass region A = 100 - 130.

In the upper panel of Fig. 19, the half-lives calculated within the spherical DF3a+CQRPA approach are plotted with respect to the evaluated values. The figure includes

(near-) spherical nuclei with Z = 25 - 35 and Z = 44 - 55 regions with $T_{1/2}$ ranging from 10 ms to 10 s. This constraint is a consequence of the strength function formalism which assumes that QRPA results are better for short-lived nuclei with relatively large Q_β energy window. Also, the limitation of the comparison to spherical and near-spherical nuclei makes it easier to understand the origin of the deviations from the experimental half-lives. Fig. 19 shows that most of the half-lives are in agreement within a factor of two with the evaluated data.

In the lower panel of Fig. 19, the ratio of the theoretical and experimental half-lives are plotted as a function of mass number A. The results indicate that the data is in general reproduced within a factor of 2 over the whole

FIG. 16. Ratios of theoretical and experimental results for the half-lives (upper panel) and P_{1n} values (lower panel) calculated using the relativistic RHB+RQRPA formalism [153], plotted versus the corresponding experimental values. Diagonally aligned nuclei in the lower plot are nuclei that have the same theoretical P_{1n} value. Lines for $P_{1n} = 0.2$ and 1% are shown to guide the eye.

mass region, with no obvious discrepancies at shell closures or for deformed nuclei around $A \approx 85$ and 120.

In a number of cases, however, such as in K and Sb isotopes, the deviation has been shown to be related to ground-state spin inversion rather than to deformation [177, 183].

Similarly, the ratio of neutron emission probabilities of (near-)spherical nuclei is shown in Fig. 20 as a function of A. Overall, the experimental data are reproduced within the same factor of two. Again the exceptions to this trend are weakly deformed nuclei in the Z = 31 - 35, $A \approx 85$ and Z = 44-45, $A \approx 120$ regions which have rather small P_{1n} values. In these cases, neglecting the spreading of the β strength due to deformation leads to a systematic

underestimation of the P_{1n} values.

It is worth stressing that the β -decay strength function can be modified by including the quasiparticle-phonon coupling. The sensitivity of the neutron emission probabilities to the strength distribution in the vicinity of the neutron emission thresholds S_{xn} is extremely high. Consequently, in the one-particle-one-hole pnQRPA approach, the accuracy of global predictions for the P_{1n} values is lower than for half-lives.

In Fig. 21, the ratio of DF3a+CQRPA predictions to experimental half-lives [125, 126] is shown for the heavier Os to Bi nuclei (Z = 76-83). As one approaches the N = 126 shell closure, nuclei are either spherical or have a small ground-state deformation. For the bulk of the

FIG. 17. Ratios of theoretical and experimental results for the half-lives (upper panel) and total P_{1n} values (lower panel) calculated using the FRDM12 +(Q)RPA +HF formalism [148], plotted versus the atomic mass number.

nuclei included in the DF3 calculations, we observe a larger spread of the half-lives of up to a factor of 5. For Hg isotopes around A = 210 with relatively low Q_β values, the DF3a+CQRPA underestimates the half-lives by one and RHB+RQRPA by two orders of magnitude, respectively (see Ref. [125]). Both DF3a+CQRPA and RHB+RQRPA underestimate the experimental half-life of ²⁰⁶Au [195, 196] by a factor of about 30 – 60.

A comparison of the existing eight experimental P_{1n} values for nuclei beyond the N = 126 shell closure [125, 196] is shown in Fig. 22. Note, however, that these are the heaviest nuclei for which P_{1n} values have been measured so far. As can be seen, the experimental uncertainties are still too large for any detailed comparison of the different model performances.

It is worth mentioning that global comparisons of β -

decay half-lives have also been performed within the deformed self-consistent QRPA model of Ref. [174]. The model uses the GT approximation and a global D1M Gogny interaction. Only the half-lives of 145 spherical and deformed even-even nuclei for which the experimental half-lives are known were included in the comparison. The calculated ratio $T_{1/2}^{theo}/T_{1/2}^{exp}$ is quite homogeneous with respect to the mass number A and, more particularly, the quadrupole deformation parameter β_2 . The treatment of deformation reduces the overall deviation from the data to basically the same factor of 10 which was obtained for spherical nuclei in Refs. [151, 153]. Including deformation in the model is therefore expected to lead to a marked improvement in the RHB+RQRPA half-lives for deformed nuclei and similar levels of accuracy that were obtained for spherical nuclei in Refs. [151, 153].

FIG. 18. Ratios of theoretical and experimental results for the half-lives (upper panel) and P_{1n} values (lower panel) calculated using the relativistic RHB+RQRPA formalism [153], plotted versus the atomic mass number.

As far as the comparison of different microscopic models with the CRP data is concerned, we observe that regardless of the treatment of deformation all models using a concept of the β -decay strength function have difficulty describing nuclei close to the valley of β stability with low Q_{β} values. The RHB+RQRPA calculations, for instance, tend to underestimate the half-lives for very heavy nuclei, around $A \approx 210$ by more than an order of magnitude [125, 126]. This generic feature is also true for the microscopic-macroscopic model and "Gross theory".

Neutron-rich nuclei near the closed shells are the main playground for developments in the microscopic theories. The theoretical predictions of their β -decay properties – while being a crucial test for any nuclear structure theory – are also critical for planning experiments at RIB facilities. Additionally, these nuclei are also key for a better understanding of the astrophysical r process.

From the global comparisons we deduce that DF3a+CQRPA [151], RHB+RQRPA [153],and FRDM+(Q)RPA(+HF) [148] models give overall a comparable description of the β -decay properties. Note that a somewhat smaller spread in the DF3a+CQRPA half-life calculations (Fig. 19) with respect to the RHB+RQRPA (Fig. 18) is partially a result of the limited comparison of (quasi-)spherical-only nuclei used in the DF3a calculations. An important source of deviations from the experimental data may come from the description of the ground-state properties.

In particular, the underestimation of the total decay phase-space Q_{β} , as well as $Q_{\beta xn}$ sub-spaces may have a destructive impact on the predicted β -decay observables. This is especially true for the P_{xn} -values, as these observables are more sensitive to the different "systematic" uncertainties of the theoretical strength functions.

FIG. 19. Ratio of theoretical and experimental values of half-lives of (quasi-) spherical nuclei with Z = 18 - 21, 25 - 35, and 44 - 55, calculated using the DF3a+CQRPA formalism and plotted versus the evaluated experimental half-lives in the top panel and versus mass A in the bottom panel.

Finally, with regards to the predictive power of the models, if we consider the smaller number of parameters involved in the self-consistent models, as well as their universality, we can conclude that the predictions of these models are more reliable than those of the "Gross theory" and FRDM-based models whose parameters are determined near the stability line.

E. Delayed neutron spectra calculations

The microscopic-macroscopic approach described in the previous sections was also used in the calculations of delayed neutron (DN) spectra of fission products in Ref. [32]. The FRDM95 [186] was combined with the (Q)RPA model [147, 198] to estimate β -strength functions which were then used as input in the Hauser-Feshbach statistical model (HF) to obtain DN branching ratios and spectra. The HF calculations require several nuclear ingredients. For neutron and γ -ray transmission coefficients, the Koning-Delaroche global optical potential [199] and the generalized Lorentzian E1 strength function [200] were adopted, respectively, with a parameter set obtained from the Reference Input Parameter Library (RIPL-2) [201]. For the nuclear level densities, they used RIPL-2 for discrete levels and the Gilbert-Cameron level density formula [202] at high energies. Spin and parity selection rules for the decay of the precursor nuclei to daughter nuclei were observed.

The microscopic-macroscopic approach (FRDM+(Q)RPA+HF) to calculating β -delayed neutron spectra is important for various applications as it can predict the spectra for nuclei located on the neutron-rich side of the nuclear chart for which experimental data are not available. Furthermore, as has been discussed in Sect. IV, it provides an improved description of the decay process leading to DN emission as it considers nuclear structure effects such as nuclear shell effects, level structures, and the spin-parity selection rules. The β -delayed neutron spectra calculated by [32] are now adopted in the ENDF/B-VIII.-0 decay-data library [25].

Within the CRP, we performed similar calculations of

FIG. 20. Ratio of theoretical and experimental values of β -delayed one-neutron emission probabilities (P_{1n}) of (quasi-)spherical nuclei with Z = 18 - 21, 25 - 35 and 44 - 55, calculated using the DF3a+CQRPA formalism and plotted versus the evaluated experimental P_{1n} values in the top panel and the mass A in the bottom panel.

DN spectra by using a Hartree-Fock-BCS model (SHF-BCS) – instead of the FRDM – combined with ORPA to obtain the β -decay properties. The DN emission part was calculated using the HF model [170]. In this SHFBCS+QRPA+HF model, the pairing correlation is treated by the BCS approximation with a zerorange volume-type force. The ground and excited states were self-consistently calculated with the SkO' Skyrme force [203] in the cylindrical coordinate, where the axial symmetry was assumed. A zero-range volume-type pairing was used in the pp-channel (T = 0 pairing), and the strength parameters were adjusted to obtain the best possible description of available half-life data for each isotopic chain. Only allowed GT transitions are considered in the β -decay channel in Ref. [170]. Odd-mass nuclei were treated in the same way as the even-mass nuclei, and the blocking and polarization effects caused by coupling between valence particle(s) and core nuclei were not considered. The HF statistical model implemented in the code CCONE [204] was used to calculate the competition between DN and γ decays. The global neutron optical potential of Ref. [199] and enhanced generalized Lorentzian (EGLO) model [200, 205] were used to calculate the neutron and γ transmission coefficients, respectively. For level densities, we used RIPL-3 [205] for discrete levels and the formula of Gilbert and Cameron with Mengoni–Nakajima parameter set [206] for higher energies.

Figure 23 shows the β -delayed neutron spectra obtained for Rb and Cs isotopes from SHF-BCS+QRPA+HF and FRDM+(Q)RPA+HF. The results are compared with the evaluated data of ENDF/B-VIII.0 [25] and the experimental data obtained from Ref. [31] that were described in Sect. III E 1.

For FRDM+(Q)RPA+HF, the β -delayed neutron spectra of ⁹⁴Rb and ¹⁴⁵Cs deviate from experimental data, while those of ⁹⁵Rb and ^{143,144,146}Cs are reproduced ap-

FIG. 21. Same as in Fig. 19 but for heavy (Z = 76 - 83, Os to Bi) spherical isotopes calculated using the DF3a+CQRPA formalism [125, 126, 197]. The experimental data is taken from the recent evaluation [36].

FIG. 22. Theoretical and experimental values for the β delayed one-neutron emission probabilities of heavy (quasi-) spherical Hg and Tl isotopes (Z = 80, 81), calculated using the DF3a+CQRPA [125, 126, 197], RHB+RQRPA [153], and FRDM12+(Q)RPA+HF models [148]. The experimental data is taken from the evaluation in Ref. [36].

proximately. The SHFBCS+QRPA+HF model cannot describe the β -delayed neutron spectra of ⁹⁴Rb and ¹⁴⁴Cs,

while those of the other nuclei are approximately reproduced. It is worth noting that some of the β -delayed neutron spectra are reproduced reasonably well by these theoretical models, even though QRPA approaches are unable to estimate the nuclear excited states within an uncertainty of a few hundreds keV. The deviations from experimental data are mainly attributed to the calculated β -strength function since both approaches use similar HF implementations. For example, the β -delayed neutron spectrum of ¹⁴⁵Cs is reasonably reproduced with SHF-BCS+QRPA+HF but not with FRDM+(Q)RPA+HF, which implies that the β -strength function of SHF-BCS+QRPA+HF is more suitable for this nucleus than the FRDM+(Q)RPA+HF strength function. This conclusion is based on the assumption that the particle evaporation process is correctly described.

Similar systematic detailed comparisons of experimental and calculated DN spectra that duly consider the uncertainties in the measured spectra and the ingredients of the models are expected to lead to further improvements of the theoretical β -decay models in the future. However, as already mentioned in Sect. III E 1, it is still not clear how to quantify the experimental uncertainties in the measured spectra of Ref. [31], therefore, until that is possible, caution should be exercised when comparing with these experimental DN spectra. The published and digitized experimental DN spectra are available on the IAEA online database [43].

FIG. 23. β -delayed neutron spectra for 94,95 Rb and $^{143-146}$ Cs calculated with SHFBCS+QRPA+HF [170] and FRDM+(Q)RPA+HF [32]. The results are compared with experimental data available in [31] and the evaluated spectra in ENDF/B-VIII.0 [24].

V. MACROSCOPIC DATA: METHODS AND MEASUREMENTS

In the following sections we deal with macroscopic delayed neutron data produced as a result of neutroninduced fission of major and minor actinides. These data are of utmost importance for studies on kinetic response and safe operation of fission reactors.

A. Methods

1. Total delayed neutron yields and time-dependent parameters

The direct methods used for measuring the macroscopic delayed-neutron characteristics from neutroninduced fission of heavy elements are based on irradiating the investigated sample by neutrons and subsequently measuring the appropriate delayed-neutron observables: the time dependence of delayed-neutron activities or the delayed-neutron energy spectrum. Neutron sources used for this purpose are mainly the neutron flux in nuclear reactors [207–214], critical assemblies [13, 215, 216], or electrostatic accelerator-based nuclear reactions: Li(p,n), T(p,n), T(d,n), D(d,n) [217–223]. All experimental methods are based on the assumption that the delayed-neutron activity arising from the irradiation of the fissionable sample can be represented by the linear superposition of the exponential decay modes, each with its own decay constant

$$\frac{dN(t)}{dt} = A \sum_{i=1}^{m} (1 - e^{-\lambda_i \cdot t_{irr}}) \cdot a_i \cdot e^{-\lambda_i \cdot t}, \qquad (14)$$
$$A = \epsilon_n \cdot \sigma_f \cdot \phi \cdot N_f \cdot \nu_d,$$

where A is the saturation delayed-neutron activity, a_i and λ_i the relative abundance and decay constant of the i-th delayed neutron group, respectively, t_{irr} the irradiation time, m the number of delayed neutron groups each of which is associated with a group of delayed-neutron precursors with similar decay constants, ϵ_n the efficiency of the neutron detector, ν_d the total delayed-neutron yield per one fission, ϕ the neutron flux (1/cm²s), σ_f the fission cross section (barn), N_f the number of atoms in a fissionable sample.

A comprehensive study of the delayed-neutron emission properties conducted by Keepin *et al.* [13] on ²³²Th, ²³³U, ²³⁵U, ²³⁸U, ²³⁹Pu, and ²⁴⁰Pu lead to the development of a 6-group model of the temporary delayedneutron characteristics (a_i, T_i) , where $T_i = \ln 2/\lambda_i$. This model has been successfully used by the reactor community for many years. Only recently, an alternative 8-group model based on a set of decay constants that are universal for all fissioning systems was proposed and justified by Spriggs *et al.* [224, 225].

In the case of instantaneous irradiation (prompt burst

irradiation, $\lambda_i t_{irr} \ll 1$), Eq. (14) becomes

$$\frac{dN(t)}{dt} = A \cdot t_{irr} \sum_{i=1}^{m} \lambda_i \cdot a_i \cdot e^{-\lambda_i \cdot t} \,. \tag{15}$$

From Eqs. (14) and (15) it becomes clear that the accuracy of the delayed-neutron parameters ν_d and (a_i, T_i) extracted from measured data depends to a large extent on parameters such as the accumulated statistics, the fission rate in the sample $R_s = \sigma_f \cdot \phi \cdot N_f$, the transportation time of the sample from the irradiation position to a neutron detector and the neutron background. The quality of the obtained delayed-neutron data is also related to the incident neutron energy because the temporary delayed-neutron parameters (a_i, T_i) are known to have a noticeable energy dependence when expressed in terms of the average half-life of delayed neutron precursors $\langle T \rangle$ ([226], [227]).

a. Nuclear reactor-based methods. The most important advantage of the nuclear reactor-based method is the high intensity of the neutron flux. With such a highintensity flux it is possible to use very small samples of fissionable nuclides (up to micrograms) as was demonstrated by Waldo *et al.* [207]. However, the long time it takes to transport the sample in the reactor measurements does not allow one to resolve all 6 groups of delayed neutrons. Furthermore, given that the energy of the primary neutrons can take a wide range of values or maybe is unspecified in many of the reactor experiments, it is not straightforward to use these data in the evaluation of delayed-neutron parameters.

As a rule, a single irradiation procedure is used in the nuclear reactor-based experiments. The time dependence of the delayed neutron activity registered by a multichannel analyzer can be obtained by integration of Eq. (14) ([222, 226].

$$\int_{t_k}^{t_{k+1}} \frac{dN(t)}{dt} dt = \frac{dN(t_k)}{dt} \cdot \Delta t_k =$$

$$A \cdot \sum_{i=1}^m (1 - e^{-\lambda_i \cdot t_{irr}}) \cdot \frac{a_i}{\lambda_i} \cdot (1 - e^{-\lambda_i \cdot \Delta t_k}) \cdot e^{-\lambda_i \cdot t_k}$$

$$+ B \cdot \Delta t_k , \qquad (16)$$

where $(dN(t_k)/dt) \cdot \Delta t_k$ is the number of counts registered in the time channel t_k with width Δt_k , B the intensity of neutron background. This decay curve is used to estimate the temporal delayed-neutron parameters (a_i, T_i) , the saturation activity A, the intensity of the background B, and the covariance matrix of the estimated parameters with the help of the least squares method (LSM). The obtained delayed-neutron decay curve, the values of the estimated parameters (a_i, T_i) and the background B are used to calculate the total delayed neutron yield [212, 226, 228–230].

