

UDKM1DSIM - A Python toolbox for simulating 1D ultrafast dynamics in condensed matter

Daniel Schick*

Max-Born-Institut für Nichtlineare Optik und Kurzzeitspektroskopie, Max-Born-Straße 2A, 12489 Berlin, Germany

Abstract

The UDKM1DSIM toolbox is a collection of Python classes and routines to simulate the thermal, structural, and magnetic dynamics after laser excitation as well as the according X-ray scattering response in one-dimensional sample structures. The toolbox provides the capabilities to define arbitrary layered structures on the atomic level including a rich database of element-specific physical properties. The excitation of dynamics is represented by an N -temperature-model which is commonly applied in ultrafast physics. Structural dynamics due to thermal stresses are calculated by a linear-chain model of masses and springs. The implementation of specific magnetic dynamics can be easily accomplished by the user employing a generalized magnetization interface class. The resulting X-ray diffraction response is computed by kinematical or dynamical X-ray theory which can also include polarization-dependent magnetic scattering. The UDKM1DSIM toolbox is highly modular and allows for injecting user-defined inputs at any step within the simulation procedure.

Keywords: ultrafast dynamics, multilayer absorption, heat diffusion, N -temperature model, coherent phonons, magnetization dynamics, thermoelasticity, magnetoelasticity, kinematical X-ray scattering, dynamical X-ray scattering, dynamical magnetic X-ray scattering

PROGRAM SUMMARY

Program Title: udkm1Dsim

CPC Library link to program files: (to be added by Technical Editor)

Developer's repository link: <https://github.com/dschick/udkm1Dsim>

Code Ocean capsule: (to be added by Technical Editor)

Licensing provisions(please choose one): MIT

Programming language: Python

Journal reference of previous version: Computer Physics Communications Volume 185, Issue 2, February 2014, Pages 651-660

Does the new version supersede the previous version?: yes

Reasons for the new version: The toolbox has been ported from MATLAB (MathWorks Inc.) to Python and is based exclusively on free and open-source components. Moreover, new features have been added that allow for a broader applicability of the toolbox.

Summary of revisions:

Porting to Python.

Introduction of amorphous layers in the sample structures.

Add magnetization property to atoms and layers.

Multilayer formalism to calculate laser absorption.

New magnetization class to allow for user-defined magnetization dynamics.

New resonant magnetic X-ray scattering employing dynamical X-ray theory.

Calculation of X-ray scattering as function of photon energy and scattering vector.

Nature of problem(approx. 50-250 words): Simulate the thermal, structural, and magnetic dynamics of 1D sample structures due to an ultrafast laser excitation and compute the corresponding transient (magnetic) X-ray scattering response.

Solution method(approx. 50-250 words): The program provides an object-oriented toolbox for building arbitrary layered 1D crystalline/amorphous sample structures including a rich database of element-specific parameters. The excitation, thermal transport, and lattice dynamics are simulated utilizing SciPy's ODE solver. Magnetization dynamics can be introduced by the user employing a magnetization interface class. The dynamical (magnetic) X-ray scattering is computed by a matrix formalism that can be parallelized.

Additional comments including restrictions and unusual features (approx. 50-250 words): The program is restricted to 1D sample structures. Phonon dynamics only include longitudinal acoustic phonons (sound waves). Magnetization dynamics have to be defined by the user. X-ray scattering only allows for symmetrical and co-planar geometries due to the 1D nature of the toolbox. The program is highly modular and allows the inclusion of user-defined inputs at any time of the simulation procedure.

1. Introduction

The investigation of electronic, magnetic, and structural dynamics in solid state physics has made great progress during the last decades due to the increasing availability of ultrashort electron and light pulses in a broad spectral range from THz to hard X-rays at large-scale facilities as well as in the lab. One of the major goals of these experiments is to follow the coupling of different degrees of freedom on the relevant time and length scales. Recent examples reveal the complexity of these experiments even for following only two sub-systems, such as the coupling of electron and lattice dynamics [1, 2, 3], of electron and spin dynamics [4, 5, 6], or the coupling of spin and lattice dynamics [7, 8, 9].

In order to understand and interpret such experimental data, one relies on a bunch of simulations for modeling and fitting, which are available as software tool-kits or as published formalisms. A list of required dynamic simulations might include the simplistic N -temperature model (NTM) as initially proposed by Anisimov et al. [10] as well as its modifications and implementations [1, 11, 12], coherent phonon dynamics in a masses-and-spring model [13, 14], molecular dynamics for simulations of spin lattice coupling [15, 16], magnetic simulations combining a 2-temperature-model with the Landau-Lifschitz-Bloch equation [17], or full magnetic simulations [18, 19, 20, 21]. Other aspects can be the spatial absorption profile of the laser excitation in the sample [22, 23] and, moreover, the calculation of the actual observable, e.g. the scattered light intensity in the framework of kinematical or dynamical scattering theories [24, 25, 26, 27, 28, 29] with possible inclusion of resonant and magnetic scattering effects. The implementation of the above mentioned formalisms or the usage and adaption of available external software packages is very time-consuming and each piece of software covers only a very limited aspect of real time-resolved experiments. To that end, the need for a generic, modular, and open-source toolbox that allows for combining many of the above mentioned functionalities is obvious.