One possible type of irradiation is the instantaneous (prompt burst) irradiation (see Eq. (15)). In this case, a measured delayed-neutron decay curve can be obtained

by the integration of Eq. (15)

$$\int_{t_k}^{t_{k+1}} \frac{dN(t)}{dt} dt = \frac{dN(t_k)}{dt} \cdot \Delta t_k =$$

$$A \cdot t_{irr} \sum_{i=1}^m a_i \cdot (1 - e^{-\lambda_i \cdot \Delta t_k}) \cdot e^{-\lambda_i \cdot t_k} + B \cdot \Delta t_k .$$
(17)

It is this type of irradiation that was used by Keepin *et al.* [13] for the measurement of the decay curves which were used for the estimation of short-lived group parameters (from 3 through 6) and the determination of the total delayed neutron yield. The Godiva reactor (a bare spherical 235 U assembly) was used as neutron source. In addition, the total delayed-neutron yield was determined with the help of the following approximation [13].

$$\sum_{t_1}^{t_2} \frac{dN(t_k)}{dt} \cdot \Delta t_k - B \cdot (t_2 - t_1) =$$

$$A \cdot t_{irr} \sum_{i=1}^m a_i \cdot \left(e^{-\lambda_i \cdot t_1} - e^{-\lambda_i \cdot t_2}\right) =$$

$$A \cdot t_{irr} \sum_{i=1}^m a_i = \nu_d \cdot \epsilon \cdot R_s \cdot t_{irr}, \qquad (18)$$

where t_{irr} is the time of the neutron pulse, $R_s \cdot t_{irr}$ the total amount of fissions in a sample, and the sum of the relative abundances is equal to 1.

b. Accelerator-based delayed neutron experiments. The neutron sources used in this method are the monoenergetic neutron fluxes from the accelerator-based nuclear reactions Li(p,n), T(p,n), $T(d,n)^4He$, $D(d,n)^3He$. The main advantage of the accelerator-based method is the possibility to investigate the energy dependence of delayed neutron properties in a wide range of incident neutron energies from thermal to 20 MeV [217–223, 231]. Eqs. (14) and (15) reflect one single cycle of measurement which includes the irradiation of the sample, the decay, and the counting of delayed-neutron activity. However, in accelerator-based experiments a sample undergoes a number of cycles with the purpose of increasing the statistics. The general equation for the determination of the total delayed-neutron yields and temporal delayed-neutron characteristics (a_i, T_i) on the basis of the delayed-neutron decay curve accumulated during n cycles is given by ([222], [232], [233], [226], [234], [230])

$$\frac{dN(t_k)}{dt} \cdot \Delta t_k = A \cdot \sum_{i=1}^m T_{hi} \cdot \frac{a_i}{\lambda_i} \cdot (1 - e^{-\lambda_i \cdot \Delta t_k}) \cdot e^{-\lambda_i \cdot t_k} + B \cdot \Delta t_k ,$$
(19)

where T_{hi} determines the history of irradiation

$$\begin{split} T_{hi} &= (1 - e^{-\lambda_i \cdot t_{irr}}) \times \\ & \left(\frac{n}{1 - e^{-\lambda_i \cdot T}} - e^{-\lambda_i \cdot T} \cdot \left(\frac{1 - e^{-n \cdot \lambda_i \cdot T}}{(1 - e^{-\lambda_i \cdot T})^2} \right) \right), \\ A &= \epsilon \cdot \sigma_f \cdot \phi \cdot N_f \cdot \nu_d \,, \end{split}$$

with n the number of cycles, T the period of one cycle (irradiation, decay, counting, delay).

This equation is used to estimate the values of the saturation activity A, the temporal delayed-neutron parameters $(a_i, T_i (i = 1, ..., m))$ and the background B on the basis of the decay curves measured with different irradiation times t_{irr} . The A and B values and group parameters of delayed neutrons are estimated using the iterative least-squares method [226]. The decay curves obtained with short irradiation times were used to estimate the parameters of the short-lived groups of delayed neutrons, and the decay curves corresponding to long exposure times were used to estimate the parameters of longlived groups. The result of the analyses of data from one run of measurements comprising n-cycles of irradiation and counting is the set of the relative abundances of delayed neutrons a_i , the half-lives of their precursor T_i , and the covariance matrix of the group parameters [235].

c. Modulated accelerator beam technique. In delayed neutron measurements, a short irradiation time (see Eq. (15)) simplifies the interpretation of the experimental data obtained in the total delayed yield measurements. This idea helped to develop an efficient method for the determination of the energy dependence of the total delayed-neutron yield from fission of several heavy nuclei [217]. This technique is based on a modulated neutron-source generated by a Cockcroft-Walton accelerator which utilizes the D(d,n) reaction for producing 3.1 MeV and the T(d,n) reaction for 14.9 MeV neutrons. Figure 24 shows the time sequences used for the modulated neutron-source technique.

FIG. 24. Time sequences in the modulated neutron-source techniques [217]. Delayed neutron counting is made in time intervals $(T_m - t_c)$.

A long-counter neutron detector operating in antisynchronism with the accelerator beam registers delayed neutrons in the time interval $(T_m - t_c)$. Interpretation of the experimental data for this method is based on the equation for the *non-cumulative* DN decay curve measured after the n-th cycle of irradiation-counting sequences

$$\frac{dN(t_k)}{dt} \cdot \Delta t_k = A \cdot \sum_{i=1}^m T_{hi} \cdot \frac{a_i}{\lambda_i} \cdot (1 - e^{-\lambda_i \cdot \Delta t_k}) \cdot e^{-\lambda_i \cdot t_k} + B \cdot \Delta t_k ,$$
(20)

$$T_{hi} = (1 - e^{-\lambda_i \cdot t_{irr}}) \cdot \left(\frac{1 - e^{-n \cdot \lambda_i \cdot T_m}}{1 - e^{-\lambda_i \cdot T_m}}\right)$$

£

where the saturation activity is $A = \epsilon_n \cdot \sigma_f \cdot \phi \cdot N_f \cdot \nu_d$, and T_m the modulation period. After reaching the equilibrium $(n \to \infty)$ in the short time periodic irradiation $(\lambda_i T_m << 1)$ with the period of modulation T_m , the summation of delayed-neutron counts in the counting time $(T_m - t_c)$ can be expressed as follows:

$$\sum_{t_1}^{t_2} \frac{dN(t_k)}{dt} \cdot \Delta t_k - B \cdot (t_2 - t_1) =$$

$$A \cdot \sum_{i=1}^m (1 - e^{-\lambda_i \cdot t_{irr}}) \cdot \frac{a_i}{\lambda_i} \cdot \frac{(e^{-\lambda_i \cdot t_1} - e^{-\lambda_i \cdot t_2})}{(1 - e^{-\lambda_i \cdot T_m})} =$$

$$A \cdot t_{irr} \frac{T_m - t_c}{T_m} \quad (21)$$

where t_1 is the time when the delayed-neutron counting t_c starts, and t_2 is the period of modulation T_m (see Fig. 24). Another advantage of this method as compared to the nuclear reactor neutron-source techniques is a minimum of scattering and thermalizing material present in the vicinity of the sample. The total delayed-neutron yield was measured from the fission of ²³²Th, ²³³U, ²³⁵U, ²³⁸U, and ²³⁹Pu [217] nuclides. Later, Krick and Evans [218], using the same methodology, measured the total delayed-neutron yield as a function of the neutron energy from the fission of 233 U, 235 U, 238 U, 239 Pu, and 242 Pu in the energy range 0.1 - 6.5 MeV. It should be noted that the on-beam arrangement of a neutron detector can lead to a degradation of its counting characteristics. Special measures should be taken to find and eliminate this effect (see paragraph devoted to measurements with the $T(d,n)^4$ He neutron source).

d. The neutron detector in delayed-neutron measurements. The neutron detector most commonly used in delayed-neutron measurements is an assembly of ³He or boron counters distributed in a polyethylene or paraffin moderator. A moderator allows one to shift the neutron energy to the region of high registration efficiency. The efficiency of the neutron detector is determined using calibrated neutron sources (Pu-Be, Am-Li, ²⁵²Cf) or the monoenergetic neutrons produced from ⁷Li(p,n), D(d,n), ⁵¹V(p,n) nuclear reactions measured at a charged-particle accelerator [236].

e. Fission rate determination in accelerator and reactor-based methods. The main method used for this purpose in nuclear reactor experiments is spectroscopy of gamma rays emitted from fission products. Keepin et al. [13] determined the total number of fission in the samples by standard counting of the 67 h β -activity from ⁹⁹Mo. Benedetti et al. [211] determined the fission rate in the samples by measuring the gamma activity of fission products (103 Ru, 131 I, 140 Ba/ 140 La) that were induced in the samples after irradiation. In the accelerator-based technique, the fission rate in the sample is determined by measuring the neutron flux with the help of a fission chamber that is placed in the immediate vicinity of the sample. In the modulated neutron-source method, the fission rate in the fissionable sample is determined by measuring the count rates in two fission chambers sandwiching the sample ([217], [218]). In the case of accelerator-based methods with off-beam arrangement of the neutron detector, the fission chambers are placed in front of and behind the sample along the beam line of the accelerator ([222],[228], [237], [229]).

The effect of the concomitant neutron source f. $D(d,n)^{3}$ He in delayed- neutron experiments with an accelerator neutron source $T(d,n)^4He$. In experiments using the $T(d,n)^4$ He reaction as the neutron source, one has to take into account the effect of a concomitant neutron source which originates from the implantation of deuteron ions in the backing of the tritium target. As the number of implanted ions grows, the intensity of the concomitant neutron source $D(d,n)^3$ He increases. This feature of the $T(d,n)^4$ He reaction makes it difficult to interpret the experimental data obtained in the respective experiments. A special method has been developed to measure the intensity of the $D(d,n)^{3}$ He neutron source in correlation with the ion charge accumulated on a tritium target [238]. This method allows one to account for the effect of the concomitant neutron source and has been used in measurements of the relative abundances and periods of delayed neutrons for neutron-induced fission of 232 Th, 233 U, 235 U, 236 U, 238 U, 239 Pu, 237 Np, and 241 Am in the energy range from 14 to 18 MeV. Details of the procedure are presented in ([238], [239]).

g. The effect of degradation of the neutron detector counting rate characteristic in an intense field of *high energy neutrons.* The delayed-neutron decay curve recorded in measurements of relative abundances and periods of delayed neutrons from the fission of heavy nuclides induced by neutrons from the $T(d,n)^4$ He reaction was found to undergo noticeable degradation in the first several seconds after switching off the ion beam. A special experiment has been conducted to measure the counting property of the neutron detector after its irradiation by neutrons from the $T(d,n)^4$ He reaction. In this experiment, the time dependence of the count rates from the Am-Li neutron source was measured immediately after the irradiation of the neutron detector by a $T(d,n)^4$ He neutron flux of different intensities in the energy range 14-18 MeV. The obtained data were used to correct the

measured decay curves of the delayed neutron activity in the measurements of the relative abundances and periods from fission of 232 Th, 233 U, 235 U, 236 U, 238 U, 239 Pu, 237 Np, and 241 Am by neutrons in the energy range from 14 to 18 MeV. Details of the procedure are presented in [239].

2. Delayed neutron integral spectra

There are two main methods used for the investigation of integral delayed-neutron spectra. These are neutron spectrometry using ³He [240] and proton-recoil detectors [17, 18, 223] and the time-of-flight method [241]. The time-of-flight method gives an excellent resolution at low energy, however this resolution worsens rapidly at energies above a few hundred keV. As an example, the full width at half maximum (FWHM) of a TOF system with flight path 50 cm and time resolution 3 ns is 1.6, 17.3, and 82.6 keV at energies 50, 300 and 900 keV, respectively. The proton-recoil spectrometer resembles the time-of-flight method: the resolution is good at low energies, while deteriorating at high energies. The full width at half maximum of a proton-recoil spectrometer with 2.5 atm of H_2 for the same energies mentioned above, is 4.2, 12.6 and 25.6, respectively. The 3 He-spectrometer seems to be the optimal tool over the whole energy range. The resolution of this type of spectrometer is about 12-30 keV for energies ranging from 10 keV to 3 MeV. A detailed description of the techniques used for measurements of delayed-neutron spectra including unfolding procedures are given in a comprehensive review by Das [242]. Since the publication of this review, experimental work on composite delayed-neutron spectra has been carried out only at IPPE using an accelerator-based neutron beam [243]. By applying the least-squares method to the composite spectra measured in several delayed time intervals following fission [244], one can unfold the group energy spectra $\chi_i(E_n)$. The main purpose of obtaining the experimental group spectra is to use them to calculate the effective fraction of delayed neutrons β_{eff} [245].

B. New measurements and compilation

Since the last evaluation of macroscopic delayedneutron parameters was performed in the framework of WPEC-SG6 [14, 246], experimental activities related to macroscopic delayed neutron data have mainly been carried out at IPPE (Obninsk). These activities have been devoted to the measurement of the energy dependence of the total delayed neutron yield and the relative abundances of delayed neutrons and half-lives of their precursors for neutron-induced fission of 232 Th, 233 U, 235 U, 236 U, 238 U, 239 Pu, 237 Np, and 241 Am in the energy range from thermal to 18 MeV [226, 228–230]. In addition, the integral energy spectra of delayed neutrons from thermal neutron-induced fission of 235 U have been measured [243]. The relative abundances and half-lives of delayed neutrons from the relativistic proton-induced fission of ²³⁸U have also been measured [247]. All the data related to neutron-induced fission have been compiled in the macroscopic section of the database developed by this CRP [40] under the guidance of the Nuclear Data Section. The database is an extension of the summary of delayed neutron parameters by Spriggs and Campbell [248] and the compilation by Tuttle [249] and comprises the total delayed neutron yields, and the relative abundances and half-lives of delayed neutrons in the 6- and 8-group models with covariance and correlation data. The main features of the new IPPE macroscopic delayed-neutron data and the earlier measured data are presented in the following sections.

1. Energy dependence of the relative abundances and half-lives of delayed neutrons

The energy dependence of the relative abundances a_i and half-lives T_i of delayed neutrons have been measured at the IPPE electrostatic accelerators for neutroninduced fission of 232 Th, 233 U, 235 U, 236 U, 238 U, 239 Pu, 237 Np, and 241 Am in the energy range from thermal to 18 MeV. Monoenergetic neutron beams were generated by means of the nuclear reactions T(p,n), D(d,n), T(d,n). The method used in these experiments is described in Section VA1. Efforts were made to improve the experimental and data processing procedures by a) shortening the transportation time, b) extending the delayedneutron counting time, and c) averaging the temporal delayed-neutron parameters obtained in different experimental runs to improve the accuracy of the delayed neutron temporal parameters (a_i, T_i) . The IPPE measurements in the high energy range (14 - 18 MeV) revealed two plausible reasons for the large discrepancies observed in the delayed-neutron temporal parameters: (i) the deterioration of the counting efficiency of the neutron detector in a high-intensity neutron flux and ii) the contamination of the accelerator target by neutrons produced by the concomitant $D(d,n)^{3}$ He neutron source in measurements using the $T(d.n)^4$ He reaction.

The comparison of the delayed-neutron parameters (a_i, T_i) obtained in the IPPE measurements with other published data is shown in Figs. 25 and 26. The quantity that is compared is the average half-life $\langle T \rangle$ of the delayed-neutron precursors introduced by Piksaikin *et al.* [227]. Since $\langle T \rangle$ is the combination of the delayed neutron parameters (a_i, T_i) obtained in the least-squares fitting procedure and represents an average property of the system, it is not affected by the correlations which inevitably exist between the delayed-neutron parameters. It should be noted that the $\langle T \rangle$ value depends neither on whether one considers N as individual precursors or delayed-neutron groups of precursors, nor on the time boundaries of the delayed neutron groups.

It can be seen from Figs. 25 and 26 that the average

TABLE III. Results of the regression analysis of the energy dependence $\langle T(E_n) \rangle = A + B \cdot E_n$.

Isotope	Intercept value A	Slope value B
	(s)	(s/MeV)

^{236}U	$8.08 {\pm} 0.08$	-0.114 ± 0.020
$^{238}\mathrm{U}$ ^a	$5.56 {\pm} 0.05$	-0.070 ± 0.012
²³⁹ Pu	$10.54{\pm}0.04$	-0.200 ± 0.014

^a The energy range for analyses of ²³⁸U data was 3.2-5 MeV.

half-life of delayed-neutron precursors for all fissioning systems under consideration decreases with increasing energy of primary neutrons in the energy range from thermal to 5 MeV. The real scale of the variation in the relative abundances and half-lives of delayed-neutrons can be estimated in terms of the average half-life of delayedneutron precursors with the help of the regression analysis of the IPPE data shown in Fig. 27 for the uranium isotopes ²³³U, ²³⁵U, ²³⁶U, ²³⁸U and ²³⁹Pu. Results of the regression analysis of the energy dependence $\langle T(E_n) \rangle = A + B \cdot E_n$ are presented in Table III.

The temporal parameters of delayed neutrons presented in this paragraph have been used in the evaluation of the relative abundances of delayed neutrons and half-lives of their precursors (see Section IX).

2. Energy dependence of total delayed neutron yield

The energy dependence of the total delayed-neutron yield from neutron-induced fission of 232 Th, 233 U, 235 U, 236 U, 238 U, 239 Pu, 237 Np and 241 Am in the energy range 0.3 – 5 MeV measured at the IPPE accelerator facility is presented in Figs. 28 and 29.

Most of the data have been obtained after the last recommendations were made for the major nuclides ²³⁵U, ²³⁸U and ²³⁹Pu [246]. The IPPE data are compared with both the earlier measured data and the evaluated data from the ENDF/B-VII.1 [24], JEFF-3.1.1 [28], and JENDL-4.0 [258] data libraries. The total delayedneutron yields obtained on the basis of the systematics and correlation properties of delayed neutrons $\nu_d(E_n) = a \cdot \langle T(E_n) \rangle^b$ [227] are also presented in Figs. 28 and 29.

The IPPE data [227–230, 256, 257] are in agreement with the corresponding data measured by Krick *et al.* [218] for target nuclides ²³³U, ²³⁵U, ²³⁸U and ²³⁹Pu. The energy dependence of both sets of data for the nuclides under consideration is well reproduced by the data analysis on the basis of the correlation properties of delayed neutrons $\nu_d(E_n) = a \cdot \langle T(E_n) \rangle^b$ at least in the energy range up to 3-4 MeV [227]. According to the WPEC-SG6 recommendations [246] based mainly on the measurements of the effective delayed neutron fraction β_{eff} at thermal and fast assemblies, the energy dependence of the total delayed-neutron yield for ²³⁵U and ²³⁹Pu does

FIG. 25. The energy dependence of the average half-life of delayed-neutron precursors from neutron-induced fission of ²³³U, ²³⁵U, ²³⁶U, ²³⁶U, ²³⁸U. The references of the data can be taken from the compilation by Spriggs and Campbell [248] except for the IPPE data [226, 230, 235, 239, 250, 251].

not exceed 1%. The energy dependence of ν_d in a 1 MeV interval calculated on the basis of Krick's data [218] shows the following relative increase: ²³³U - 1.98% (±0.6%), ²³⁵U - 0.52 % (±1%), ²³⁹Pu - 2.06 % (±0.5%). In Table IV these data are compared with the corresponding data by Keepin [13] and values calculated on the basis of the systematics $\nu_d(E_n) = a \cdot \langle T(E_n) \rangle^b$ [227]. As can be seen in the table both the experimental data and the data obtained on the basis of the systematics show noteworthy energy dependence of the total delayed neutron yield. The difference between the thermal and fast energy ν_d values obtained for ²³⁵U and ²³⁹Pu by the summation calculation on the basis of the JEFF-3.1.1 fission yield data [28] is 24.5% and 21.2%, respectively [260].

Thus, this strong indication of an energy dependence of ν_d for ²³³U, ²³⁵U, and ²³⁹Pu observed in direct measurements is in contrast to the results obtained with help of the β_{eff} methods [246]. More work is needed to determine the energy dependence of the total delayed neutron yields reliably. The most efficient and straightforward

TABLE IV. Comparison of the energy dependence of the total delayed neutron yield from fission of $^{233}\rm{U},\,^{235}\rm{U},\,^{239}\rm{Pu}.$

		$d\nu_d/\iota$	$\nu_d/1 { m MeV}(\%)$
Isotope	Krick et al.	Keepin	IPPE [227]
	[218]	[13]	from $\nu_d(En) = a \cdot \langle T(En) \rangle^b$
$^{233}\mathrm{U}$	$1.98{\pm}0.6$	4.80	$1.84{\pm}0.62$
^{235}U	$0.52{\pm}1.0$	2.47	$2.04{\pm}1.31$
239 Pu	$2.06{\pm}0.5$	3.13	6.26 ± 1.69

way to do this is to conduct relative measurements with accuracy $\pm 1\%$ [261]. Apart from this, the reason why the summation method gives such a large difference between thermal and fast ν_d values also needs to be explored [260].

FIG. 26. The energy dependence of the average half-life of delayed-neutron precursors from neutron-induced fission of ²³²Th, ²³⁷Np, ²³⁹Pu, ²⁴¹Am. The references of the data can be taken from the compilation by Spriggs and Campbell [248] except for the IPPE data [226, 230, 232–234, 252–255].

3. Integral energy spectra of delayed neutrons from fission of ^{235}U by thermal neutrons

A comprehensive analysis of the composite delayed neutron (DN) spectra measurements can be found in the review by Das [242]. This review includes also the energy spectra from individual precursors measured by [19], [15, 16] and [17, 18], and the spectra of 235 nuclides calculated with the help of the evaporation model. Recently the integral energy spectra were measured from the epithermal neutron induced fission of 235 U at the IPPE accelerator based neutron beams. The measurements were made to emphasize particular groups of delayed neutron precursors using the high-resolution ³He-spectrometer of FNS-1 type and applying different irradiation and counting time intervals. Two sets of measurements were performed. The first one was made with an irradiation time interval of 120 s, which was followed by measurements of delayed neutron spectra in a sequence of time intervals as follows: 0.12-2 s, 2-12 s, 12-22 s, 22-32 s, and 32-152

s after the end of irradiation. The second set of measurements was made with an irradiation time interval of 20 s and measurements of delayed neutron spectra in the time intervals: 0.12-1 s, 1-2 s, 2-3 s, 3-4 s, and 4-44 s after the end of irradiation. About 3000 irradiation-counting cycles have been made within these measurements. The time sequence of irradiation and counting intervals used made it possible to consider some of the measured spectra as quasi-equilibrium. The comparison of these quasiequilibrium spectra with the corresponding spectra from other experiments are presented in Fig. 30.

It can be seen from Fig. 30 that the IPPE [243] nearequilibrium spectrum has more pronounced peak structure compared to the corresponding experimental data obtained by other authors. The peak structure observed in the data of Evans *et al.* [240] is similar to the peak structure of the IPPE data but the low-energy part of the spectra (below 300 keV) is about 30% lower than both the IPPE data and the data obtained by the summation method using the microscopic spectra from indi-

FIG. 27. The energy dependence of the average half-life of delayed-neutron precursors from neutron-induced fission of 233 U, 235 U, 236 U, 238 U and 239 Pu based on the data from IPPE [226, 230] and Keepin *et al.* [13]. The data of Maksyutenko *et al.* [248] presented in Figs. 25-26 were not considered.

vidual precursors. This could be explained by possible errors in the determination of the efficiency of the ³Hespectrometer or the correction that accounts for the neutron flux attenuation in the shielding used for rejection of gamma rays [243]. Another important feature of the present near-equilibrium spectrum is the lower intensity of DN below 200 keV as compared to the earlier experiments with the exception of the data of Evans *et al.* [240]. Comparison of the IPPE integral energy spectra measured at different time intervals after the end of the irradiation with the spectra calculated on the basis of microscopic DN data is presented in Section VIC. More details of the experimental procedure employed in the IPPE experiments can be found in [243].

4. ALDEN: new measurements of delayed neutron data

Apart from the experimental activities at IPPE (Obninsk), recently new experiments have been conducted at the Institut Laue-Langevin (ILL) to measure aggregate delayed-neutron data. The ALDEN (Average Lifetime of DElayed Neutrons) project consists of a series of experiments designed to measure delayed neutron group abundances with the aim of improving the data and providing realistic uncertainties and correlations for the most important fissioning systems involved in reactor applications (235 U, 238 U, 239 Pu, 241 Pu) [262].

The first experimental campaign of ALDEN was held at the end of 2018 at ILL (Institut Laue-Langevin) [262]. The ILL reactor produces a very intense and wellcharacterized thermal neutron flux. The experiment consisted of irradiating the fissile target and letting it decay naturally. Delayed neutrons were measured by LOENIE, a ³He detector, optimally designed to have an efficiency that is independent of the incident neutron energy [262]. LOENIE is composed of a cylindrical polyethylene block with a central hole for the fissile material and 16 smaller holes for the ³He counters. An airtight fission chamber containing a deposit of fissile material was used as target in the experiment. With the fission chamber one estimates the fission rate during the irradiation phase, which is then used to normalize the delayed-neutron activity curve.

During the decay phase, the ³He counters register delayed neutrons as a function of time. This timedependent activity curve was used to derive the groups abundances in the 8-group model. Several irradiation cycles were performed, each with a different irradiation duration in order to saturate a specific group of precursors.

The result obtained for thermal neutron-induced fission of 235 U from this first experimental campaign in 2018 is compared with other experimental data and evaluated libraries in Fig. 31. More ALDEN measurements for the other major actinides are planned to take place in the near future.

C. Estimation of energy dependence of total delayed neutron yields

As discussed in Section V B 2, the incident-energy dependence of the total delayed neutron yield has been measured extensively by the IPPE group in the past twenty years [222, 228–230, 236]. On the other hand, the theoretical study of the energy-dependence of the total delayed neutron yield has not been pursued that actively. The evaluated libraries, such as ENDF/B-VIII [25], JEFF-3.1.1 [28] and JENDL-4.0 [258], either perform an interpolation of the existing data or use the systematics proposed by Tuttle [263], Benedetti [211], Waldo [207], and Manero [264]. As a result, the evaluated values lie on a structureless curve.

The dependence of total delayed neutron yields on the incident neutron energy results from two factors. One is the dependence of fission product yields on the incident neutron energy. Fission yield distributions are usually determined by the potential energy surface of fissioning nuclei, which varies with incident neutron energy and excitation energy of the compound nuclei. The other factor is the competition with open channels other than (n, f). In particular, (n, n'f) and (n, 2nf) channels have a large impact on the energy dependence of the total delayed neutron yields. Similarly, other channels accompanying multiple particle emissions like (n, 3nf) also affect the energy dependence of delayed neutron emission.

In Ref. [265], a new method for evaluating the incident neutron energy dependence of total delayed neutron yields using least square fitting was presented. The model adopted the incident neutron energy dependence of fission product yields, the multi-chance fission, and the evaluated decay data of Ref. [35] (Z = 2 - 28). As mentioned

FIG. 28. The energy dependence of the total delayed-neutron yield from neutron induced fission of ²³³U, ²³⁵U, ²³⁶U, ²³⁸U. The references can be taken from the evaluation by Tuttle [249] except for the IPPE data by Piksaikin *et al.* [227, 228, 230, 256, 257] and Roshchenko *et al.* [229].

in Section III, new evaluated $(T_{1/2}, P_n \text{ data for } Z > 28 \text{ nuclei}$ were produced within the CRP [36] in addition to Ref. [35]. New calculations of the incident neutron energy dependence have thus been performed using the new CRP data of section III, and the results are presented in the following.

In the model of [265], the most probable charge Z_p is expressed by the following equations;

$$Z_p(A, E_n) = \alpha Z_p^0(A) + \beta c(A) E_n + \gamma E_n^2.$$
⁽²²⁾

The function c(A) accounts for the fact that the energy dependence of Z_p changes smoothly for light fragments and relatively rapidly for heavy fragments [266, 267]. The parameter $Z_p^0(A)$ is taken from the evaluation of England and Rider [268].

To take into account the odd-even effect observed in fission yield distributions, the method proposed by Madland and England [269] was adopted, where $(1 + C_1)$, $(1 - C_1)$, $(1 - C_2)$, and $(1 + C_2)$ are multiplied by the fission yields of even-even, odd-odd, odd-even, and evenodd nuclei, respectively. The renormalization is carried out after applying the multiplication factors. The energy dependence of the odd-even effect is approximated as

$$C_k(E_n) = C_k^0 \frac{2}{1 + \exp(\xi E_n)}$$
(23)

where C_k^0 (k = 1, 2) are taken from Madland and England's evaluation [269]. The values of α, β, γ in Eq. (22) and ξ in Eq. (23) are determined by a least squares fitting to experimental data on total delayed neutron yields for ^{233,235,236,238}U and ^{239–242}Pu. More details about the method can be found in Ref. [265].

For ^{240,241,242}Pu, the parameter γ was set equal to zero because there are not enough available experimental data points for all the parameters to be determined uniquely. The least square fitting was thus performed only for α, β , and ξ for the above-mentioned actinides. The parameters obtained from fitting the new evaluated CRP data are listed in Table V, The differences observed between the values in this table and those in Table 3 of [265] re-

FIG. 29. The energy dependence of the total delayed-neutron yield from neutron-induced fission of ²³²Th, ²³⁷Np, ²³⁹Pu, ²⁴¹Am. The references can be taken from the evaluation by Tuttle [249] except for the IPPE data of Piksaikin *et al.* [227, 230, 256, 257, 259].

flect the impact of the new evaluated CRP data $(T_{1/2}, P_n)$ from Section III. It should be noted that in this work, the total delayed neutron yield of ²³⁴U (i.e. from ²³⁴U(n, f)) taken from JENDL-4.0 is multiplied by a factor of 1.2. This increase improves the results obtained for the delayed neutron yields of ²³⁵U and ²³⁶U at energies where the second-chance fission ²³⁵U(n, n'f) or the third-chance fission ²³⁶U(n, 2nf) occurs. This prescription is validated by the large ambiguity affecting the original total delayed neutron yield value of ²³⁴U of JENDL-4.0 as it is obtained from Tuttle's systematics [263].

The total delayed neutron yields for uranium isotopes of A = 233, 235, 236, 238 are shown in Fig. 32 together with the experimental data and the evaluated values from JENDL-4.0 [258], ENDF/B-VII.1 [24] and JEFF-3.1.1 [28] libraries. The energy dependence of the experimental data for 233,235,236,238 U is reproduced reasonably well with the new parameterization.

The present results agree roughly with the evaluated data, however, several differences are noted: First, the

new results give a smooth curve up to about 4 MeV, while the evaluated data give a straight line. Second, they are systematically higher than the evaluated data in the energy region from 8 to 10 MeV. At energies above 15 MeV, the new results are lower than the evaluated data for 236,238 U. At these high energies, measurements

FIG. 30. Quasi-equilibrium spectrum of delayed neutrons from the fission of 235 U by epi-thermal neutrons [243]. IN IPPE spectrum (1): counting time is 1.88 s after irradiation of 120 s. In IPPE spectrum (2): counting time is 0.88 s after irradiation of 20 s. Quasi-equilibrium spectra by other authors have been calculated with the help of the group spectra obtained by decomposition of appropriate aggregate spectra in different time windows. The data references can be found in the review of Das [242].

FIG. 31. The energy dependence of the total delayed-neutron yield from neutron induced fission of 235 U. The red cross comes from the 2018 ALDEN campaign [262]. The other experimental data are taken from the evaluation of Tuttle [249] except for the IPPE data which are from by Piksaikin *et al.* [256, 257].

of total delayed neutron yields are required to improve the evaluated data.

Figure 33 shows the total delayed neutron yields for plutonium isotopes of A = 239, 240, 241, 242. As seen in the uranium isotopes, the energy dependence of the total delayed neutron yields is well reproduced. When compared with the evaluated data, the present results are closest to JENDL-4.0 up to around 12 MeV, but tend to be lower above 14 MeV except for 239 Pu. However, there are fewer available experimental data for the plutonium isotopes 240,241,242 Pu compared to the uranium isotopes. As in the case of the uranium isotopes, measurements of total delayed neutron yields at energies close to the second-chance fission threshold are required, in order to make a reliable extrapolation up to 20 MeV.

FIG. 32. Delayed neutron yield of uranium isotopes with A = 233 to 238. The data are taken from Bobkov *et al.* [270], Loaiza *et al.* [216], Brady *et al.* [132], Gudkov *et al.* [214], and the evaluation by Tuttle [249, 263], while the IPPE data are taken from Piksaikin *et al.* [227, 228, 230, 256, 257] and Roshchenko *et al.* [229].

FIG. 33. Delayed neutron yield of plutonium isotopes with A = 239 to 242. The data are taken from Bobkov *et al.* [270], Benedetti *et al.* [211], Cesana *et al.* [271, 272], and the evaluation by Tuttle [249], while the IPPE data are taken from Piksaikin *et al.* [230].

Figure 34 shows the delayed neutron activities for thermal neutron fission of 235 U, 239 Pu and 233 U. The activities are plotted as a function of time after fission burst, t, and the figures compare the results obtained with the current model with Keepin's six group constants [13] and the summation calculations using the fission product yields from the JENDL/FPY-2011 library and the radioactive decay data from the JENDL/FPD-2011 library (JENDL/FPY,FPD- 2011) [26]. For ²³⁵U, the present calculations and JENDL/FPY,FPD-2011 reproduce Keepin's data reasonably. However, JENDL/FPY,FPD-2011 overestimates the delayed neutron activity at times t < 5 sec. For ²³⁹Pu and ²³³U, the delayed neutron activities of JENDL/FPY,FPD-2011 overestimate those of Keepin's six group evaluation [13] significantly, while the present calculations are rather close to Keepin's results within errors.

Figure 35 shows the delayed neutron activities for the fast neutron fission of ²³⁵U, ²³⁸U, ²³³U, ²³⁹Pu and ²⁴⁰Pu. Similar to the results observed for thermal neutron fission, the delayed neutron activity obtained with the new model calculations is close to Keepin's six group evaluations within errors. JENDL/FPY,FPD-2011 overestimates Keepin's data significantly except for ²³³U.

FIG. 34. Delayed neutron activities multiplied by time t after neutron radiation for thermal neutron fission of 235 U (top), 239 Pu (middle), and 233 U (bottom). Instant neutron radiation is assumed. The present calculation indicated by the dashed lines are compared with the summation calculation of JENDL/FPY-2011 and FPD-2011 (JENDL/FPY,FPD-2011) [26] (solid line) and the results of Keepin's six group [13] (errors are shown by the shade).

To conclude, the incident neutron energy dependence of the delayed neutron yields of uranium and plutonium isotopes was re-estimated with the model of Ref. [265] using the new evaluated CRP data introduced in Sect. III. The present model reproduces the experimental total delayed neutron yields reasonably well. Moreover, the delayed neutron activities at thermal and fast neutron fissions evaluated by Keepin's six group model are also well reproduced.

FIG. 35. Same as Fig. 34, but for fast neutron fission of $^{235}\mathrm{U},$ $^{238}\mathrm{U},$ $^{233}\mathrm{U},$ and $^{239}\mathrm{Pu}.$

However, new evaluations of fission yield data which are able to reproduce both decay heat and delayedneutron emission data simultaneously, using the summation method, are urgently needed. New measurements of total delayed neutron yields at different incident neutron energies are also important for the evaluation of both fission yields as well as delayed neutron yields.

VI. SUMMATION CALCULATIONS

Summation and time-dependent calculations of total delayed neutron yields, delayed neutron spectra and delayed neutron activities using the CRP evaluated microscopic $(T_{1/2}, P_n)$ data are compared with recommended data and evaluated libraries in this section. The aim is to assess the new CRP data against a broad range of available macroscopic data.

A. A numerical $(T_{1/2}, P_n)$ data file for practical applications

A numerical file of definitive $T_{1/2}$ and P_n values has been created for use in summation and other calculations for applications spanning fission reactor technologies, anti-neutrino spectra and nuclear astrophysics. The file is based exclusively on the evaluated data produced by the CRP as described in Sect. III [43]. These data are purely experimental without any input from systematics or theory. It is left to the user to decide how to treat discrepant values (when compared with theory or systematics) or missing values due to lack of experimental data.

Furthermore, the "non-numerical" features of the $(T_{1/2}, P_n)$ tables, such as limits or approximate values, have been replaced with purely numerical values, and asymmetric limits have been symmetrized. A list of all the modifications implemented in the numerical file with respect to the tables available online is given below:

- upper limits were symmetrized, i.e. if $P_{1n} < 0.2$ then the adopted value in the numerical file would be $P_n = 0.1 \pm 0.1$.
- lower limits are 'symmetrized' as follows: $P_n > x$ becomes $P_n = y \pm z$ so that x = y - z and 100 = y + z. When the latter cannot be enforced, then the lower limit is doubled with an uncertainty of 50%, i.e. y = 2x and z = x, with $y + z = 3x \le 100$.
- asymmetric uncertainties were symmetrized following the prescription:

$$x(^a_b) \rightarrow y \pm z; \, y = x + \frac{a-b}{2}, \, z = \frac{a+b}{2}$$

- approximate values were assigned 50 % uncertainty, i.e. $P_{1n} \approx 0.2$ was replaced by $P_{1n} = 0.2 \pm 0.1$
- when multiple activities are measured but cannot be distinguished, i.e. when a P_n is given for both the ground state and isomeric states, then the latter is split equally among the states while the uncertainty for each state remains the same as the original recommended one. As an example, one takes for ⁸⁰Ga a recommended value for both, the ground state and the isomeric state , of $P_{1n} = 0.90(7)\%$. In the numerical file, the value $P_{1n} = 0.45(7)\%$ was adopted for the ground state and isomeric state, respectively. If the original uncertainty is larger than the split P_{1n} value, one can adopt a 100% uncertainty for the split value. For example, in the case of ¹¹⁶Rh, where $P_{1n} < 2.1\%$ for both ground state and isomeric state, the limit is symmetrized to give $P_{1n} = 1.05 \pm 1.05 \%$ and the resulting P_n is split among the two states with 100% uncertainty, i.e. as $P_{1n} = 0.525 \pm 0.525$ % for the ground state and isomeric state, respectively.

- there are a few cases (^{38,39}Al, ⁴³P) where the reported measured P_n value can take unphysical values within the reported uncertainty range. In such cases the uncertainty was adjusted so that P_n lies within the physical limits ($0 \le P_n \le 100 \%$).
- zero values for Q_{βxn} and P_{xn} have the following meaning: (i) there are no measurements available, (ii) the decay mode is forbidden.
- nuclides that have only been identified in measurements and have no measured $T_{1/2}$ or P_n value are not included in the numerical file.

The format of the file is as follows:

Nuclide name, Z, A, liso (index indicating order of states, i.e. for ground state liso = 0, for 1st isomeric state liso = 1, etc.), Level Energy, Δ Level Energy, $\%\beta$ -, $\Delta\%\beta$ -, $Q_{\beta n1}$, $\Delta Q_{\beta 1n}$, $Q_{\beta n1}$, $\Delta Q_{\beta 2n}$, $Q_{\beta n3}$, $\Delta Q_{\beta 3n}$, $T_{1/2}$, $\Delta T_{1/2}$, P_{1n} , ΔP_{1n} , P_{2n} , ΔP_{2n} , P_{3n} , ΔP_{3n} .

The numerical file has been used in the summation calculations described in the following sections with the aim of verifying and validating the new evaluated P_n tables produced by the CRP. It is available for downloading at the IAEA Beta-delayed neutron database [43]. A more detailed description of the contents of the IAEA Betadelayed neutron database is given in Section X.