The UDKM1DSIM toolbox allows to create arbitrary one-dimensional (1D) structures made of crys-

talline and/or amorphous layers, including stoichiometric mixtures, typically on the nanometer length-scale. These 1D structures hold all relevant material information such as structural, elastic, thermal, magnetic, and optical parameters. The toolbox allows for calculating thermal, structural, and magnetic dynamics on these 1D structures utilizing an NTM, a linear masses-and-springs-model, as well as an interface for user-defined magnetization dynamics, respectively. Finally, different types of light-scattering theories can be applied to retrieve the static as well as transient response from these sample structures due to the above mentioned dynamics, similar to real pump-probe experiments. With that the generally non-linear dependence of the actual observable (scattered light intensity) and the physical quantity of interest (temperature, strain, magnetization, ...) can be revealed. This includes also methods to apply realistic instrumental broadening to the simulated results for better comparison with experimental data. For now the UDKM1DSIM toolbox focus on light scattering from the extreme ultra-violet (XUV) up to hard X-rays but can be easily extended to larger wavelength radiation or totally different probing techniques that can be modeled in 1D.

The original MATLAB (MathWorks Inc.) UDKM1DSIM toolbox [30] has been successfully used in 40 publications (Feb. 2021) and is still available for download [31]. However, due to Python's increasing performance, popularity, and availability the new version of the UDKM1DSIM toolbox has been ported to this programming language. At the same time, the project has moved to github.com/dschick/udkm1Dsim to provide full version control, issue, and feature tracking, as well as project management capabilities in order to allow for better collaboration between users and developers. This also includes automatic code validation and unit testing, as well as source-code-based generation of the documentation at udkm1Dsim.readthedocs.org as part of the continuous integration (CI) concept.

Despite of the major step of porting the UDKM1DSIM toolbox to Python there are several new features included in this release while only a few minor features of the old version have been dropped. Accordingly, existing simulations in MATLAB (Math-

Works Inc.) are easily portable to this new Python version as the general concept and syntax of the toolbox has been unaffected. The new functionalities of the release include: the introduction of amorphous layers in addition to crystalline unit cells; magnetic properties of atoms including magnetic scattering factors; a multilayer formalism for calculating laser absorption profiles [22, 23]; a new magnetization dynamics module; a dynamical magnetic scattering formalism [28]; as well as a unified interface to calculate light scattering as function of scattering vector and photon energy.

Most of the underlying physics has already been described in the initial version of the UDKM1DSIM toolbox [30] as well as in the [API documentation](#) of the corresponding modules. Therefore we will concentrate mainly on the new features/physics as well as on the slight changes of the workflow in Python. After a general description of the implementation and workflow of the UDKM1DSIM toolbox, we will introduce the new release features within an exemplary simulation of laser-induced dynamics in a magnetically-coupled superlattice of Fe and Cr layers.

As a convention throughout this document all code is written in typewriter font (`code = [1, 2, 3]`).

2. Implementation & Workflow

The structure of the UDKM1DSIM toolbox as a Python module tries to reflect the physical reality of the modelled experiments, see Fig. 1. In the beginning a `Structure` object needs to be build out of any number and combination of `AmorphousLayer` and/or `UnitCell` objects which themselves need to consist of one or more `Atom`/`AtomMixed` objects. The `Structure` holds all relevant physical parameters which are required for the actual static and dynamic simulations. Within the `simulations` module different types of dynamic simulations can be carried out on the `Structure` object, e.g. `Heat`, `PhononNum/Ana`, `Magnetization` simulations.

In general, the `Heat` class models the laser-excitation and the resulting energy-flow by an NTM. The resulting phonon and magnetization dynamics can be calculated sequentially or in any user-defined class, that allows for coupling of the dif-

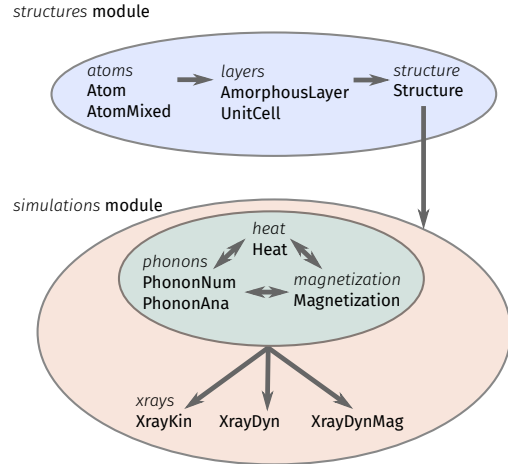

Figure 1: Workflow of the UDKM1DSIM toolbox. (Sub-)Module names are *italic* and class names are in **bold** letters. All classes of the `simulations` module require a `Structure` object on initialization.