B. Total delayed neutron yields

1. Basic summation calculations

In this section, summation calculations of the total delayed neutron yield ν_d performed with the CRP data $(T_{1/2}, P_n)$ are compared with other decay data libraries and with recommended values.

a. Comparison with evaluated libraries. The first step in verifying and testing the new evaluated CRP $(T_{1/2}, P_n)$ values using the numerical file was to perform a basic inter-comparison of summation calculations of the delayed neutron yields among the CRP participants. Total delayed neutron yields (DN) were calculated for thermal and fast neutron-induced fission of major and minor actinides by four independent groups, namely CEA-Cadarache (Foligno), CIEMAT (Cano), JAEA (Minato) and SUBATECH-Nantes (Fallot).

The calculations are based on the summation method whereby the total delayed neutron yield ν_d is defined as

$$\nu_d = \sum_i N_{ni} \cdot CFY_i \tag{24}$$

where N_{ni} is the average delayed neutron multiplicity emitted by the precursor *i* and is given by $N_n = 1 \cdot P_{1n} + 2 \cdot P_{2n} + 3 \cdot P_{3n} \dots$, P_{xn} are the delayed neutron emission probabilities P_{xn} and CFY_i are the cumulative fission yields for precursor *i*. The above equation holds for equilibrium irradiation where the production and decay rates of the precursor nuclides are proportional to their cumulative fission yields.

Assuming the N_n and CFY quantities in the above expression are independent, the uncertainty of the total DN yield is given by

$$\sigma_{\nu_d}^2 = \sum_i N_{ni}^2 \cdot \sigma_{CFY_i}^2 + \sum_i \sigma_{N_n i}^2 \cdot CFY_i^2$$
(25)

where $\sigma_{N_n i}$ and σ_{CFY_i} are the uncertainties of the delayed neutron multiplicities N_{ni} and cumulative fission yields CFY_i of the individual precursors.

In the following calculations, the cumulative fission yields CFY_i are taken from the JEFF-3.1.1 fission yield library [28] which has been widely tested in a broad range of applications, including in summation calculations of DN yields, and has proved to perform well. The β -decay and β -delayed neutron data, $(T_{1/2}, P_n)$, are taken from the new CRP tables. Nuclides for which there are no P_n values in the new CRP tables are not considered as β -delayed neutron emitters, i.e. $P_n = 0$. The remaining decay data (γ decays-IT), when used in the basic summation calculations or time-dependent calculations, are taken from ENDF/B-VIII.0 [25]. This combination of input data is hereafter referred to as CRP+ENDF/B-VIII.0. The calculations are compared with total DN yields obtained by combining CFY_i from JEFF-3.1.1 and decay data from the ENDF/B-VIII.0 decay data sublibrary. This comparison enables us to observe the direct impact of the new CRP data $(T_{1/2}, P_n)$ on the total DN yields as all the other data inputs are the same. It is also interesting to explore the differences between the new improved CRP+ENDF/B-VIII.0 decay data sublibrary and the other available evaluated decay-data sublibraries. Therefore, additional calculations were performed by combining the CFY_i from JEFF-3.1.1 [28] with the decay data from JEFF-3.1.1 [28] and JENDL/DDF-2015 [27] sub-libraries. Note that the release of JEFF-3.3 library occurred after most of the work carried out by the CRP was completed. Since JEFF-3.3 and JEFF-3.1.1 do not differ with respect to the DN data, it was decided that for the purposes of the CRP work it was sufficient to present the results that had already been obtained with JEFF-3.1.1 as they would in practice be identical with those obtained with JEFF-3.3.

The results of the summation calculations for the major actinides ²³⁵U, ²³⁸U, ^{239,241}Pu are given in Table VI. Perfect agreement is observed among the four different summation calculations which confirms that the calculations performed by the different groups within this project are equivalent and hence reliable. We do not need to report the results of all four groups hereafter, but just the results of the CRP. The values in Table VI are considered as reference values for the given combination of decay data and fission product yields library.

The results displayed in Table VI show that overall the CRP P_n data lead to larger values of the total DN

TABLE VI. Total delayed neutron yields (ν_d) for thermal and fast neutron-induced fission of major actinides obtained from the summation method using three different decay data libraries (CRP+ENDF/B-VIII.0, ENDF/B-VIII.0, JEFF-3.1.1, JENDL/DDF-2015) in combination with the cumulative fission yields CFY from JEFF-3.1.1.
Four groups participated in the inter-comparison, namely CEA (France), CIEMAT (Spain), JAEA (Japan), and NANTES (France). The numbers in brackets are the relative uncertainties neglecting correlations.

yields (ν_d) compared to the other evaluated decay data libraries ENDF/B-VIII.0, JEFF-3.1.1 and JENDL/DDF-2015. The observed differences are larger with respect to JEFF-3.1.1, which generally gives the lowest values of total DN yields among all three evaluated libraries. In the case of fast fission of ²³⁸U and thermal fission of ²⁴¹Pu, the CRP+ENDF/B-VIII.0 total DN yields are in agreement with the ENDF/B-VIII.0 and JENDL/DDF-2015 results.

The 20 most important contributors to the total DN yields (ν_d) displayed in Table VI are listed in Table VII. The first column includes the percentage contribution of the precursors resulting from the CRP ($T_{1/2}, P_n$) data, while the neighboring columns include the contributions of the same precursors obtained when using the ENDF/B-VIII.0, JEFF-3.1.1 and JENDL/DDF-2015 decay data, respectively. Both ENDF/B-VIII.0 and JENDL/DDF-2015 have adopted P_n values from ENSDF [23], however, depending on the date they were retrieved from the ENSDF database, the values may differ among each other and with respect to the current ENSDF data value. JEFF-3.1.1 uses P_n values from an evaluation by Nichols [30] as well as from ENSDF.

From Table VII we see that overall, the differences between the contributions of the top 20 precursors among the various libraries are less than 10%. Some notable cases are discussed below:

¹³⁷I is the main contributor to ν_d for nearly all the major actinides and incident neutron energies. The ¹³⁷I contribution is enhanced (on average by a few %) when using the CRP data and is mainly responsible for the small increase in the total DN yields observed in Table VI. The increased relative contribution of ¹³⁷I is related to a small increase in the CRP P_n value for this precursor, which is now $P_n = 7.63(14)$ %, compared to the value of 7.14(23)% used in ENDF/B-VIII.0 and JENDL/DDF-2015. The increase is more pronounced with respect to JEFF-3.1.1 which has an adopted value of $P_n = 6.5(4)$ % from [30].

The precursor ⁸⁵As is among the top twelve contributors in the CRP list with $P_n = 62.5(10)\%$. It also figures high in the ENDF/B-VIII.0 and JENDL/DDF-2015 contributors lists due to the large value $P_n = 59.4(24)\%$ adopted in both files, from ENSDF. The difference between the CRP contribution and JEFF-3.1.1 is considerably larger (over 100%) due to the relatively lower value of $P_n = 22(3)\%$ adopted in JEFF-3.1.1 [30].

⁹¹Br is among the top 20 contributors in the CRP list with $P_n = 29.8(8)\%$, which is similar to the JEFF-3.1.1 value $P_n = 20(2)\%$ taken from [30] and JENDL/DDF-2015 $P_n = 20(3)$ taken from ENSDF. In ENDF/B-VIII.0, however, this precursor does not have a delayed-neutron decay branch, therefore it does not contribute to the delayed neutron activity.

¹³⁶Te appears in the top 20 list of the CRP calculations although it has a relatively small β -delayed neutron fraction of $P_n = 1.37(5)\%$. Similar results are obtained with ENDF/B-VIII.0 and JENDL/DDF-2015 which have both adopted the value of $P_n = 1.311(5)$ from ENSDF. On the other hand, this precursor does not have a delayedneutron branch in the JEFF-3.1.1 decay data library.

The contribution of ⁸⁹Br to the CRP list is lower by more than 13% in comparison to JEFF-3.1.1. This difference is observed across several of the major actinides, and is related to the small difference in P_n values, with $P_n =$ 13.7(6) being the CRP value and $P_n = 14.1(4)$ [30] the value in JEFF-3.1.1. ENDF/B-VIII.0 and JENDL/DDF-2015 contributions are identical which is due to the fact that they have adopted the same value $P_n = 13.8(4)$ from ENSDF.

The above-mentioned differences in the individual precursor P_n values may have a non-negligible impact on the DN group spectra which are estimated from summations over the energy spectra of individual precursors weighted by their relative contributions to the total DN yield, in addition to the differences observed in the total delayed neutron yields.

The uncertainties associated with the new total DN yields in Table VI are fairly small compared to the large uncertainties affecting the cumulative fission yields CFYs. However, this is expected considering that the estimation of the uncertainties ignores the effect of correlations which are particularly strong between the CFY uncertainties. A more rigorous treatment of the propagation of uncertainties including correlations would yield different results.

b. Comparison with recommended values. The total DN yields presented in Table VI are compared with recommended DN yields from [246] and the recommended DN vield data from JEFF-3.1.1, ENDF/B-VIII.0 and JENDL-4.0 [258] libraries in Figs. 36-38. It should be noted that the total DN yields from JEFF-3.1.1 are identical to the JEFF-3.3 data therefore the results in Fig. 36 are valid for both libraries. As shown in the figures, the total DN yields obtained with the CRP $(T_{1/2}, P_n)$ data for thermal fission of 235 U and 239 Pu are in good agreement with the recommended data [246] and the data from the other libraries except for the thermal value of ²³⁹Pu from JENDL-4.0. The results for the fast fission of 238 U are substantially closer to the recommended data compared with the previous summation calculations of [187]. The differences between the calculated and recommended values of the total DN yields for the fast neutron-induced fission of ²³⁹Pu and ²³⁵U and for both fast and thermal fission of ²⁴¹Pu are more than 10%. These differences highlight the need for better treatment of uncertainties and further improvement of the microscopic data for these nuclides, mainly the fission yield data. Another important feature of the CRP results presented in Table VI is the clear evidence of the energy dependence of the total DN yields for fission of 235 U and 239 Pu. This is in agreement with the latest experimental data presented in this paper (see Section VC) and supports the need for further investigation of this dependency.

FIG. 36. Comparison of the total DN yields obtained from the summation method using the CRP $(T_{1/2}, P_n)$ data and the JEFF-3.1.1 decay-data sub-library, respectively, with the recommended DN yields [246]. The total DN yields for the fission of various nuclides (listed on the abscissa axis) are plotted with symbols. The right ordinate shows the percentage difference between the total DN yield data calculated using the CRP data and the corresponding data from JEFF-3.1.1 (bar chart).

FIG. 37. Same as in Fig. 36 but for the ENDF/B-VIII.0 decay sub-library.

2. Time-dependent calculations

Apart from summation calculations that use cumulative fission yields to account for the abundances of the fission products in equilibrium, time-dependent calculations that start from independent fission yields and follow the evolution of the system into the decay phase, can also shed light on the impact of the new CRP $(T_{1/2}, P_n)$ data on integral quantities. In this section, we describe two different time-dependent calculations of the integral DN activity and total DN yields that were performed with

FIG. 38. Same as in Fig. 36 but for the JENDL-4.0 decay sub-library (bar chart).

the new CRP data.

a. Time-dependent calculations during the irradiation and decay phase. The integral DN activity experiment is simulated by summing up the microscopic contribution of each of the precursors produced during the fission process. The Bateman solver [262] is a computer program that uses the decay data to reconstruct the family tree of the precursors and then solves the Bateman equations to obtain the precursors' concentration during both the irradiation and the decay phase. The concentrations-intime are then multiplied by the effective delayed-neutron emission probability of the precursor (Eq. 26).

$$n_d(t) = \sum_{i=1}^N C_i(t) \overline{P}_{n \text{ eff } i}, \qquad (26)$$

where $\overline{P}_{n \text{ eff } i} = \sum_{x=1}^{4} x P_{xn}$ is the effective delayedneutron emission probability of the precursor *i*, which takes into account multiple decay branches leading to the

neutron emission. The following decay-processes are considered in the code [262]: IT, β^- , β^-_n , β^-_{2n} , β^-_{3n} and β^-_{4n} . The Bateman solver has been validated through comparisons with the DARWIN code [273].

Figure 39 shows the DN activity for thermal neutroninduced fission of 235 U computed by combining the CRP+ENDF/B-VIII.0 and ENDF/B-VIII.0 decay data with JEFF-3.1.1 fission yields. The figure shows the two DN activities as w ell as their ratio, as a function of time after the irradiation.

The ratio does not start from 1 because the ν_d is different (1.60 neutrons/100 fissions for ENDF/B-VIII.0 and 1.66 neutrons/100 fissions for CRP+ENDF/B-VIII.0 for ²³⁵U). Table VIII displays the 20 most important precursors according to the CRP calculations (see also Table VII), together with their partial yield $\nu_{d,i}$, the difference with respect to the partial yields calculated

FIG. 39. Comparison between the CRP+ENDF/B-VIII.0 and ENDF/B-VIII.0 decay data. The two plots represent the two DN activities and their ratio, respectively, following the thermal fission of 235 U.

with ENDF/B-VIII.0, and the change in the corresponding precursor P_n emission probability when going from ENDF/B-VIII.0 to CRP+ENDF/BVIII.0.

The discrepancies observed in the partial $\nu_{d,i}$ of the first 20 precursors are responsible for a difference in the total ν_d of $+7.3 \times 10^{-4}$. The fact that, when considering all the precursors, such a difference decreases to $+6.4 \times 10^{-4}$, means that there is a compensation due to the underestimation of less important precursors in the CRP P_n tables with respect to the ENDF/B-VIII.0 decay library. From a comparison of the individual isotopes, it appears that the largest $\Delta \nu_{d,i}$ belongs to ¹³⁷I and ⁹¹Br. The latter precursor in particular, has $P_n =$ 0 in ENDF/B-VIII.0, whereas in the previous version ENDF/B-VIII.1 [24] it had a non-zero P_n value. This is quite a marked difference between the libraries since in the recommended CRP tables this β -delayed neutron precursor alone, accounts for almost 3% of the ν_d .

As far as the results for the DN activity shown in Fig. 39 are concerned, the two absolute activities seem to agree perfectly, however their ratio shows a discrep-

TABLE VIII. Detailed comparison of the microscopic data of the 20 most important precursors for thermal neutron-induced fission of ²³⁵U: atomic number (Z), mass (A), isomeric number (index) (I), the partial delayed neutron yield computed by using CRP+ENDF/B-VIII.0 decay data ($\nu_{d,i}$), the difference in the partial yield when using CRP+ENDF/B-VIII.0 rather than ENDF/B-VIII.0 ($\Delta \nu_{d,i}$) and the change in microscopic P_n from ENDF/B-VIII.0 to CRP+ENDF/B-VIII.0 (P_n (VIII.0) $\rightarrow P_n$ (CRP)).

ancy that varies from +4% after about 30 s to -3% after 400 s. The relative uncertainty in these calculations has been estimated to increase with time, due to the model that is used. At the beginning of the decay (just after an infinite irradiation), the activity corresponds to the ν_d , so the uncertainty associated with the two points is about 5% per point. This means that the ratio has an uncertainty of about 7% (not taking into account the correlations induced from using the same fission yields). This is the time after irradiation at which the deviation between the 2 curves is at its maximum (4%). Therefore, when the deviation between the two curves is at its maximum (4%), the uncertainty is at its minimum (7%), and we may conclude that the two DN activity curves agree.

The variations observed in the ratio of the DN activities are due to the differences in the P_n values of the ¹³⁷I and ⁸⁷Br precursors in the two libraries. As can be seen in Table VIII, the ¹³⁷I P_n value from the CRP is increased while the corresponding ⁸⁷Br P_n value is decreased. This explains the bump at 30 s - where the importance of ¹³⁷I is maximum - as well as the -3% plateau that extends till the end of the decay when only ⁸⁷Br is left.

Figure 40 shows the relative contribution of the most important precursors as a function of time. It is clear that 137 I dominates after about 30 s from the end of the irra-

FIG. 40. Relative contribution of the most important precursors in time, following the thermal fission of $^{235}U_t$. It is clear that ^{137}I dominates after about 100 s from the end of the irradiation, while after 300 s the activity is only due to ^{87}Br

diation, while after 300 s the activity is only due to 87 Br. The latter finding for 87 Br is quite interesting, as this precursor did not appear among the most important contributors in the basic summation calculations discussed in the previous section. This confirms that time-dependent calculations allow us to gain deeper insight in the role of each DN precursor in the β -delayed neutron process following fission.

Overall, as seen in the previous section, the CRP P_n data differ from those adopted in the ENDF/B-VIII.0 decay data library for several precursor nuclides. In timedependent calculations, these differences lead to different precursor family trees, both in shape and *intensity*, where intensity is the amount of precursors created by the fathers' decay. The impact of the new CRP $(T_{1/2}, P_n)$ data is evident in the ν_d and DN activity ratio. In particular, the shape of the curve in the decay phase is strongly affected by the microscopic data of the long-lived precursors, namely ¹³⁷I and ⁸⁷Br.

b. Time-evolution calculations of major and minor actinides at thermal. fast and spallation energies. The CRP data have also been used in time-evolution calculations of the composition of pure spheres filled with major and minor actinides. The calculations have been performed at three incident neutron energies (thermal, fast and spallation) for which fission yield data are available in the evaluated libraries. To begin with, the JEFF-3.1.1 independent fission yields were combined with the JEFF-3.1 decay data to compute the activities at various time steps using the MURE code [274]. The total DN yields per fission ν_d were then calculated by means of the summation method using the P_n values obtained from the CRP, ENDF/B-VIII.0 and the JEFF-3.1.1 libraries. The results are compared with the recommended values of ν_d found in the JEFF-3.1 evaluated library (Table IX).

A first observation from Table IX is that the informa-

tion on delayed neutron yields available in the evaluated database JEFF-3.1 is sparce. For example, there is no value available in the fast range for 233 U, while for several actinides ν_d values are provided at rather different 'fast' energies, i.e. 200 keV in one case and 4 MeV in another case.

Nevertheless, from the comparison of the results obtained at the available incident energies we observe similar trends: the ν_d values obtained with the CRP P_n data (third column in Table IX) are systematically larger than those obtained with the ENDF/B-VIII.0 (fourth column) and JEFF-3.1.1 P_n data (fifth column). The results obtained with JEFF-3.1.1 decay data are the lowest of the three and deviate from the recommended values the most. This is in agreement with the findings of Sect. VIB 1.

For major actinides in the thermal range (fast in the case of 238 U), the ν_d s obtained from the summation calculations are quite close to the recommended values of JEFF-3.1.1 (second column). ENDF/B-VIII.0 is in better agreement with recommended JEFF-3.1.1 values in the case of 235 U and 239 Pu, while for 238 U and 241 Pu the CRP data are closer to the recommended values. However, once the conditions regarding fuel or impinging neutron energy differ from those of a pressurized water reactor (PWR), the discrepancies among the summation calculations and recommended values increase. Overall the three summation calculations (using different input data) are in better agreement among themselves than with the recommended ν_d values of JEFF-3.1.1. The introduction of the new CRP P_n values does not lead to an improvement with respect to the recommended values, but rather enhances the discrepancies, with the sole exception of ²³⁸U and ²⁴¹Pu as already mentioned. This is due to the enhanced P_n values of the most important contributors which was also observed in the previous sections VIB1 and VIB2a.

The results show that additional work is needed to improve the other microscopic data used in the summation calculations besides the β -delayed neutron emission data, i.e. the fission yield data. It is of high importance to improve the evaluated fission yield data for a range of incident neutron energies needed in various applications. Furthermore, considering the inconsistencies observed in some of the recommended data in JEFF-3.1.1 (identical values for thermal and fast fission), and the availability of integral data at incident neutron energies that are not directly comparable with those of the fission yields, it is clear that new integral measurements of ν_d is merited.

C. Time-dependent delayed-neutron integral spectra

In this section we use the new CRP $(T_{1/2}, P_n)$ data in calculations of time-dependent DN integral spectra for thermal neutron-induced fission of ²³⁵U and compare them with measured, as well as recommended spectra in the existing evaluated libraries.

TABLE IX. Delayed neutron yields ν_d obtained from simulations of individual fuels with thermal ("t"), fast ("f") and spallation ("s") independent fission yields from JEFF-3.1.1 coupled to JEFF-3.1 half-lives and P_n values from the CRP (3rd column), ENDF/B-VIII.0 (4th column) and JEFF-3.1.1 (5th column). The ν_d recommended in JEFF-3.1 are displayed in the 2nd column. In cases where the energies of the impinging neutrons differ substantially from the average neutron energies associated with the fission yields, the energies at which the ν_d were extracted from JEFF-3.1 are given in parentheses.

In Figs. 41-44, the spectra measured for thermal neutron-induced fission of ²³⁵U at different time intervals by [243] as described in Section VB2 are compared with the corresponding spectra calculated on the basis of the microscopic delayed neutron data, namely, the delayed neutron spectra from individual precursors [41], the emission probability of delayed neutrons P_n and the halflife of delayed neutron precursors $T_{1/2}$ taken from the CRP tables $(T_{1/2}, P_n)$. Three sets of delayed neutron spectra were used in the calculations. The first one is the delayed neutron spectra from the ENDF/B-VII.1 [24] decay data file which has been developed by Brady and England [132]. These data comprise thirty four experimental spectra combined and adjusted on the basis of the raw spectra data measured in Mainz [19], Studsvik [15, 16] and INEL [17, 18] and additionally, the spectra for 235 nuclides calculated with the help of the evaporation model. The second set of energy spectra represents the data from the ENDF/B-VII.1 file in which the spectra for ${}^{89-90}\text{Br}$, ${}^{93-97}\text{Rb}$, ${}^{136}\text{Te}$, ${}^{138-139}\text{I}$, ${}^{143-145}\text{Cs}$ precursors were replaced by the corresponding data of Greenwood et al. [17, 18]. The third set is the 8-group spectra from the JEFF-3.1.1 file [28]. The cumulative fission yield data used in all these calculations were taken from the JEFF-3.1.1 FY file [28].

The energy spectra in definite time-windows were calculated with the help of the time-dependent formula written for N delayed neutron precursors [243]

$$\chi(E_n, t)dE_n = A \cdot \sum_{i=1}^N \left(\frac{P_{ni} \cdot CY_i}{\lambda_i}\right) \left(1 - e^{-\lambda_i \cdot t_{irr}}\right) \\ \times \left(e^{-\lambda_i \cdot t_d}\right) \left(1 - e^{-\lambda_i \cdot \Delta t_c}\right) T_i \chi_i(E_n) dE_n ,$$
(27)

$$T_i = \left[\frac{n}{1 - e^{-\lambda_i \cdot T}} - e^{-\lambda_i \cdot T} \cdot \frac{1 - e^{-n\lambda_i T}}{\left(1 - e^{-\lambda_i \cdot T}\right)^2}\right]$$

where T_i term describes the dependence of delayed neutron activity on the number of cycles; A the saturation activity; P_{ni} the emission probability of the i-th precursor; CY_i the cumulative yield of the *i*-th precursor taken from JEFF-3.1.1 file [28]; $\chi_i(E_n)$ the delayed neutron energy spectrum associated with the i-th precursor; λ_i the decay constant of the *i*-th precursor; t_{irr} the irradiation time, s; t_d the delay time (cooling), s; Δt_c the neutron counting time (time window); *n* the number of cycles; *T* the period of one cycle (irradiation-cooling-countingdelay).

As can be seen from Figs. 41 and 42 both the general form and peak structure of the summation spectra in time intervals 2-12 s, 12-22 s, 22-32 s, 32-152 s and in the whole energy range are in excellent agreement with

FIG. 41. Comparison of the integral delayed spectra obtained from thermal neutron-induced fission of 235 U in the time intervals 0.12-2 s, 2-12 s, 12-22 s, 22-32 s [243] with corresponding spectra calculated by means of the summation method using different sets of microscopic delayed neutron data (irradiation time of experiments - 120 s).

the corresponding integral spectra measured with the irradiation time 120 s. In the first time interval 0.12-2 s both summation data overestimate the low-energy part of the energy spectrum as compared with the experimental data but nevertheless, they show the same peak structure at 10, 50, 80, 120 and 170 keV. Upon inclusion in the ENDF/B-VII.1 decay data file [24] of the Greenwood et~al.~ spectra for precursors $^{89-90}{\rm Br},~^{93-97}{\rm Rb},~^{136}{\rm Te},$ $^{138-139}$ I, $^{143-145}$ Cs [17, 18], the agreement between the ENDF/B-VII.1 based summation spectra and the experimental data severely deteriorates (see Figs. 41 and 43). The main difference between these spectra is that the low-energy part of the spectrum (below 100 keV) is heavily overestimated when the Greenwood precursor spectra are included. The summation energy spectra calculated on the basis of the 8-group data are very close to the ENDF/B-VII.1 based data [24]. This observation can be considered as a clear indication that the procedure used for the generation of the 8-group spectra from microscopic data is reliable and that the 8-group spectra reproduce

the time evolution of the composite spectra. In the case of the short irradiation data (see Fig. 44), we observe good agreement between experimental and calculated spectra data in the 4-44 s time interval except for some deviations at the high energy peaks at 740, 850, 950, 1050, and 1140 keV, which are overestimated in the summation spectra. The main difference between the summation spectra and experimental short irradiation data in the other time intervals is the low intensity of the 317 and 352 keV peaks and the unresolved peaks at about 420 and 513 keV in the summation spectra (see Fig. 43).

Thus, the agreement between the summation and composite experimental spectra observed in the long irradiation data validates the approach taken by Brady and England [132] in developing the ENDF/B-VII.1 precursor spectra. Furthermore, this agreement justifies our confidence in the summation method using the current microscopic CRP β -delayed neutron database. The discrepancies observed in the short irradiation data show the necessity to continue efforts to improve the microscopic

FIG. 42. Thermal neutron-induced fission of 235 U. Left side: comparison of the integral delayed spectra in the time interval 32-152 s [243] with corresponding spectra calculated by means of the summation method using different sets of microscopic delayed neutron data. Right side: the integral delayed spectra in the time interval 0.12-2 s. The Greenwood *et al.* [17, 18] spectra are added to the ENDF/B-VII.1 data base [24] (irradiation time of experiments - 120 s).

data on the short-lived precursor spectra on the basis of the up-to-date model developed by [32]. The IPPE integral energy spectra obtained from thermal neutroninduced fission of 235 U in different time intervals [243] that were successfully used in the comparison studies in this section, should be used further as a benchmark for both testing individual precursor spectra and improving the short-lived group spectra.

D. Time-dependent delayed-neutron parameters

The CRP data are also used to calculate timedependent parameters in the 8-group model. For this purpose, the DN activity curve is obtained from summation calculations over the microscopic β -delayed neutron CRP data $(T_{1/2}, P_n)$. The 8-group parameters (a_i, λ_i) are extracted from the activity curve and compared with recommended 8-group parameters [14]. This is another way of assessing the impact of the CRP $(T_{1/2}, P_n)$ data on integral quantities.

a. Time-dependent parameters from microscopic calculations The delayed neutron-activity is simulated through microscopic summation calculations, as explained in Subsection VID. Fission Yields (FY) are taken from JEFF-3.1.1 and Radioactive Decay Data (RDD) from CRP+ENDF/B-VIII.0 and ENDF/B-VIII as described in Section VIB1. Where needed, the excitation state of the daughter nucleus after the decay (*RFS*) is taken from ENDF/B-VIII.0 [25].

The DN activity obtained from the summation calculations is then fitted by the CONRAD code [275], which is developed at CEA (France) with the purpose of performing high-quality uncertainty analysis. Instead of fitting the delayed neutron activity directly, we have chosen to fit the difference between the two models: microscopic and macroscopic (Eq. 28).

$$\frac{n_d(t)}{n_d(0)} - \sum_{i=1}^8 a_i (1 - e^{-\lambda_i t_{\rm irr}}) e^{-\lambda_i (t - t_{\rm irr})} = 0, \quad (28)$$

where $t_{\rm irr}$ is the irradiation time and $n_d(0)$ is the DN emission rate at the end of the irradiation phase, which corresponds to the average DN yield in case of an infinite irradiation.

The CONRAD code implements Baye's theorem, which allows adjusting the model parameters - in this case, the group abundances - according to the available experimental information. In this work, however, the experimental data are replaced by the calculated DN emission rates. The parameters of the macroscopic model are therefore adjusted to fit the microscopic model. This procedure, coupled with an analytical marginalization technique, allows one to propagate the uncertainty in hundreds of microscopic data to just the eight abundances a_i . At the same time, CONRAD provides the correlations among the uncertainties of the fitted parameters (see Fig. 45), which compensate for the apparently higher uncertainty in the single abundances.

The results of the simulation of the experiment, i.e. of the DN activity curve, and the subsequent extraction of the group parameters are presented in Tab. X. The associated uncertainties given in brackets reflect the uncertainties arising from the hundreds of parameters marginalized in the CONRAD fit. Tables XI to XXI display the correlation matrices of the abundances obtained with the analytical marginalization technique. The small correlations among the abundances derive from the fact that each group is responsible for a part of the decay curve

FIG. 43. Comparison of the integral delayed spectra obtained for thermal neutron-induced fission of 235 U in the time intervals 0.12-1 s, 1-2 s, 2-3 s and 3-4 s [243] with corresponding spectra calculated by means of the summation method using different sets of microscopic delayed neutron data (irradiation time of experiments - 20 s).

and is supposed to represent only those precursors having a similar half-life. A *physical* correlation among abundances could only arise from the family tree, for example, a short-lived precursor being created by the decay of a long-lived precursor. This would create a small correlation between the two groups containing the mentioned precursors. The average precursors' half-lives, computed using the new set of abundances, are listed in Tab. XXII, together with the uncertainty calculated with and without correlations.

b. Comparison with recommended values. The kinetic parameters obtained by summation calculations are compared with those recommended by the CRP in the 8-group model (see Section IX). The CRP recommended values consist of those recommended by WPEC-SG6 (2002) [14], except for the sets of abundances measured by IPPE after 2002 ([226, 228–230]) for which special recommendations are made in Section IX. The abundances (a_i) and decay-constants (λ_i) recommended by WPEC-SG6 (2002) were obtained from the expansion of

the 6-group parameter set measured by Keepin in 1957, to an 8-group parameter set [14]. In the framework of WPEC-SG6 [14], it also appeared convenient to fix the decay-constants for all fissioning systems in order to simplify the kinetic calculations involving more than one fissioning system.

Figures 46 to 49 show the comparison between measured and calculated kinetic parameters. Each figure refers to one group abundance and compares several fissioning systems and energies.

From the results it is evident that the calculated abundances are affected by larger uncertainties since they reflect the uncertainties in hundreds of microscopic parameters. The integral experiment does not consider the uncertainties in the microscopic data explicitly, but rather captures the global behavior, which leads to smaller uncertainties on the fitted abundances. Furthermore, the summation calculations have been performed starting from the independent fission yields, which - due to the complexity of the measurements - are affected by larger

FIG. 44. Thermal neutron-induced fission of 235 U. Left side: comparison of the integral delayed spectra in the time interval 4-44 s [243] with corresponding spectra calculated by means of the summation method using different sets of microscopic delayed neutron data. Right side: the integral delayed spectra in the time interval 0.12-1 s. The Greenwood *et al.* [17, 18] spectra are added to the ENDF/B-VII.1 data base [24] (irradiation time of experiments - 20 s).

uncertainties than the cumulative fission yields. The comparison with the experimental values unveils some patterns between calculated and measured parameters. Depending on the group, the calculated a_i is either overestimated or underestimated, and this is true independently of the fissioning system or of the energy. The first abundance is fairly well estimated. The values are very close with the recommended data and the uncertainty ranges overlap (see Fig. 46). This is true for all fissioning system and all energies, suggesting that the long-lived precursors, such as ⁸⁷Br and ⁹¹Rb, are well identified and their data are well known. The CRP+ENDF/B-VIII.0 database gives a slightly smaller a_1 than ENDF/B-VIII.0, because the P_n of ⁹¹Rb has been set to zero. The reason is that its $Q_{\beta n}$ happens to be very small and experimental values are still preliminary (see Table XXIII). On the other hand, the ENDF/B-VIII.0 value is adopted from systematics [129].

The second abundance, which should only include ¹³⁷I and ¹⁴¹Cs, is very well estimated for the fast fission of ²³²Th, while it is badly estimated for the fast fission of ²³³U. For the rest of the fissioning systems and energies, the calculated values always agree with the experimental a_2 within the range of uncertainty. In some cases, ENDF/B-VIII.0 is closer to the recommended value than CRP+ENDF/B-VIII.0 (²³⁵U_t, ²³⁸U_f, ²³⁷Np_f, ²³⁹Pu_t, ²⁴¹Pu_f). In other cases, however, it is the other way around (²³⁵U_f, ²³⁶U_f, ²³⁹Pu_f). The CRP+ENDF/B-VIII.0 value, due to the fact that the P_n value for ¹³⁷I has been increased from 0.0714 to 0.0765 (see Table XXIV). It is evident though, that both libraries slightly underestimate a_2 . This may indicate that a revision of the microscopic data of ¹⁴¹Cs and ¹³⁷I is needed or that the

fission yields need to be investigated.

The third abundance, which should only include 136 Te and 88 Br, is very well estimated for the thermal fission of 235 U and the fast fission of 241 Pu, while it is badly estimated for the fast fission of 232 Th. For the rest of the fissioning systems, it seems that the ENDF/B-VIII.0

 a_3 values are always closer to the experimental values than the CRP. The differences between the two libraries are reported in Tab. XXV and concern the ¹³⁶Te half-life and ⁸⁸Br branching ratio P_n . However, for both libraries, the general trend is a slight underestimation of a_3 with respect to experiments.

Both ENDF/B-VIII.0 and CRP+ENDF/B-VIII.0 converge towards the same largely underestimated a_4 . The only actinides for which the parameter is fairly well estimated are 232 Th_f, 235 U_f, 238 U_f and 241 Pu_f. On the other hand, 235 U_t, 236 U_f, and 237 Np_f are very far from the recommended values.

Figures 48 and 49 show that the estimation of the

short-lived precursors' abundances needs improvement. The fifth abundance which includes precursors 94 Rb, 139 I, 85 As and 98m Y, is systematically overestimated with the exception of some isolated cases (238 U_f and 232 Th_f). On the other hand, the seventh abundance, which involves 91 Br and 95 Rb, is systematically underestimated, with the exception of 236 U_f and 237 Np_f. The sixth and eight abundances do not follow any specific pattern. It should be stressed that these results and conclusions are dependent upon the FY dat used to calculate the DN activity, and could be different if a different FY library was adopted.

FIG. 48. Fifth and Sixth group abundance for several fissioning systems and energies. Comparison between summation calculation results and recommended values. The uncertainty in the calculated abundances is obtained through an analytical marginalization technique.

c. Effect of the abundances set on the quantities of *interest.* In this paragraph, the effect of the abundances sets on quantities of interest, such as the mean delayed neutron half-life and the delayed neutron activity, is discussed. Table XXVI shows the average half-life values $\langle T \rangle$ computed using different sets of DN abundances. In particular, $\langle T \rangle$ values obtained using ENDF/B-VIII.0 and CRP+ENDF/B-VIII.0 decay data are compared with recommended values for the fast neutron-induced fission of ²³³U, ²³⁵U, ²³⁹Pu and the thermal-induced fission of ²³⁵U, ²³⁹Pu. The average half-life of DN precursors obtained by summation calculations has larger uncertainties than the recommended ones, due to the marginalization of hundreds of microscopic input data. Correlations have negligible effect on the uncertainty since they account for approximately 1% of the total uncertainty. The mean half-lives for ²³⁹Pu (thermal), ²³⁵U (thermal) and ²³⁸U (fast) are well estimated. On the other hand, the results for ²³³U (fast) and ²³²Th (fast) deviate from the measured values therefore the relevant microscopic nuclear data require significant improvement. For the other isotopes and energies, the results are rather satisfactory,

FIG. 49. Seventh and Eight group abundance for several fissioning systems and energies. Comparison between summation calculation results and recommended values. The uncertainty in the calculated abundances is obtained through an analytical marginalization technique.

even though further work is needed to reduce the observed disagreement with recommended data.

TABLE XXVI. Average half-lives $\langle T\rangle$ and uncertainties compared with measured values for fast (f) and thermal (t) neutron-induced fission of minor and major actinides presented in Tables XXXVII-XXXVIII.

Nuclide	CRP+ENDF/B-VIII.0	ENDF/B-VIII.0	Measured
${}^{233}U_{f}$	10.44 ± 0.87	10.74 ± 0.89	12.50 ± 0.20

${}^{235}U_{f}$	8.42 ± 0.54	8.57 ± 0.55	8.96 ± 0.06
239 Pu _t	10.68 ± 0.96	10.59 ± 0.96	10.59 ± 0.17
239 Pu _f	9.16 ± 0.84	9.24 ± 0.85	10.27 ± 0.13

Figure 50 shows the DN activity obtained using the calculated set of a_i versus the delayed neutron activity obtained using the measured set of a_i . The plotted quantity is the ratio of the two activities. The graph is composed of several curves, each representing a different fissioning system or a different incident neutron energy. The behavior of the ratio reflects the differences in the group abundances. The recommended set of abundances is expected to reproduce the measured DN activity fairly well, so the comparison with the calculated one reflects the quality of the nuclear data. From the figure, it appears that, with the current microscopic data, it is possible to perfectly estimate the DN activity for the thermal fission of 235 U. The same is not true for other fissioning systems or energies, where the discrepancies can reach up to 20% (see 232 Th_f or 241 Pu_f). Since the activity is represented by a sum of exponentials of the abundances, it is expected to be highly sensitive to small variations in the abundances. The asymptotic value of the ratio between the activities is directly linked to a_1 , which is, in principle, fairly well estimated. As far as ²⁴¹Pu_f is concerned, the calculated a_1 is 0.013, while the recommended one is 0.016. Such a small difference is responsible for the 20% difference in the DN activity.