ferent degrees of freedom. The modular structure of the in- and outputs of the simulation classes allow for easy exchange or alteration of the simulation results with user-defined data or external calculations. The classes of the `xray` module allow for calculation of static symmetric X-ray scattering from the given sample `Structure` as function of photon energy, scattering vector, as well as of light polarization. In addition, the results from the dynamic `Heat`, `PhononNum/Ana`, `Magnetization` simulations can be input to the X-ray scattering calculation in order to retrieve the dynamic scattering response of the excited sample. This functionality of the UDKM1DSIM toolbox is of major importance, since the transient change of the actual physical quantity of interest, such as strain or magnetization, must not be proportional to the actual observable - the scattered light intensity.

The common experimental scheme is sketched in Fig. 2 and shows the general definition of coordinates and angles that are used throughout the UDKM1DSIM toolbox. Due to the limitation to 1D sample structures the scattering plane must be coplanar to the sample surface and only symmetrical scattering with a scattering vector $\vec{q}_z = \vec{k}_{\text{out}} - \vec{k}_{\text{in}}$

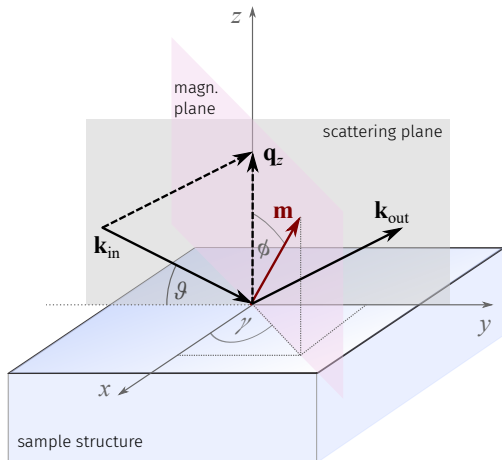

Figure 2: Experimental scheme of the UDKM1DSIM toolbox. The co-planar scattering plane contains the scattering vector $\vec{q}_z = \vec{k}_{\text{out}} - \vec{k}_{\text{in}}$. The magnetization \vec{m} of the individual `Atom` objects can be defined in 3D by an amplitude and the according angles γ and ϕ . The out-of-plane coordinate z points away from the sample surface.

can be calculated in the X-ray simulations. Here the norm of the scattering vector $q_z = \frac{4\pi}{\lambda} \sin \vartheta$ is defined by the X-ray wavelength λ and the incidence angle ϑ . The multilayer absorption uses the same definition as shown in Fig. 2 for the laser incidence angle. The magnetization \vec{m} of each `Atom` is defined by the according angles γ and ϕ . The magnetization can point into all directions in 3D in order to allow for any overlap with the incident X-ray polarization. Since the sample structure is defined from top to bottom the distances within the sample start at its surface and proceed along $-z$ direction.

All classes of the `simulations` module share an advanced caching mechanism which allows to save computationally heavy results to a user-defined path for later reuse. If enabled, the individual simulations generate a unique hash for only the relevant physical parameters that affect the requested calculation. The result of the calculation will then be saved and tagged with this unique hash. It will be automatically reloaded if the simulation is carried out again with the exact same parameter set.

The UDKM1DSIM toolbox fully relies on SI units within its internal calculations. However, the exter-

nal user interface allows to define all relevant parameters as physical quantities using the `Pint` package [32]. Accordingly, the unit conversion to proper SI units will be done automatically within the code. If no units are defined, parameters are assumed to be already in SI units.

3. Example

We choose to simulate the laser-driven structural and magnetic dynamics in an antiferromagnetically (AFM) coupled Fe/Cr superlattice (SL) [33] as an example to demonstrate the recent capabilities of the UDKM1DSIM toolbox. The test sample consists of $20x(\text{Fe}+\text{Cr})$ on a Si substrate with a layer thickness of $d_{\text{Fe}} = d_{\text{Cr}} = 1$ nm. In the Fe/Cr SL the individual Fe layers are ferromagnetically aligned in the plane of the sample. In dependence of the Cr layer thickness the adjacent Fe layers can align anti-parallel to each other [34]. Generally so-called SL Bragg peaks will appear in the X-ray diffraction due to the artificial periodicity of an Fe/Cr doublelayer (DL) [35]. For the special case of resonant magnetic scattering, e.g. at the Fe L_2 and L_3 edges, the doubled AFM periodicity of two DLs is observable and leads to pure magnetic Bragg peaks at half order of the structural Bragg peaks [36].