To conclude, in this section we attempted to verify the quality of the new microscopic CRP data $(T_{1/2}, P_n)$ by extracting 8-group parameters (a_i, λ_i) from the DN activity obtained from summation calculations over these data. The first abundance is fairly well estimated for all fissioning systems and energies, while the others depend strongly on the case under investigation. A pattern seems to emerge in the systematic overestimation of a_5 and underestimation of a_7 , implying that precursors belonging to the fifth (⁹⁴Rb, ¹³⁹I, ⁸⁵As and ^{98m}Y) and seventh group $(^{91}Br \text{ and } ^{95}Rb)$ may need to be revisited. Abundance correlation matrices have been obtained and used in the estimation of the uncertainty of quantities of interest, like $\langle T \rangle$. Although the correlations appear to be weak, their consideration in the estimation of the total uncertainty of $\langle T \rangle$ is important. In spite of the discrepancies observed between calculated and measured a_i , the average half-lives are comparable while the large underestimation obtained for ²³³U (fast) and ²³⁹Pu (fast) suggests that too much weight is assigned to short-lived precursors in the fast neutron-induced fission. As far as the DN activity is concerned, the current microscopic data are not able to reproduce the experimental curve for all fissioning systems and energies. Figure 50 shows that the discrepancy can reach $\pm 20\%$ for 241 Pu_f and 233 U_f, while 235 U_t is perfectly reproduced. One should bear in mind though, that the reactivity, which is the quantity of interest for reactor physicists, is less sensitive to the abundances than the activity. Therefore, a 20% discrepancy in the DN activity does not necessarily translate into a similar discrepancy in the reactivity. Rather, 300 s after irradiation, the latter has a tendency to depend on the mean half-life of the precursors.

On the other hand, one should bear in mind that the results for the time-dependent parameters depend not only on the microscopic decay data but also on the FY library that was used. Therefore, apart from revisiting certain decay data $(T_{1/2}, P_n)$ as suggested from the comparison of abundances, it is also crucial to review and improve the

FIG. 50. Delayed neutron activity ratio for several fissioning systems and energies. The CRP activity has been computed using the abundances derived from the summation calculation using CRP decay data $(T_{1/2}, P_n)$. The Recommended activity has been obtained by using the recommended sets of abundances.

existing evaluated FY libraries before any final conclusion can be drawn on the CRP β -delayed neutron emission data.

VII. INTEGRAL CALCULATIONS

In Sect. VI, summation calculations were used to determine the total delayed neutron yields from fission as a function of the incident neutron energy $\nu_d(\mathbf{E})$. Moreover, they were used to check the consistency of the new $(T_{1/2}, P_n)$ data through systematic comparisons with recommended values. In this section, we attempt to validate the new CRP $(T_{1/2}, P_n)$ data by studying their impact on specific reactor designs and comparing their results against well-measured benchmark experiments.

A. Comparison with integral experiments

The first step in the comparison with integral experiments was to perform summation calculations of $\nu_d(E)$ using the following combinations of input data from ENDF/B-VIII.0 [25] and JEFF-3.3 [29] evaluated nuclear data libraries, and the new CRP P_n tables: i) fission yields and decay data from the same nuclear data library (v01); ii) fission yields from nuclear data libraries and CRP P_n values complemented with decay data from the same library (v02); iii) JEFF-3.3 fission yields and decay data form ENDF/B-VIII.0 (v03); and iv) JEFF-3.3 fission yields and CRP P_n values complemented with data from ENDF/B-VIII.0 decay library (v04) which is identical to CRP+ENDF/B-VIII.0 from the previous sections. In the following, these calculated ν_d values will be referred to as *modified* ν_d , while the recommended ν_d contained in the evaluated nuclear data libraries will be referred to as *recommended*. Differences between 5% and 10% can be found between recommended JEFF-3.3 and ENDF/B-VIII.0 ν_d values. Furthermore, recommended ν_d and modified ν_d values differ by up to 70% in some cases. An example of this behaviour can be seen in Figure 51 for ²³⁵U.

To validate the CRP $(T_{1/2}, P_n)$ data, the ν_d values obtained from the above-mentioned summation calculations have been used in simulations of integral experiments from the International Criticality Safety Benchmark Evaluation Project (ICSBEP) Handbook [276] using the MCNP 6.1.1 code [277]. Integral benchmarks consist of extensively peer-reviewed data that can be used by the international nuclear data community for testing and improvement of nuclear data files. They are also used by the international reactor physics, criticality safety, and math & computation communities for validation of analytical methodologies used for reactor physics, fuel cycle, nuclear facility safety analysis and design, and advanced modeling and simulation efforts [278].

For our purposes, we have chosen 9 integral experiments with available measured effective delayed neutron fraction β_{eff} : POPSY, TOPSY, JEZEBEL, SKI-DOO and FLATTOP-23, which all have a simple spher-

FIG. 51. Comparison between recommended and modified delayed neutron yields for 235 U.

ical geometry; and in addition, BIG TEN, SNEAK-7A, SNEAK-7B and IPEN, all of which have a reactor-type configuration. The IPEN integral experiment is the only one based on a thermal spectrum, whereas the rest of them are fast spectrum systems.

According to Keepin [279], the effective delayed neutron fraction is defined as the ratio between the adjoint weighted delayed $(P_{d,eff})$ and total (P_{eff}) neutron production:

$$\beta_{eff} = \frac{P_{d,eff}}{P_{eff}} \tag{29}$$

with:

$$P_{eff} = \int \phi^*(\vec{r}, E', \Omega') \chi(E') \nu(E) \Sigma_f(\vec{r}, E) \phi(\vec{r}, E, \Omega) \delta E \delta \Omega \delta E' \delta \Omega' \delta \vec{r}$$
(30)

$$P_{d,eff} = \int \phi^*(\vec{r}, E', \Omega') \chi_d(E') \nu_d(E) \Sigma_f(\vec{r}, E)$$

$$\phi(\vec{r}, E, \Omega) \delta E \delta \Omega \delta E' \delta \Omega' \delta \vec{r}$$
(31)

where $\phi(\vec{r}, E, \Omega)$ and $\phi^*(\vec{r}, E', \Omega')$ are the direct and adjoint angular fluxes, $\chi(E')$ is the energy spectrum of the generated fission neutrons, $\nu(E)$ is the average neutron multiplicity per fission. Correspondingly, $\chi_d(E')$ and $\nu_d(E)$ are the same quantities but for delayed neutrons and $\Sigma_f(\vec{r}, E)$ is the macroscopic fission cross section of the material. β_{eff} has been selected as reference integral parameter since the sensitivity of β_{eff} to changes in delayed neutron data is significantly greater than to other data [280].

A sensitivity analysis was carried out first with the SUMMON [281] code to identify the main fissioning systems contributing to β_{eff} in each integral experiment.

FIG. 52. C/E comparison with the recommended and modified ν_d values from ENDF/B-VIII.0 (top) and JEFF-3.3 (bottom) for the 9 integral experiments.

The results are presented in Table XXVII. Although some experiments are characterized by a major contribution to β_{eff} coming from a single isotope, such as JEZEBEL, in others such as BIG TEN, we observe nearly equal contributions coming from two isotopes. In the latter case, it is difficult to assess the impact of ν_d changes in β_{eff} due to compensation effects.

The next step was to perform the simulations using an adequate number of particle histories to achieve negligible statistical uncertainties (< 2 pcm) in β_{eff} . The results of the simulations are shown in Fig. 52, where the top x-axis shows the isotopes which are the main contributors to β_{eff} for each integral experiment (see Table XXVII).

The β_{eff} results obtained with the recommended ENDF/B-VIII.0 ν_d values are in reasonable agreement with the experiments. Good agreement is also observed for the recommended JEFF-3.3 ν_d values. Regarding the DN yields obtained from the summation calculations, the v01 values obtained from JEFF-3.3 severely underestimate β_{eff} in most of the cases. Since this is the only

Integral exp.	Relative contribution to β_{eff}	Brief description

TABLE XXVII. Relative contributions of main isotopes to the β_{eff} for every integral experiment.

combination of JEFF-3.3 FYs that gives such large deviations, it is very likely that the source of these deviations is the JEFF-3.3 decay data library. On the contrary, the v01 values derived from ENDF/B-VIII.0 agree with six out of the nine experimental results. In the remaining three cases, which are the ones where the main contributor to β_{eff} is ²³⁵U, an overestimation is observed. Of all the summation combinations using ENDF/B-III.0 libraries, v02 and v03 which use ENDF/B-VIII.0 FYs are the most discrepant, so it is most likely that the latter ENDF/B-VIII.0 FYs do not perform that well. The combination of fission yields from JEFF-3.3 and decay data from ENDF/B-VIII.0 (v03) gives overall good agreement with the experimental results which is comparable to the recommended data. Finally, when the ENDF/B-VIII.0 decay P_n data in v03 are replaced by the new CRP P_n data to form v04, the agreement is not improved instead it is slightly worsened as we observe an increase in the respective β_{eff} . Overall, we find that the CRP P_n data lead to an increase in β_{eff} with respect to the β_{eff} obtained when using the two other decay data libraries. Note that the modified decay-data libraries (v03) and (v04) give different results when used with ENDF/B-VIII.0 and JEFF-3.3 cross-section libraries, as seen in the upper and lower panels of Fig. 52, respectively.

_

We have shown that the summation technique is a useful tool for calculating ν_d values that can reproduce reactor parameters with acceptable accuracy. This is particularly relevant for the minor actinides, for which no experimental fission pulse data are available, but for which fission yields and decay data are available. On the other hand, the use of the new CRP data in integral calculations results in increased values of β_{eff} , at least for the 9 benchmark experiments studied herein. These results agree with the findings of the previous section (Sect. ??) and confirm the need to investigate the evaluated fission yield libraries before conclusions are drawn with respect to the β -delayed neutron data.

B. Impact on reactor calculations

The impact of the new CRP data on reactor calculations has also been assessed by performing two different analyses described in this section.

a. Analysis I. A pressurized water reactor (PWR) and two GEN-IV fast reactor concepts have been selected in this first analysis: a pin design (with reflective boundary surfaces) representative of the Obrigheim PWR [282], the sodium cooled ASTRID (Advanced Sodium Technological Reactor for Industrial Demonstration) reactor [283] and the lead-bismuth cooled MYRRHA (Multipurpose hYbrid Research Reactor for High-tech Applications) reactor [284].

Calculations of β_{eff} were performed using the modified libraries (v01-v04), as well as recommended libraries, described in Sect. VII. Results from these calculations are presented in Table XXVIII, where statistical uncertainties of the order of 4% in β_{eff} have been neglected. The β_{eff} values obtained with the modified libraries deviate from those obtained using the recommended ν_d data by up to $\sim 10\%$ in ASTRID and MYRRHA for both ENDF/B-VIII.0 and JEFF-3.3 libraries. This is in agreement with the differences observed in the integral experiment calculations presented in the previous Sect. VII. Regarding the PWR model, for JEFF-3.3 the largest difference observed is again $\sim 10\%$, however in the ENDF/B-VIII.0 cases the deviations are larger by up to $\sim 44\%$ (v02). This result agrees with the findings for the Ipen experiment (the only one with thermal spectrum) discussed in the previous section which showed larger deviations with respect to the recommended values when using the ENDF/B-VIII.0 library combinations.

To conclude, similar to the results of β_{eff} obtained in the previous section, we find that the best combination of input data is v03 with JEFF-3.1.1 FYs and ENDF/B-VIII.0 decay data. When the ENDF/B-VIII.0 P_n data are replaced with the CRP values (v04), the agreement is slightly worsened except for one case, the PWR JEFF-3.1.1 recommended value. The deviations with respect to recommended data increase when the ENDF/B-VIII.0 FY library or the JEFF-3.1.1 decay data library is used in the combination.

b. Analysis II. In the second analysis, a Sodium Fast Breeder reactor (FBR) model has been used to compute the β_{eff} with MCNPX2.6.f coupled to an evolution code within the MCNP Utility for Reactor Evolution (MURE) software [274]. The model is extracted from [285] and the simulation has been originally developed for the study

TABLE XXVIII. Calculated effective delayed neutron fraction values for PWR, ASTRID and MYRRHA reactors using recommended and modified libraries.

of the anti-neutrino emission from a sodium FBR (Na-FBR). Several versions of the model associated with various fuel compositions were used. The detailed description of the model can be found in [286], here we present only the information necessary for understanding the present results.

In the FBR model, a central zone corresponds to the internal core, which is enriched at 21% in plutonium, while the external core is enriched at 28% in plutonium, while axial and radial blankets surround the core. A set of assemblies made of stainless steel surrounds the whole configuration, acting as a reflector.

The core composition in its internal and external parts is given in Table XXIX. The isotopic plutonium vector corresponds to that of the Monju reactor [286]. This Mixed Oxide fuel (MOX) has a density of $11 g/cm^3$.

TABLE XXIX. Fuel composition in the internal and external cores of the sodium Fast Breeder model reactor (FBR) which are enriched by 21% and 28% in plutonium, respectively.

Isotope	Internal Core	External core

typical for transmutation. 79% of depleted uranium extracted from CANDU used fuel and 21% of actinides are mixed according to the table XXX.

With regards to the depleted uranium composition, the isotopic composition of a depleted plutonium/uranium vector extracted from a CANDU reactor at 6.7GWd/t was used as simulated. This composition does not account for the decay of ²⁴¹Pu of half-life 14.33 yrs [28]. The fuel temperature is 1500 K.

A Protected-Plutonium-Production version of the fuel composition has been used as well (called "Fuel 2"), in which a significant fraction of ²³⁸Pu is added to the plutonium vector in order to prevent fuel diversion. The fission rates associated with the two fuel compositions are displayed in table XXXI.

The β_{eff} was extracted at the beginning of the cycle. Two methods were used. In the first method, β_{eff} was extracted using the fission rate of each actinide obtained from the reactor model combined with the recommended delayed and total neutron fractions $\nu_{t,d}$ from the JEFF3.1 database [28]. In the second method, the summation method was used, whereby the fission product activities obtained in the various simulations using JEFF-3.1.1 fission yields and JEFF-3.1 decay data were coupled to the new CRP P_n data.

Table XXXI shows the results of the computed β_{eff} as a function of the loaded fuel.

The β_{eff} values obtained with both methods are displayed in the two bottom lines of Table XXXI. One can see that the CRP results are in very good quantitative agreement with the results using recommended JEFF-3.1.1 ν_d values for both fuels, with a difference of less than 10 pcm. The β_{eff} value obtained for fuel 1 is larger than for fuel 2 because of the larger fission rate of ^{239}Pu in the former fuel compared to the latter. This is due to the added fraction of ^{238}Pu in fuel 2, which has a very low ν_d .

The results confirm the findings of Analysis I showing

TABLE XXXI. Fission rates at the beginning of the cycle corresponding to the two fuels loaded in the FBR model, and corresponding β_{eff} (pcm) obtained with the recommended JEFF-3.1 decay data (JEFF) and the CRP P_n data.

that the combination of JEFF-3.1.1 FYs with the CRP P_n data yields overall good results for β_{eff} which are comparable to the recommended values. However, there is an obvious trend that has been observed in all the previous integral calculations, and that is that the CRP P_n data yield larger ν_d values and subsequently, larger β_{eff} values. Possible culprits for this increase have been suggested to be ¹³⁷I and ⁹¹Br based on the comparison of the corresponding P_n data in Sect. VIB1. However, due to compensation effects from the variations of P_n values of several important contributors and the dependence of these results on the fission yield library used in the summation calculations, it is not straightforward to draw a definitive conclusion on the impact of the new CRP data.

VIII. SYSTEMATICS OF MACROSCOPIC DATA: TIME-DEPENDENT PARAMETERS

A. New approach for estimation of temporary parameters for unmeasured nuclides

The systematics of the delayed neutron (DN) characteristics and their correlation properties gives valuable information for developing a reliable database of DN data. The total delayed neutron yields ν_d are represented by an exponential function of the parameters involving the mass A_c and the atomic numbers Z of the compound fissioning nucleus (A_c, Z) [227]. Moscati and Goldemberg [287] proposed the $exp [-K \cdot (2 \cdot Z - N)]$ dependence which was modified to $exp [-K \cdot (3 \cdot Z - A_c)]$ by Caldwell and Dowdy [288] and then investigated in detail by Pai [289], Waldo and co-workers [207] and Ronen [290]. The parameterization $-(A_c - 3 \cdot Z) \cdot (A_c/Z)$ has been used by Tuttle [249] along with the experimental data in the evaluation of the total DN yields for the isotopes ²³¹Pa, ²³⁴U, ²³⁶U, ²³⁸Pu, ²⁴⁰Pu, ²⁴¹Pu and ²⁴²Pu. The systematics of the temporal DN parameters became possible after introducing in practice the value of the average half-life $\langle T \rangle$ of DN precursors [227]. The $\langle T \rangle$ value can be calculated using expression

$$T\rangle = \sum_{i=1}^{N} a_i \cdot T_i, \sum_{i=1}^{N} a_i = 1,$$
 (32)

where a_i and T_i is the relative abundance and the halflife of the *i*-th DN group, respectively; N the number of DN groups. When calculating this value on the basis of the microscopic DN data and fission yield data the following expression is used

(

$$\langle T \rangle = \frac{\sum_{i=1}^{N} CY_i \cdot P_{ni} \cdot T_{1/2i}}{\sum_{i=1}^{N} CY_i \cdot P_{ni}},$$
(33)

where CY_i is the cumulative yield of the i-th DN precursor; P_{ni} and $T_{1/2i}$ the probability of DN emission and the half-life of the i-th DN precursor, respectively.

It turns out that the $\langle T \rangle$ data for the isotopes of one element can be systematized with the help of the exponential dependence using the Tuttle's parameter - $-(A_c - 3 \cdot Z)/(A_c/Z)$, where A_c and Z is the mass and the atomic numbers of the fissioning compound nucleus, respectively [227]. Furthermore it was found that the total DN yields ν_d and the average half-life values $\langle T \rangle$ for isotopes of one element are related to each other by the dependence $\nu_d = a \cdot \langle T \rangle^b$, a and b being constants. These findings made it possible to show that the exponential dependence of the ν_d value on the parameter $-(A_c - 3 \cdot Z) \cdot (A_c/Z)$ has essentially an isotopic character [227]. This means that isotopes of each fissionable element have their own dependence of ν_d on the parameter $-(A_c - 3 \cdot Z) \cdot (A_c/Z)$ that must be taken into account in the evaluation process especially for the nuclei lying far from the valley of β -stability. The properties of the systematic $-(A_c - 3 \cdot Z) \cdot (A_c/Z)$ both for the total DN yields and the average half-life of DN precursors are discussed in detail in [227]. The systematics of the average half-life of DN precursors is useful for the validation of the DN group parameters for the isotopes of Th, U, Pu and Am and the prediction of the average half life of unmeasured isotopes of these elements. But unlike the $-(A_c - 3 \cdot Z) \cdot (A_c/Z)$ systematics of the total DN yield, this systematics does not allow us to predict the average half-life of DN precursors $\langle T \rangle$ for isotopes of such elements as Pa, Cm, Cf and others. Below a new approach for the prediction of the average half-life of DN precursors and the appropri-

FIG. 53. The systematics $(A_c/Z) \cdot 92$ of the average half-life of DN precursors. The solid line is the approximation of the average half-life by expression $\langle T \rangle = \exp\left[a + b \cdot (A_c/Z) \cdot 92\right]$. The average half-life values $\langle T \rangle$ were taken from the recommended data sets (a_i, T_i) [225].

ate set of relative abundances and periods of individual DN groups for unmeasured nuclides is considered.