The AFM Fe/Cr SL is already a very complex example and the UDKM1DSIM toolbox will be far from covering all involved dynamics here. However, it can provide important insights into the laser excitation using the multilayer absorption formalism, the energy transport on ultrafast timescales using a heat diffusion model, resulting coherent acoustic phonons due to thermal stresses, and a simplified demagnetization model due the laser-driven temperature increase. Moreover, the resulting magnetic X-ray scattering response allows for a direct comparison between experiment and simulations.

After successful installation of the UDKM1DSIM toolbox, it can be easily imported in any Python script or Jupyter notebook:

```
import udkm1Dsim as ud
u = ud.u
```

Here `u` is the so-called unit-registry based on the `Pint` package [32] which is used internally in the toolbox and must be used externally to allow for physical quantities and automatic unit conversion.

3.1. Structure

In the first step the `Atom` and `AmorphousLayer` objects are created to build the sample `Structure`:

```
Fe_right = ud.Atom('Fe', mag_amplitude=1,
    mag_phi=90*u.deg, mag_gamma=90*u.deg,
    atomic_form_factor_path='./Fe.cf')
Fe_left = ud.Atom('Fe', mag_amplitude=1,
    mag_phi=90*u.deg, mag_gamma=270*u.deg,
    atomic_form_factor_path='./Fe.cf')
Cr = ud.Atom('Cr')
Si = ud.Atom('Si')
```

The two atoms `Fe_left` and `Fe_right` represent the two different anti-parallel magnetization states in the sample. The parameters `mag_amplitude`, `mag_phi`, and `mag_gamma` define the magnitude and pointing of the Fe magnetization in accordance to Fig. 2. Here the magnetization can be understood as the so-called macro-spin as within the Landau-Lifschitz-Bloch theory [17], that allows for a temperature-dependent variation of the magnetization amplitude. The element-specific atomic scattering factors are taken from the Chantler [37] or Henke [38] tables which are both included in the toolbox. The magnetic form factors are taken from the Dyna project [39]. In case an `atomic_form_factor_path` or `magnetic_form_factor_path` to a user-defined data file is given, the according values will be used instead.

Layer objects of Fe, Cr, and Si as substrate material are initialized as amorphous layers and by providing a dictionary of the relevant physical parameters:

```
prop_Fe = {}
prop_Fe['heat_capacity'] = 449*u.J/u.kg/u.K
prop_Fe['therm_cond'] = 80*u.W/(u.m *u.K)
prop_Fe['lin_therm_exp'] = 11.8e-6
prop_Fe['sound_vel'] = 4.910*u.nm/u.ps
prop_Fe['opt_ref_index'] = 2.9174+3.3545j

layer_Fe_left = ud.AmorphousLayer('Fe_left',
    'Fe left amorphous', thickness=0.2*u.nm,
    density=7874*u.kg/u.m**3, atom=Fe_left, **prop_Fe)
layer_Fe_right = ud.AmorphousLayer('Fe_right',
    'Fe right amorphous', thickness=0.2*u.nm,
    density=7874*u.kg/u.m**3, atom=Fe_right, **prop_Fe)
```

```
...
layer_Cr = ud.AmorphousLayer('Cr', "Cr amorphous",
    thickness=0.2*u.nm, density=7140*u.kg/u.m**3,
    atom=Cr, **prop_Cr)
layer_Si = ud.AmorphousLayer('Si', "Si amorphous",
    thickness=0.2*u.nm, density=2336*u.kg/u.m**3,
    atom=Si, **prop_Si)
```

The thickness of the basic Fe and Cr layers is chosen to be only 0.2 nm in order to allow for a finer spatial grid for the ordinary differential equation (ODE) solvers in the dynamics simulations. The sample `Structure` is created of a nested double-layer `Structure` which allows to simplify rather complex sample geometries:

```
S = ud.Structure('Fe/Cr AFM Super Lattice')
# create a sub-structure
DL = ud.Structure('Two Fe/Cr Double Layers')
DL.add_sub_structure(layer_Fe_left, 5) # = 1nm
DL.add_sub_structure(layer_Cr, 5) # = 1nm
DL.add_sub_structure(layer_Fe_right, 5) # = 1nm
DL.add_sub_structure(layer_Cr, 5) # = 1nm
# add substructure to structure
S.add_sub_structure(DL, 10)
S.add_sub_structure(layer_Si, 500) # = 100nm
```

The sample `Structure` can be easily visualized by the command `S.visualize()`, see Fig. 3

3.2. Simulations

All transient simulations of the UDKM1DSIM toolbox need a spatial and temporal grid defined in the beginning:

```
delays = numpy.r[-1:20:0.1]*u.ps
_, _, distances = S.get_distances_of_layers()
```

Here one can freely choose the temporal grid while the spatial grid is generally given by the sample geometry which can be easily accessed from the `Structure` object itself.