B. The $(A_c/Z) \cdot 92$ systematics of the average half-life

It has been shown in [255] that the average half-life of the DN precursors of all isotopes of heavy nuclides measured in the fast neutron induced fission can be approximated by the expression $\langle T \rangle = exp \left[a + b \cdot (A_c/Z) \cdot 92 \right]$, where A_c and Z is the mass and the atomic numbers of the fissioning compound nucleus, respectively. As compared with the systematics $-(A_c - 3 \cdot Z) \cdot A_c/Z$ [227], which is valid for isotopes of one element, the systematics $(A_c/Z) \cdot 92$ allows to predict the average half-life for isotopes of all elements with the help of the only one set of constants a and b. In Fig. 53 the values of the average half-life calculated on the basis of the recommended experimental data (a_i, T_i) for the fast neutron induced fission of U, Pu, Am, Np and Th isotopes [225] are shown by separate points. The solid line is the approximation of these data by the dependence $\langle T \rangle = exp [a + b \cdot (A_c/Z) \cdot 92], \text{ where } a = 41.371 \pm 1.042,$ $b = -0.166 \pm 0.004$. This dependence can be used for the prediction of the average half-life of Pa, Cm, Bk, Cf, etc., isotopes. It should be noted that the observed $\langle T \rangle$ dependence has a fine structure that is due to the differences in the dependences observed for U, Pu, and Am elements. So for example the coefficients a and b for the $\langle T \rangle = exp \left[a + b \cdot (A_c/Z) \cdot 92 \right]$ dependence for uranium isotopes are 41.219 ± 1.072 and -0.165 ± 0.005 , respectively.

C. Systematics $(A_c - 2 \cdot Z)$ of relative abundances in the 8-group model

In practice, the time parameters of DN are represented by such characteristics as the relative yields and the periods of individual DN groups. Therefore, the development of the systematics of the relative yields and periods of DN for individual groups is required. This task cannot be performed using the 6-group model, because of the strong correlation of the periods and the relative abundances of DN. Until now the only method for prediction of the temporary characteristics (a_i, T_i) of DN was based on the summation calculations [187]. The 8-group model should be used for the systematics of the relative abundances because in this representation of the group parameters there is no correlation between the relative abundances and periods of DN, and the values of DN periods are universal for the isotopes of all the elements.

To estimate the relative abundances of delayed neutrons from the fast neutron induced fission of the uranium isotopes the parameter $(A_c - 2 \cdot Z)$ was used. In Figs. 54 and 55 the 8-group relative abundances of uranium isotopes $a_i \cdot (i = 1, ..., 8)$ are approximated by expression $a_i = exp [c_i + b_i \cdot (A_c - 2 \cdot Z)]$, where c_i, b_i are constants. These constants are estimated for each DN group and then the obtained dependences a_i have been used for the calculation of the relative abundances of all uranium isotopes including unmeasured uranium isotopes ²³⁴U and ²³⁷U. The results of this estimate are presented in Table XXXII.

It can be seen from Table XXXII that the average half-lives $\langle T \rangle$ obtained on the basis of the $(A_c - 2 \cdot Z)$ systematics agree both with the recommended data and the data calculated by the summation techniques with the exception of the value for ²³⁵U calculated with the help of the summation method [187]. These data are also presented in Fig. 56 from which one can see that the predicted values for ²³⁴U and ²³⁷U agree with the systematics $(A_c/Z) \cdot 92$.

From the present studies it may be concluded that both the $(A_c/Z) \cdot 92$ systematics of the average half-life of DN precursors and the $(A_c - 2 \cdot Z)$ systematics of the relative abundances a_i have a good predictive power and can be used for the prediction of the temporary DN parameters of unmeasured nuclides.

IX. RECOMMENDED DATA IN 6- AND 8-GROUP MODELS

In modern nuclear power development programs, priority is given to the development of new concepts of nuclear reactors characterized by a more stringent energy spectrum of neutrons, a complex composition of nuclear fuel, and the possibility of their use for transmutation of nuclear waste. Issues such as safety and efficient operation of reactors have increased the need for a reliable and complete set of nuclear physical constants used in reac-

tor practice, including the database on delayed neutrons (DN).

Since the latest recommendations by WPEC-SG6, i.e. the DN group parameters based on the experimental data presented in [224, 225], a number of measurements of the DN group parameters has been performed at IPPE (Obninsk) for neutron induced fission of uranium, plutonium, thorium, americium, and neptunium isotopes for neutron energies ranging from thermal to 18 MeV. The short review of these data can be found in Section V of this report. The compilation of these data is included in the database created within the IAEA Coordinated Research Project [41]. There is an increasing need for reliable DN data uncertainties, including information on the covariance matrix of the DN group parameters. The task of estimating the DN group parameters (the relative abundances a_i and the half-life T_i of their precursor) has become more pressing due to the availability of new experimental data and current trends in nuclear technologies.

In reactor physics practice two models of the DN group parameters are used: the unconstrained 6- and constrained 8-group model [224, 225]. In the former, the relative abundances a_i and the half-life T_i of the individual DN groups are obtained from analysis of the decay curves of the DN activity by the least-squares method (LSM) with 12 free parameters (a_i,T_i) [13, 226]. In the 8- group model the set of the group half-lives T_i is universal for all nuclides and primary neutron energies. The T_i values of this data set are presented in Table XXXIII.

The motivation for the development of the 8-group model and the resulting advantages, as compared with the 6-group model, are discussed in detail in [224, 225] and include: a significant reduction in the cross correlation of the DN group parameters, a more simple dynamic model for generating DN in a multi-component mixture of fissile nuclides, an improved procedure for the estimation of the DN group energy spectra and a better description of the relationship between reactivity and periods for negative values of reactivity. In the present evaluation the recommended sets of DN group parameters are given in 6- and 8-group representation for all nuclides under consideration.

Analysis of the relative abundances and half-lives a. of delayed neutrons. The selection of the DN decay curve and the corresponding set of the temporal DN parameters has been carried out on the basis of the time of the sample transfer from an irradiation position to the neutron detector, the time of recording the decay curve of DN neutron activity, the number of DN groups resolved in the experiment, the method for estimating the DN parameters (graphical or LSM), the uncertainties of the DN parameters, the consistency of the DN group parameters with the systematics of the average half-life of the DN precursors, and the energy dependence of the temporal DN parameters expressed in the average half-life of the DN precursors [224, 225]. In the present evaluation additional criteria were considered that allow making a wider analysis of the compared DN data: the ratio of the decay curves in the 6- and 8-group model to the corresponding recommended data and the quality of the expansion of the 6-group data into the 8-group model. When carrying out this analysis, it was assumed that the 6-group parameters reproduce the experimental DN decay curve more accurately in comparison to the 8-group representation. However, it should be borne in mind that this statement is only valid for the time interval in which these data were measured. In the overwhelming number of experiments this interval did not exceed 500 s [248]. The aggregate DN curve for each DN data set (a_i, T_i) was modeled in the range 0-724 s using expression

$$N(t) = A \cdot \sum_{i=1}^{m} (1 - e^{-\lambda_i \cdot t_{irr}}) \cdot a_i \cdot e^{-\lambda \cdot t}, \qquad (34)$$

where A is the saturation activity, t_{irr} the irradiation time (300 s), (a_i, λ_i) the relative abundance and the decay constant of the *i*-th DN group, *m* the number of DN groups. The DN data sets $(a_i, T_i = ln2/\lambda_i)$ were taken from the compilation by Spriggs and Campbell [248]. The 8-group data sets were taken from the evaluation by Spriggs *et al.* [224, 225] with the exception of the 8group data sets from the IPPE data obtained after 2002

TABLE XXXIII. Consistent set of half-lives T_i in the 8-group model.

Group number	1	2	3	4	5	6	7	8
Half-life T_i (s)	55.6	24.50	16.30	5.21	2.37	1.039	0.424	0.195

TABLE XXXIV. Average half-life of DN precursors $\langle T \rangle$ and half-life of the first group of DN T_1 in [s] from fission of ²³³U, ²³⁵U and ²³⁹Pu. F is for fast incident neutrons and T for thermal incident neutrons.

Target		T_1	$\langle T \rangle$	T_1	$\langle T \rangle$
		[1	[3]	[226]	, 230]
$^{233}\mathrm{U}$	F	55.11 ± 1.86	$12.38 {\pm} 0.40$	$54.55 {\pm} 0.38$	$12.50 {\pm} 0.20$
	Т	$55.00 {\pm} 0.54$	$12.80{\pm}0.38$	$54.64 {\pm} 0.19$	$12.69 {\pm} 0.11$
^{235}U	\mathbf{F}	54.51 ± 0.94	$8.82 {\pm} 0.25$	$54.90 {\pm} 0.15$	$8.96 {\pm} 0.06$
	Т	54.72 ± 1.28	$9.03 {\pm} 0.34$	$53.95 {\pm} 0.28$	$8.98 {\pm} 0.11$
239 Pu	\mathbf{F}	$53.75 {\pm} 0.95$	$10.16 {\pm} 0.24$	$53.81 {\pm} 0.41$	$10.27 {\pm} 0.13$
	Т	54.28 ± 2.34	$10.70 {\pm} 1.11$	$53.1 {\pm} 0.46$	$10.59 {\pm} 0.17$

which are not included in the evaluation by Spriggs *et al.* [225]. A procedure used for the selection of the DN group data is shown in the example of the DN data sets measured from the thermal and fast neutron induced fission of 233 U, 235 U and 239 Pu. The DN decay curves of different authors $N_6(t)$ are presented as the ratio to the corresponding DN decay curves calculated using the DN sets (a_i, T_i) from the Keepin data $N_{6(K)}(t)$ [13]. The obtained data are shown in Figs. 57 and 58.

In the interval 0-500 s, the IPPE data [226, 230, 232, 235, 250] show the smallest discrepancy with Keepin's data [13]. The difference between these data does not exceed 5% for all fissioning systems with the exception of the thermal neutron induced fission of ²³⁹Pu. At the end of the considered interval ($\Delta t = 0.724$ s) this difference is increased and reaches 18% for the thermal neutron induced fission of ²³⁹Pu. The observed difference between decay curves at the end of the considered interval is mainly caused by the differences between the half-life values of the 1-st DN groups. The half-life values of the 1-st DN group T_1 and the average half-life of DN precursors $\langle T \rangle$ for fission of ²³³U, ²³⁵U and ²³⁹Pu are presented in Table XXXIV for both the IPPE and the Keepin data [13]. Table XXXIV shows that for all fissioning systems the T_1 values in the Keepin data are systematically lower than the corresponding values of the IPPE data sets. One of the reasons for this may be related to the averaging procedure used for the estimation of DN parameters on the basis of different experimental runs which does not take into account the correlation between DN parameters. The second reason for the difference in the T_1 values is related to the different time intervals in which the DN curves were measured. The IPPE temporary DN parameters have been estimated on the basis of the experimental data measured in the extended time interval (0.12-724 s) [222] while in Keepin's experiment this interval was 500 s. In addition a new averaging procedure for data sets (a_i, T_i) measured in different experimental runs has been developed at the IPPE that accounts for a correlation property of DN group parameters [226, 235].

As mentioned above the measurements of the DN decay curves in [13] have been carried out during 500 s after the end of irradiation while in [222, 226] this interval is much wider - 724 s. Consequently, the comparison of DN data in the region t > 500 s is not entirely correct since the Keepin data and data of other authors (with a few exceptions) in this region have been *extrapolated* because the shape of the DN decay curve here is mainly determined by the half-life of the 1-st DN group obtained from data in the range of t < 500 s. In addition, the comparison of the uncertainty of the DN parameters of the 1-st DN group obtained in [13] and [226, 230] shows that the IPPE data have better statistical accuracy and. most likely, better background conditions. To study the influence of interval width used for DN counting on the estimate of the half-life value of the 1-st DN group, the experimental DN decay curves from the IPPE data [226, 230, 255] measured in separate measurement runs from fission of ²³⁵U, ²³⁸U and ²³²Th by fast neutrons have been analyzed in the time intervals 224-714 s, 300-714 s and 400-714 s in the frame of a single-group approximation. The results are shown in Table XXXV.

It can be seen from Table XXXV that the value for all nuclides in the interval 224 - 724 s is lower than the halflife of ⁸⁷Br ($T_{1/2} = 55.6$ s) which can be explained by the contribution of ¹³⁷I ($T_{1/2} = 24.5$ s) to the aggregate DN decay curve. In the interval 300-724 s the values of the half-life are comparable with the half-life of ⁸⁷Br which implies a small contribution of 137 I activity which in turn means that the $T_{1/2}$ value reaches its asymptotic value. The $T_{1/2}$ value in the interval 400-724 s has large uncertainties because of the low statistics at the end of the decay curve. The results show that the half-life value of the 1-st DN group obtained by the LSM using the 6-group model, can differ significantly from the ⁸⁷Br half-life (see the data for 238 U in Table XXXV) in spite of the fact that single-group processing of the experimental curve in the interval 300-724 s gives a value close to the half-life of 87 Br - 55.41 ± 1.65 s. Thus, the value of the parameters of the 1-st DN group obtained in the measurements of the DN decay curves is determined not only by the time interval in which the measurements are performed, but also by the peculiarities of the data processing procedure (LSM) and strong cross-correlation between group parameters as it has already been concluded by Spriggs et al. [224, 225]. In order to eliminate the disagreement in the DN decay curves in the range t > 400 s arising from the uncertainties in the parameters of the 1-st DN group observed in the 6-th group model one has to transfer 6-group data to the 8-group model. Figs. 59 and 60 show the ratio of the DN decay curves in the 8-th group representation from the IPPE data $N_8(t)$ to the corresponding Keepin 8-group data $N_{8(K)}(t)$ [13] for thermal and fast neutron induced fission of ²³³U, ²³⁵U and ²³⁹Pu.

It can be seen from Figs. 59 and 60 that the discrepancy between the Keepin and the IPPE data for all considered fissioning systems with the exception of the thermal neutron induced fission of 239 Pu significantly decreased and does not exceed 5% in the whole time interval 0-724 s. The residual difference in the shape of the DN decay curves is due to a distinction in the values of the relative abundances of the 1-st DN group a_1 .

FIG. 57. The ratio of the DN decay curves in the 6-group representation measured from fission of 233 U and 235 U by thermal and fast neutrons to the corresponding DN decay curve calculated using the (a_i,T_i) data sets from Keepin's data [13]. The data references can be taken from the compilation by Spriggs and Campbell [248] except for the data by Piksaikin *et al.* [226, 230, 235, 250]

TABLE XXXV. Half-lives of DN precursors obtained in different time intervals of DN decay curves for the fast neutron induced fission of 232 Th, 235 U, 238 U.

Target nuclides	Single-g	roup approx	imation	6-group approximation [13]	6-group approximation [226, 230, 255]						
	Ti	me interval	(s)	half-life of	half-life of						
	Ha	alf-life $T_{1/2}$ ((\mathbf{s})	1st DN group T_1	1st DN group T_1						
	224-724	300-724	400-724	Interval 0-500 s	Interval 0-724 s						
^{238}U	$50.72 {\pm} 0.59$	55.41 ± 1.65	57.51 ± 5.37	52.38 ± 1.29	$52.9 {\pm} 0.17$						
232 Th	$53.09 {\pm} 0.96$	54.17 ± 2.58	54.3 ± 10.32	$56.03 {\pm} 0.095$	55.42 ± 0.27						
²³⁵ U	$51.24 {\pm} 0.68$	54.02 ± 1.09	55.27 ± 3.22	$54.51 {\pm} 0.94$	54.9 ± 0.16						

This observation as well as the resulting similar values of the average half-life $\langle T \rangle$ (see Table XXXIV) can be considered as the confirmation of the agreement between the IPPE and Keepin data for the fission of 233 U and 235 U by thermal and fast neutrons and for the fission of 239 Pu by fast neutrons, if they are presented in the 8-th group model. Thus the data presented in Figs.59-60 demonstrate the advantage of the 8-th group model,

since it eliminates the discrepancies in the time range t >400 s associated with uncertainties in determining the parameters of the 1-st DN group within the framework of the 6-model. The divergence in case of the thermal neutron-induced fission of ²³⁹Pu is caused by a large difference in the relative abundances of the 1-st DN group $(a_1 = 0.038 \pm 0.003 \text{ and } 0.035 \pm 0.001 \text{ in the Keepin [13]}$ and the IPPE data [226] sets, respectively). This may be

FIG. 58. The ratio of the DN decay curves in the 6-group representation measured from the fission of ²³⁹Pu by thermal and fast neutrons to the corresponding DN decay curve calculated using the (a_i, T_i) data sets from Keepin's data [13]. The data references can be taken from the compilation by Spriggs and Campbell [248] except for the data by Piksaikin *et al.* [226, 230, 232, 235]

FIG. 59. The ratio of the DN decay curves in the 8-group representation from the IPPE data [226, 230, 235, 250] to the corresponding DN decay curve calculated by using the data sets (a_i,T_i) from the Keepin data [13] measured in the fission of ²³³U, ²³⁵U by thermal and fast neutrons.

connected to the poor statistics in Keepin's experiment which can be seen seen from the large uncertainties of the average half-life of DN precursors observed for the thermal neutron induced fission of ²³⁹Pu: $\langle T \rangle = 10.70 \pm 1.11$ s (see Table XXXIV).

b. Quality of the expansion method. Validation of the expansion methods [225, 226] used for the transfor-

mation of 6-group data to 8-group model data has been made on the basis of the ratio of the DN decay curve in the 8-group representation to the corresponding DN decay curve in the 6-group model. As a result of this comparison it has been shown that in the recommended DN data set [225] the 8-group expanded data and the corresponding original 6-group data set for the fast neutron

FIG. 60. The ratio of the DN decay curves in the 8-group representation from IPPE data [226, 230, 232, 235] to the corresponding DN decay curve calculated by using Keepin's data (a_i, T_i) [13] measured in the fission of ²³⁹Pu by thermal and fast neutrons.

induced fission of 238 U are not consistent. The 8-group data set for 238 U obtained on the basis of the IPPE data has been proposed as the recommended one.

c. High energy data. The IPPE measurements in the high energy range (14-18 MeV) have revealed the possible reasons for the large discrepancy observed in the delayed neutron temporary parameters: a deterioration of the counting property of the neutron detector in a high intensity neutron flux coming from the $T(d,n)^4$ He reaction [239] and the influence of a concomitant $D(d,n)^3$ He neutron source generated at an accelerator target in measurements using the $T(d,n)^4$ He reaction [238, 239]. At present, these data are only available in the 6-group representation. The expansion of these data to the 8-group model will be undertaken in the near future.

d. *Conclusion.* The efforts undertaken at IPPE for improving the experimental techniques and data processing procedures included the shortening of the transportation time, the extension of delayed neutron counting time, the exact determination of the incident neutron energy as well as a new approach for averaging the temporary DN parameters obtained in different experimental runs. As a result, the accuracy of the DN group parameters (a_i, T_i) was greatly improved. In general, these studies can be considered as the next step following the last evaluation by Spriggs *et al.* [225] in 2002 leading to the improvement of the macroscopic database of the relative abundances of delayed neutrons and half-lives of their precursors. The revisions introduced to the WPEC-SG6 recommended DN temporary data sets [225] are presented in Table XXXVI. A complete set of the present recommendations for thermal, fast and high energy fission are given in Tables XXXVII and XXXVIII. The relative abundances and half-lives of delayed neutrons are presented in the 6- and 8-group model representation with their uncertainties and the values of the average half-life. Information on correlations and covariance matrices can be found in the IAEA compilation database created under the CRP project [41]. The references for the original 6group data sets and the 8-group data sets can be found in the compilation by Spriggs and Campbell [248] and

X. REFERENCE DATABASE

All the compilations, evaluations, systematics as well as theoretical results and recommendations produced by the CRP are available on the online Reference Database for β -delayed neutron emission [43].