3.2.1. Heat

In order to simulate the laser-driven dynamics, we need to initialize a `Heat` object first and set all relevant excitation parameters.

```
h = ud.Heat(S, True)
h.excitation = {'fluence': [20]*u.mJ/u.cm**2,
    'delay_pump': [0]*u.ps,
    'pulse_width': [0.1]*u.ps,
```

Figure 3: Automatic visualization of the AFM-coupled Fe/Cr SL **Structure**. The blue and green regions indicate *left* and *right* magnetized Fe layers, respectively. The orange and red regions indicate Cr and Si layers, respectively. The distances within the **Structure** are along the $-z$ coordinate.

```

'multilayer_absorption': True,
'wavelength': 800*u.nm,
'theta': 45*u.deg}
h.heat_diffusion = True

```

The fluence F_{incident} has to be input for normal incidence. For the projection of the laser onto the sample surface, the angle of incidence ϑ is automatically taken into account, which is for $\vartheta = 45^\circ$ about 70 % of F_{incident} . In order to calculate the laser absorption profile, the user can either enable a multilayer absorption formalism [22, 23] or use the Lambert-Beer formula as fall-back. Depending on the complexity of the sample geometry and the variation of the complex refractive index, the difference in the differential absorption dA/dz between both algorithms can be significant, see Fig. 4. The Lambert-Beer formula also neglects any reflection from the sample surface, while the multilayer formalism includes even multiple reflections inside the sample. For the current sample the optical reflectivity is about 48 % and the transmission is about 10 %. From these parameters one can calculate that the absorbed fluence in the sample is only about $F_{\text{abs}}/F_{\text{incident}} = 29$ %.

The calculation of the 1D heat diffusion equation on the above defined sample structure can then be simply called by:

```

temp_map, delta_temp_map = h.get_temp_map(delays,
                                          300*u.K)

```

Here the second argument of the `get_temp_map()` method is the homogeneous initial temperature of the sample which could be also an array containing initial temperatures for all individual layers. The resulting spatio-temporal temperature map of the sample is shown in Fig. 5. In the background the UDKM1DSIM toolbox will also take care of sufficient

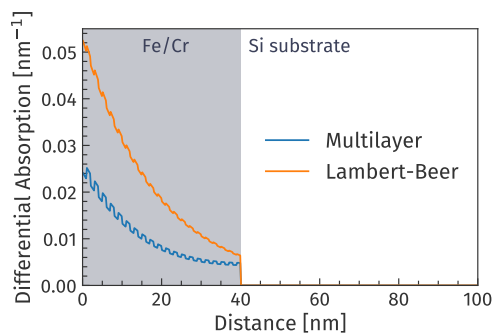

Figure 4: Differential absorption calculation comparing the Lambert-Beer law vs. the multilayer formalism. Despite internal multi-reflections, the multilayer formalism also includes reflection from the front surface of the sample. The absorption contrast between Fe and Cr layers is significantly different for both methods.

spatial and temporal interpolation at layer interfaces and pump events in order to improve the performance of the ODE solver dramatically. This includes also the separation of temporal regions, that do not require the calculation of heat diffusion because full equilibrium conditions (no temperature gradients, no excitation, isolating boundary conditions). More advanced settings like boundary conditions, multipulse excitations, or ODE settings can be found in the according examples of the UDKM1DSIM toolbox.

3.2.2. Numerical Phonons

Using the above calculated `temp_map` and its temporal derivative `delta_temp_map` it is easily possible to calculate the coherent acoustic phonon dynamics within the same sample **structure** by using the numerical solver for the masses-and-spring model implemented

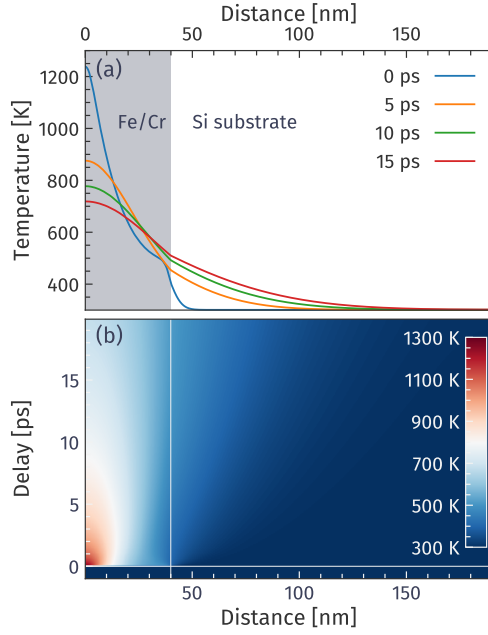

Figure 5: Spatio-temporal temperature map after laser excitation. The line-outs in (a) and the full color-coded map in panel (b) represent the relaxation of the laser-induced temperature gradient between absorptive Fe and Cr layers and the transparent Si substrate. Due to the finite laser pulse width of 100 fs the small temperature gradients between Fe and Cr layers within the first 40 nm are immediately relaxed.

in the `PhononNum` class:

```
p = ud.PhononNum(S, True)
strain_map = p.get_strain_map(delays,
                             temp_map,
                             delta_temp_map)
```

The resulting `strain_map` represents the strain for every layer at every delay point of the `Heat` simulation, see Fig. 6.