The database is split into two parts, the microscopic data and macroscopic data section. Each section contains a search engine that allows the user to search per nuclide, energy, and in the case of the microscopic database, also per ranges of half-lives $T_{1/2}$ and P_n values.

All the microscopic data, including compilations, comments, and evaluations can be downloaded as Excel spreadsheets while the theoretical results can be downloaded as '.csv' files. The final numerical file of microscopic $(T_{1/2}, P_n)$ values which is a computer readable file that has been especially prepared for use in summation calculations (Sect. VI) and other applications can also be downloaded as a '.csv' file. In the following, some special features of the two distinct microscopic and macroscopic sections are described.

A. Microscopic data

This database contains all the compiled and evaluated values of $T_{1/2}$ and P_n produced by the CRP evaluators and published in [35] (Z < 29) and [36] (Z > 28). The data are displayed in tabular form following the same nomenclature adopted in the respective published tables. In addition, the user can retrieve all the comments on the data and evaluation process which are not included in the published articles. The references of the compiled articles are given in terms of their NSR key-numbers which are also hyperlinked to the NSR database.

Beta-delayed neutron spectra are also included in the database. In cases where these data were published in graphical form only, the graphs were digitized and the numerical values were included in the database in simple ASCII files. This is a major development as prior to this CRP there was no database dedicated to a compilation of experimental delayed neutron spectra for individual precursors. The database includes all the graphical spectra published in the thesis of M. Brady in 1989 [31].

The complete microscopic data tables (compilation and evaluation separately) can be downloaded in the format they were published ([35, 36]), but also as pure numerical files which can be readily used in calculations. The spectra files can also be downloaded in a zipped file.

The systematics that were developed on the basis of the evaluated data of [35] and [36] (Sect. III D) are also available from the database: these use the empirical formula or approaches described in McCutchan *et al.* [129] and [130] but were adapted to the new evaluated data.

In addition to the compiled experimental and evaluated data, the online database contains theoretical $T_{1/2}$ and P_n values, for comparison. At present, the global calculations of Ref. [147] and [153] (see Sect. IV) have been included, while more models are planned to be made available in the near future.

The online interface provides a search tool which allows the user to search in terms of Z, N, A and ranges of halflives and P_n values. The result of the search can also be plotted. Different options for plotting are available (in terms of $T_{1/2}$, Q_{β} , $Q_{\beta n}$, P_n).

B. Macroscopic data

The macroscopic database includes three types of aggregate data:

a. Total delayed neutron yields. This part contains previous compilations of measured total delayed neutron yields published in [219–221, 263, 291], as well as new measurements performed by the IPPE group [230, 236, 259] (see Sect. VA). The data are accompanied by recommendations and comments on necessary adjustments to the data. The whole table including comments can be downloaded as a .csv file.

In addition to the experimental total delayed neutron yields, the user can also retrieve the respective recommended yields included in the various evaluated libraries such as ENDF/B-VII.1 [24], JEFF-3.1.1 [28] and JENDL-4.0 [258].

b. Time-dependent group parameters (a_i, T_i) . It includes a compilation of all the time-dependent group parameters measured over the past decades using 4-, 5-, 6-, 7- and 8-group models including the new measurements performed at IPPE [226, 239, 243] (see Sect. V and IX). In the case of the latter data, experimental covariance matrices revealing the correlations between the members *i* of the groups are also provided. The recommended group parameters of [225] are included as well as the recommended group-parameters adopted by the evaluated libraries (ENDF/B-VII.1 [24], JEFF-3.1.1 [28] and JENDL-4.0 [258]).

c. Composite delayed neutron spectra. A complete set of measured delayed neutron spectra obtained from Ref. [243] (see Sect. V) are contained in this part. The spectra can be downloaded in numerical tables. Plots comparing the measured spectra with results of the summation method using the newly evaluated P_n values are also available.

XI. SUMMARY AND CONCLUSIONS

In 2019 we celebrated the 80th anniversary of the discovery of β -delayed neutrons by Roberts *et al.* [1, 2]. The next generation of radioactive beam facilities that will become operational in the next years will allow the access of even more neutron-rich nuclei in the experimental "Terra Incognita". This will be a busy time for β -delayed neutron measurements since the vast majority of these 3000-4000 still-to-be-discovered nuclides will decay by β delayed neutron emission. However, the main driver for these new measurements are no longer fission reactors but the question how about half of the elements heavier than iron are created in explosive stellar events like the "rapid neutron capture (r) process" in core collapse supernova explosions and binary neutron star mergers [121].

The last decade has seen an increased interest in the measurement of individual nuclear decay properties of the most neutron-rich nuclei that can be produced. The need for more reliable data for r-process calculations is strongly intertwined with the better understanding of the evolution of single-particle and collective levels in neutron-rich matter.

Detection techniques have been developed and improved for operation at the next generation of radioactive beam facilities, and thoroughly used to map the existing β n-emitter landscape. Worldwide collaborative efforts have lead to the discovery of many new neutron-rich isotopes, and the measurement of their half-lives and neutron-branching ratios. The majority of these recent

Development of a Reference Database ... NUCLEAR DATA SHEETS

P. Dimitriou et al.

results has yet to be published, and then evaluated and included in the database.

The collaborative work performed under the auspices of the International Atomic Energy Agency (IAEA) was timely as it will not only guide future experiments on β n emitters but will also lead to more reliable calculations for *r*-process nucleosynthesis and the new generation of fission reactors.

A. Microscopic experiments

The members of the CRP assessed all methods for the measurement of half-lives, neutron-branching ratios, and neutron energy spectra, taking into account recent technological developments and the requirements for future measurements. The " β -n" method using the coincident detection of β 's and neutrons (and optional with subsequent detection of γ 's) was identified as the most reliable method for the measurement of neutron-branching ratios (see Sect. II A 1). If the decay scheme of a nucleus is well-known (including absolute decay intensities and isomeric states), also detection methods without neutrons can provide very reliable results, for example the coincident "Double γ counting method" (" γ , γ ", Sect. II A 6).

In the past years also new, pure ion-counting methods have been developed that circumvent the necessity to detect neutrons, β 's or γ 's. These experiments have been grouped in the "Double ion counting" method ("ion,ion", Sect. II A 8) and comprise techniques using various types of traps, time-projection chambers, or even storage rings (see Sect. II C)

Some of these new ion-counting techniques, namely the ion-recoil detection methods, can also be used to extract the respective neutron energy spectra. This has been shown recently for the Beta-decay Paul trap (BPT) where a good agreement with the measured spectrum for ¹³⁷I was found, although with limited resolution due to the trap geometry.

Besides traditional techniques the neutron time-offlight (TOF) method with fast plastic or liquid scintillators has shown to be the best method to measure the neutron energy spectra. Thanks to their relatively high intrinsic efficiency they can be also employed for the measurement of rare isotopes but their limitation is the achievable resolution at higher neutron energies (>3 MeV).

Total Absorption γ -ray Spectrometers (TAGS) have been used since many years to measure β - and γ -strength functions, as well as level densities. More recently it has been shown that they can also be used to determine P_{1n} values and delayed neutron spectra (see Sect. II C 1). This offers new exciting opportunities for the investigation of important β n-emitter at RIB facilities worldwide with complementary detection techniques.

Recent experimental studies included a revisiting of the properties of β n-emitter abundantly produced during a nuclear fuel cycle in power and research reactors. Re-

measurements of half-lives and neutron-branching ratios for nuclei on priority lists for the most important contributors to the delayed neutron fraction ν_d (see e.g. p. 15 in Ref. [40]) have been carried out, as well as complete studies of the β -strength distribution below and above the neutron emission threshold and resulting β n-energy spectra. These measurements helped to refine the analysis of the processes occurring in nuclear fuel during the operation of nuclear reactors and provided data for a better theoretical analysis of the β -strength distribution.

One important focus for β n-emitter studies in the following years will be the role of competitions between different decay channels. This includes the competition between one- and multi-neutron emission with the deexcitation via γ transitions from highly excited states above the neutron separation energy. In earlier theoretical models these competitions have not been included (in the case of γ competition) or only with a simplified cut-off picture (as in the case of competition between the 1n and 2n channel). However, as has been shown in the past years, the correct treatment of these competing decay channels is crucial since it can lead to systematically wrong predictions. This can have an influence, for example, on the amount of neutrons available in late phases of the astrophysical r process and thus lead to different calculated abundance distribution patterns.

B. Compilation and evaluation of microscopic data

The compilation and evaluation of the half-lives and neutron-emission probabilities of all 653 presently identified β n emitters between ⁸He (Z=2) and ²³³Fr (Z=87) has been carried out [35, 36].

In total, 507 of these β n-emitter have measured β decay half-lives and 306 have a measured P_{1n} value. However, only for 32 nuclides the β -delayed two-neutron emission ratio (P_{2n}) has been measured. The P_{3n} value is only known for four nuclei so far (¹¹Li, ^{17,19}B, and ²³N), and the result of the P_{4n} of ¹⁷B is only tentative.

Nine standards for P_{1n} measurements with a precision of better than 5% and four with a precision between 5-10% have been recommended by the CRP: ⁹Li, ¹⁶C, ¹⁷N, ⁴⁹K, ⁸²Ga, ^{87,88}Br, ^{94,95}Rb, ¹³⁷I, and ^{145,146,147}Cs (see Table I).

In general, the precision of the measured neutronbranching ratios is much lower than for β -decay half-lives (see Fig. 61), and the neutron branching ratios of many nuclei are only available as upper (shown with 100% uncertainty) or lower limits.

With the expected vast amount of new data in the next years, an annual re-evaluation of β n emitters is planned so that this new data can be included in the IAEA Reference Database [43] in a timely manner. The evaluation of the light mass region (Z=2-28) has been published more than 5 years ago [35], and work on the update has started recently by the Canadian nuclear data community.

FIG. 61. Schematic comparison of uncertainties for P_{1n} values (top) and half-lives (bottom) for evaluated β n emitters [35, 36]. Upper limits are shown with 100% uncertainty.

C. Microscopic theory

Two global self-consistent microscopic models have been used in comparisons with the CRP evaluated microscopic data $(T_{1/2}, P_n)$: the spherical continuum pn-QRPA [151] (DF+CQRPA) based on the Fayans functional [149] in its new version DF3a that is suitable for (quasi-) spherical nuclei with low or zero deformation, and the spherical relativistic pnQRPA model [153] based on the D3C* functional [154] (RHB+RQRPA) that has been applied to all the nuclei across the nuclear chart including the deformed ones.

The comparisons have focused on spherical and deformed nuclei both in the light and heavy fission fragment regions, and on isotopes around the doubly closed shell nuclei 78 Ni and 132 Sn which are important for the astrophysical *r*-process nucleosynthesis.

The models perform equally well or even better than the widely used restricted (Q)RPA-like scheme which is based on the microscopic-macroscopic Finite Range Liquid Drop Model (FRDM12+(Q)RPA+HF [148]). The global self-consistent models can thus be recommended for planning RIB experiments and for predictions in mass regions where measurements are not possible and which are important for astrophysical modeling.

Both models, DF+CQRPA and RHB+QRPA, treat the contributions of the first-forbidden (FF) and the allowed Gamow-Teller (GT) transitions fully microscopically and on equal footing. However, the comparison with the evaluated $(T_{1/2}, P_n)$ data shows that the β -decay observables are extremely sensitive to the competition between the GT and FF strengths, the isoscalar pn-pairinglike NN-interaction, and the ground-state spin inversion caused by the neutron-proton tensor interaction which may cause a *stabilization effect*. This leads to a slowing down of the rate at which the half-life decreases with increasing mass number, as well as other irregularities in the P_n values.

These findings underscore the need to further improve the nuclear energy-density functional, in particular the pairing and tensor parts of the functional. The recently proposed hybrid density functional [292] that uses the Skyrme functional with a pairing part depending on the gradient of density, as in the Fayans functional [149], has the potential to describe both the odd-even staggering effects in the Q_{β} values and charge radii [293], and the twoneutron emission probabilities [177, 183]. Also promising are the newly developed "beyond the QRPA" selfconsistent models that take into account the impact of the phonon-phonon [164, 165] or quasiparticle-phonon [166– 168, 294] couplings on the β -decay properties.

D. Summation and time-dependent calculations

The evaluated $(T_{1/2}, P_n)$ values were used in summation and time-dependent calculations of total delayed neutron yields ν_d , DN activity, and DN spectra in combination with the cumulative fission yields from the JEFF-3.1.1 library. Overall, the CRP microscopic data lead to enhanced ν_d values, partly due to the increased P_n value of ¹³⁷I which is the main contributor to nearly all the fission systems studied. The results of the present summation calculations, nevertheless, are in better agreement with the ν_d values recommended by WPEC-SG6 [14] compared to those of Wilson [187] which were based on previous compilations of P_n data. The best agreement with recommended ν_d values is obtained for thermal fission of 235 U and 239 Pu, for which we have the most reliable fission yield data, while for ²³⁸U fast fission there is significant improvement. In the case of fast fission of 235 U and 239 Pu, as well as fission of 241 Pu, however, the recommended values are overestimated.

Time-dependent kinetic parameters were calculated starting from the microscopic recommended CRP data $(T_{1/2}, P_n)$ and the JEFF-3.1.1 independent fission yields, taking into account correlations in the decay path. The estimated group abundances are affected by larger uncertainties than the measured ones indicating that a more comprehensive approach to treating correlations is needed that would include contributions from fission yield data. Both summation and time-dependent calculations provide clear evidence of the energy dependence of the total DN yields for the fission of ²³⁵U and ²³⁹Pu. These results confirm the need for a more detailed investigation of the energy dependence of fission yields and a subsequent updating of the fission yield libraries.

Though the new microscopic CRP $(T_{1/2}, P_n)$ database is significantly improved with respect to previous dated compilations, the impact on integral DN properties also depends strongly on the fission yield library that was used. In addition, the uncertainties in the integral quantities do not take into account correlations affecting the fission yield data, therefore they could be underestimated. We strongly recommend, as a next step, that the evaluated fission yield libraries are updated with due consideration of correlation effects and the dependence on incident energy.

E. Integral experiments and reactor calculations

The impact of the new evaluated microscopic data on integral experiments and specific reactor designs has been assessed. Integral calculations were performed using different evaluated libraries and the CRP $(T_{1/2}, P_n)$ data. The results show that β_{eff} values obtained from the combination of JEFF-3.1.1 fission yields with the CRP data and supplementary ENDF/B-VIII.0 decay data give slightly increased β_{eff} values with respect to the other libraries for the benchmark experiments POPSY, TOPSY, JEZEBEL, SKI-DOO, FLATTOP-23, BIG TEN, SNEAK-7A,SNEAK-7B and IPEN.

Similar results were obtained for three different reactor designs, a pressurized water reactor (PWR), the sodium cooled ASTRID reactor and the lead-bismuth cooled MYRRHA reactor. The combination of the CRP data with JEFF-3.1.1 fission yields leads to β_{eff} values that deviate from the reference values by 1-2% for PWR and MYRRHA and 11% for ASTRID.

These results depend strongly on the fission yield library that was used, therefore, as has been stressed above, further studies using updated fission yield libraries would be required before a definitive conclusion is drawn.

F. Macroscopic measurements and systematics

The total delayed neutron yields have been measured in the energy range from 0.3 to 5 MeV for nuclides of importance to reactor technology and applications. In contrast to the results obtained from β_{eff} methods, these measurements show an energy dependence that does not agree with the recommended data currently available in the evaluated libraries.

The time-dependent integral DN energy spectra have been measured for thermal neutron-induced fission of 235 U. For the first time, the consistency of macroscopic DN spectra with the spectra obtained from the summation calculations over microscopic data $(T_{1/2}, P_n)$ for individual precursors has been demonstrated.

The energy dependence of DN temporary group parameters (a_i, T_i) have been studied in the energy range from thermal to 18 MeV. A procedure for averaging DN parameters obtained in different experimental runs has been developed. DN group parameters have been determined experimentally in an extended time of DN counting compared to previous measurements by Keepin [13]. The correlation and covariance matrices for the DN temporary group parameters have been extracted.

These studies have revealed the reasons behind the large discrepancies observed in the temporary parameters in the energy range 14-18 MeV. They have also led to the development of new systematics for the DN temporary parameters which have enhanced predictive power.

G. New recommendations of group constants

Finally, new recommendations have been made for the DN temporary group parameters (a_i, T_i) in 6- and 8group models based on the evaluation of the new experimental macroscopic data. As the validation of these group models was beyond the scope of this CRP, it remains for the user community to use these new recommended data in verification and validation studies. The new recommended (a_i, T_i) data are available in this report and from the online CRP database [43].

ACKNOWLEDGMENTS

This work has been performed in the framework of a Coordinated Research Project of the International Atomic Energy Agency (IAEA) on "Development of a Reference Database for β -delayed neutron emission data" (F41030).

I.D.'s work was partly funded by the Natural Sciences and Engineering Research Council (NSERC) and the Natural Research Council (NRC) Canada. B. S.'s work was partly funded by the Nuclear Data Section of the IAEA. I.N.B. was supported by the Russian Science Foundation under Grant No. 16-12-10161.

K.R. was partially supported by the US DOE Office of Science, Nuclear Physics) under the contract number DE-AC05-00OR22725 with UT Battelle, LLC. Work at Brookhaven National Laboratory was sponsored by the Office of Nuclear Physics, Office of Science of the U.S. Department of Energy under Contract No. DE-AC02-98CH10886 with Brookhaven Science Associates, LLC. Work at Lawrence Livermore National Laboratory was performed under the auspices of the U.S. Department of Energy under Contract DE-AC52-07NA27344.

Work at IFIC (A.A., J.L.T.) was supported by the Spanish Ministerio de Economía y Competitividad under Grants No. FPA2011-24553, No. FPA2014-52823-C2-1-P, FPA2017-83946-C2-1-P, and the program Severo Ochoa (SEV-2014-0398).

Work at CIEMAT was supported by the Spanish national company for radioactive waste management EN-RESA, through the CIEMAT-ENRESA agreements on "Transmutación de radionucleidos de vida larga como soporte a la gestión de residuos radioactivos de alta actividad" and by the Spanish Ministerio de Economía y Competitividad under Grants No. FPA2014-53290-C2-1-P and FPA2016-76765-P.

Work at SUBATECH was supported by the CNRS challenge NEEDS and the associated NACRE project, and by the CNRS/in2p3 Master Project OPALE.