The map features complex oscillatory structures due to the excitation of so-called SL optical phonon modes or zone-folded acoustical phonons (ZFLAPs) [14] within the Fe/Cr region. These spatial and temporal oscillations of the strain are also imprinted on the bi-polar strain wave that is launched into the Si substrate at later delays. One can easily read the sound velocity of Si from the slope of the color gradient in Fig. 6 (b) as about 8 nm/ps. More details on

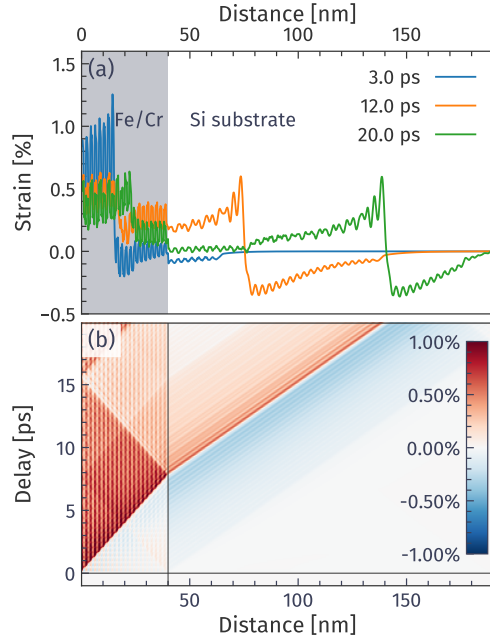

Figure 6: Spatio-temporal strain map due to the laser excitation of coherent acoustic phonons. The full map in (b) features a complex pattern of SL phonons mode within the first 40 nm of the sample with tensile strain amplitudes of more than 1.0 %. Panel (a) shows the bi-polar strain wave that is launched from the SL into the substrate at later delays. The bi-polar strain wave features additional oscillations that stem from the SL geometry.

the ODE settings, phonon damping, and non-linear phonon propagation can be found in the according examples of the `UDKM1DSIM` toolbox.

3.2.3. Magnetization

The simulation of magnetization dynamics is a rather complex topic on its own and the `UDKM1DSIM` toolbox is currently not meant to provide any high-profile code here. Optionally, we provide an example of the microscopic 3-temperature-model by Koopmans et al. [11] in the documentation. This model provides decent fits of the average magnetization amplitude for the early delays after photoexcitation but already neglects thermal transport by phonons. Instead of implementing complex spin dynamics simulations here, we decided to provide a

generic interface to inject results from external magnetization dynamic calculations [40, 17, 18, 20, 19, 15] or to easily add user-defined code. For that we provide the `Magnetization` interface class. By inheriting from this interface class the user can reuse all features of the `Simulation` class, such as caching, and only needs to overwrite the `calc_magnetization_map()` method. This method can have the `temp_map` and `strain_map` as inputs and can access all properties of the sample `Structure`. Its return value must be a `magnetization_map`, which contains the magnetization amplitude and direction (γ and ϕ in radians), see Fig. 2, for every layer at every delay of the dynamic simulation.

As an example we employ the Bloch formula, c.f. Eq. 1, to calculate the spontaneous magnetization M as function of the layer temperature T for every delay.

$$M(T) = M_0((1 - (T/T_C)^\alpha)^\beta) \quad (1)$$

We use the parameters $T_C = 770$ K, $\alpha = 3/2$ and $\beta = 0.32$ and set M_0 such that $M(300K) = 1$. Running the calculation is accomplished by:

```
mag = Magnetization(S, True)
magnetization_map = mag.get_magnetization_map(
    delays, strain_map=strain_map, temp_map=temp_map)
```

The amplitude of the resulting `magnetization_map` is shown in Fig. 7.

3.2.4. Dynamical Magnetic X-ray Scattering

In the last step we are going to calculate the static resonant magnetic scattering response of the sample before we use the `strain_map` and `magnetization_map` from the calculations above to simulate a dynamical scattering response similar to a real pump-probe experiment. The `xray` module of the `UDKM1DSIM` toolbox currently includes three different X-ray scattering formalisms. A kinematical and dynamical X-ray scattering formalism is implemented in the `xrayKin` and `xrayDyn` classes, respectively. They work only for crystalline unit cells and do not include magnetic scattering effects. Therefore we use here the dynamical magnetic formalism of the `xrayDynMag` class, which is one of the most important new features of the `UDKM1DSIM` toolbox. This formalism has been adapted from the open-source Dyna Project [39, 28]

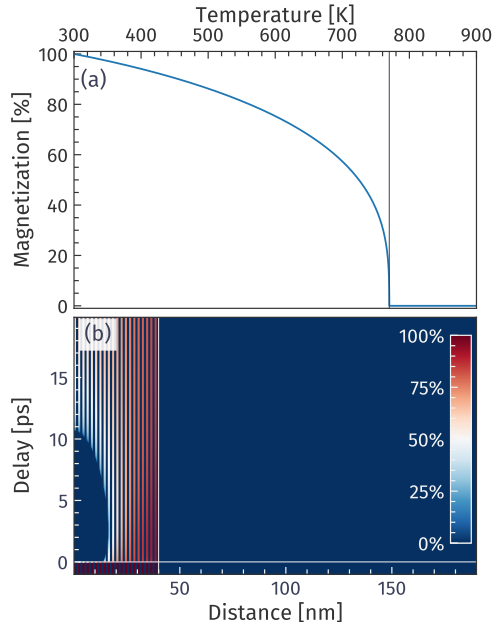

Figure 7: Spatio-temporal map of the magnetization amplitude. The magnetization amplitude of the Fe layers is completely quenched for high local temperatures above $T_C = 770$ K.

and was further improved by adding parallelization features, increasing the vectorization, and allowing for simultaneous energy- and q_z -dependent calculation of the reflectivity and transmissivity for both amorphous layers and crystalline unit cells. For the later case no Bragg peaks from mono-atomic unit cells can be calculated as the Dyna formalism relies on scattering differences between adjacent layers.

In order to perform resonant magnetic scattering simulations the atomic and magnetic form factors need to be carefully determined. This is usually done by measuring the dichroic absorption of circularly polarized light for the ferromagnetic state of the according element across the resonances of interest. The average and difference spectra can then be carefully calibrated and scaled to theoretical values [37, 38] in order to determine the absorptive parts f_2 and m_2 . By applying the Kramers-Kronig-relation the refractive contributions f_1 and m_1 can be retrieved as well. This procedure is currently not within the scope of

Figure 8: Energy-dependence of the refractive f_1, m_1 and absorptive f_2, m_2 parts of the atomic and magnetic form factors of Fe.

the UDKM1DSIM toolbox but can be easily achieved with other free packages [41, 42]. Figure 8 shows the atomic and magnetic form factors for the current simulations.

The reflected intensity R of the static sample for a given range of photon energies and scattering vectors q_z can be easily calculated by the `homogeneous_reflectivity()` method of the `XrayDynMag` class:

```

dyn_mag = ud.XrayDynMag(S, True)
dyn_mag.energy = numpy.r_[690:730:0.1]*u.eV
dyn_mag.qz = numpy.r_[0.01:5:0.01]/u.nm
R, _, _, _ = dyn_mag.homogeneous_reflectivity()

```

The resulting scattering map is shown in Fig. 9 and features a strong structural SL Bragg peak around $q_z^{\text{SL1}} = 3.13 \text{ nm}^{-1}$ for all photon energies. The purely AFM Bragg peaks around $q_z^{\text{SL0.5}} = 1.56 \text{ nm}^{-1}$ and $q_z^{\text{SL1.5}} = 4.7 \text{ nm}^{-1}$ appear only at the Fe L_3 and L_2 resonances which provide magnetic contrast.

To verify the magnetic origin of the AFM Bragg peaks we conduct a polarization analysis within the

Figure 9: Energy and q_z -dependent scattering from the AFM-coupled Fe/Cr superlattice. Selected line-outs from panel (b) before as well as at the L_3 and L_2 resonances of Fe are shown in panel (a). The AFM Bragg peaks only appear on-resonance at $q_z^{\text{SL0.5}} = 1.56 \text{ nm}^{-1}$ and $q_z^{\text{SL1.5}} = 4.7 \text{ nm}^{-1}$, while the structural Bragg peak is present for all energies at $q_z^{\text{SL1}} = 3.13 \text{ nm}^{-1}$.

dynamical magnetic X-ray scattering simulations. Figure 10 compares three different analyzer settings for fixed σ polarization of the incident X-rays. While normal charge scattering is not altering the polarization of the scattered light, this is not true for magnetic scattering. Accordingly, without analyzer both charge and magnetic scattering are included as in Fig. 9 before, the $\sigma \rightarrow \sigma$ channel only includes charge scattering and the $\sigma \rightarrow \pi$ channel only includes magnetic scattering. As expected, the AFM Bragg peaks do not appear in the $\sigma \rightarrow \sigma$ channel. Due to the symmetric layer thicknesses in the SL also even orders of the AFM Bragg peak are forbidden in the $\sigma \rightarrow \pi$ channel.

Figure 10: Polarization dependence of magnetic X-ray scattering from the Fe/Cr SL at 708 eV. The $\sigma \rightarrow \sigma$ channel only includes charge scattering and the $\sigma \rightarrow \pi$ channel only magnetic scattering. Without analyzer both contributions are included.

In the last step we calculate the dynamic response of the sample due to the above calculated spin and lattice dynamics, providing the `magnetization_map` and `strain_map` as inputs to the `inhomogeneous_reflectivity()` method of the `XrayDynMag` class:

```
R_seq, _, _, _ = dyn_mag.inhomogeneous_reflectivity(
    strain_map = strain_map,
    magnetization_map=magnetization_map)
```

The result around SL1.5 at 720 eV is shown in Fig. 11. Due the quasi-instantaneous demagnetization, as input by the `magnetization_map`, the AFM Bragg peak intensity is quenched and recovers on a 10 ps time scale. At the same time coherent acoustic phonon dynamics lead to an obvious shift of the magnetic Bragg peak and the structural Laue oscillation beneath it.

In Fig. 12 (b) we compare relative intensities $I(q_z, t)/I(q_z, t < 0)$ for different scattering vectors q_z with the input average strain and magnetization of within the Fe/Cr SL, c.f. panel (a). Depending on the selected q_z the observed transients resemble dominantly the coherent acoustic phonon or magnetization dynamics or a mixture of both. Note that even on the AFM Bragg peak maximum at $q_z = 4.7 \text{ nm}^{-1}$ the relative drop of the intensity by about 75 % is

Figure 11: Transient resonant magnetic X-ray scattering around $q_z^{\text{SL1.5}} = 4.7 \text{ nm}^{-1}$ at 720 eV featuring a strong quenching and recovery of the AFM Bragg peak intensity as well as a peak shift due to coherent acoustic phonon dynamics.

not comparable with the change of the average magnetization in the Fe layers of less than 60 %. This results clearly indicates the importance of a careful analysis of time-resolved scattering data especially if magnetic effects are involved.

4. Conclusions & Outlook

With the porting of the UDKM1DSIM toolbox from MATLAB (MathWorks Inc.) to Python several new features have been added to the toolbox. The implementation of magnetic properties as well as the resonant magnetic scattering formalism drastically extends its outreach. The toolbox allows to carry out a full set of static and dynamics simulations on one and the same sample structure without switching between packages or even programming languages. At the same time it relies to 100 % on free and open-source software making it accessible to a broader au-

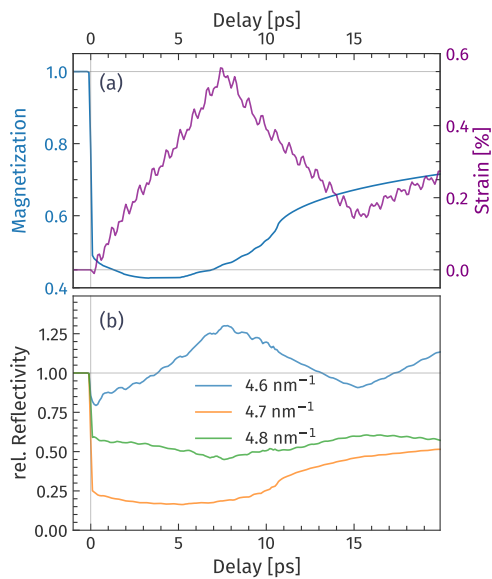

Figure 12: (a) Average magnetization of Fe layers and average strain of Fe and Cr layers within the SL structure. (b) Relative reflectivity at selected q_z positions from Fig. 11.

dience in research and teaching. This is further supported by its ease of use and detailed documentation.

The open-source aspect of the UDKM1DSIM toolbox allows for easy adaption and adding extensions to it. These can be either done by the users themselves or discussed at the project page at github.com/dschick/udkm1dsim. Possible new features can be interfaces to other existing simulation packages, such as Ubermag [18] in order to allow for more detailed magnetization dynamics. Also the inclusion of temperatures in the X-ray scattering simulations will be interesting in terms of Debye-Waller-effects and transient changes of the scattering factors due to excitation of the band structure. Additional probing techniques, such as visible light or electron scattering could be included in the future as well.

5. Acknowledgment

We would like to acknowledge the discussions with Marc Herzog, Stéphane Grenier, Lukas Alber, Valentino Scalera, Vivek Unikandanunni, and Ste-

fano Bonetti. We further thank Loïc Le Guyader for providing us with the source code for the optical multilayer formalism as well as Lisa-Marie Kern, Martin Borchert, and Martin Hennecke for extensive testing of the toolbox.
