(Dated: August 11, 2021)

The scattering of Rb atoms on an anti-relaxation coating was studied. No significant change in the spin relaxation probability of Rb atoms by single scattering from a tetracontane surface was observed by cooling the film from 305 to 123 K. The mean surface dwell time was estimated using a time-resolved method. Delay-time spectra, from which mean surface dwell times can be estimated, were measured at 305, 153, and 123 K, with a time window of 9.3×10^{-5} s. The increase in mean surface dwell time with cooling from 305 to 123 K was smaller than 4.4×10^{-6} s, which is significantly smaller than the value expected from the mean dwell time at room temperature measured using the Larmor frequency shift. These results can be explained by assuming a small number of scattering components, with a mean surface dwell time at least three orders of magnitude longer than the majority component.

52

INTRODUCTION

Anti-relaxation coatings are used to reduce the spin ⁵³ relaxation of alkali metal atoms resulting from wall colli- ⁵⁴ sions in the alkali-metal vapor cells of atomic clocks [1–3] ⁵⁵ and atomic magnetometers [4–6]. Paraffin[7, 8], octade- ⁵⁶ cyltrichlorosilane (OTS)[9, 10], and polydimethylsilox- ⁵⁷ ane (PDMS)[11] are representative materials for anti- ⁵⁸ relaxation coatings. It has been reported that paraffin- ⁵⁹ coated surfaces can support 10⁴ spin-preserving collisions ⁶⁰ for Rb atoms [8]. The performance of an anti-relaxation ⁶¹ coating depends on the surface dwell time, as well as the ⁶² strength of the interaction between alkali metal spins and ⁶³ the surface. The mean dwell time τ_s can be described by ⁶⁴ the Arrhenius formula:

$$\tau_{\rm s} = \tau_0 \exp\left(\frac{E_{\rm des}}{k_{\rm B}T_{\rm s}}\right),\tag{1}$$

where τ_0 is the pre-exponential factor, $E_{\rm des}$ is the desorption energy, $k_{\rm B}$ is Boltzmann constant, and $T_{\rm s}$ is the 70 temperature of the surface. In the case of Rb atoms on 71 tetracontane (C40H82), which is a representative type of 72 paraffin, the experimentally obtained desorption energy 73 is 0.06 eV[12, 13]. By adopting a commonly used assump-74 38 tion, i.e., that the pre-exponential factor is 1×10^{-12} s, 75 39 which is the typical period of thermal vibration of atoms, 76 40 we can roughly estimate $\tau_{\rm s}$ as 1×10^{-11} s at 300 K. 77 41 However, using the Larmor frequency shift, Ulanski et 78 42 al. reported a mean dwell time of $(1.8 \pm 0.2) \times 10^{-6}$ s 79 43 for Rb atoms on paraffin coatings at 345 K [14]. The $_{\rm 80}$ 44 reason for the large difference in the mean dwell time 81 45 calculated from the desorption energy compared to that 82 46 measured by experiments is still unclear [15]. One pos- 83 47 sibility is that the assumption $\tau_0 \simeq 1 \times 10^{-12}$ s is incor-48 rect. By substituting $E_{\text{des}} = 0.06 \text{ eV}$, $T_{\text{s}} = 345 \text{ K}$, and $_{85}$ 49 $\tau_{\rm s} = 1.8 \times 10^{-6}$ s into equation (1) and regarding τ_0 as ⁸⁶ 50

a variable, we obtain $\tau_0 = 2.4 \times 10^{-7}$ s. However, this is two orders of magnitude larger than the pre-exponential factor $\tau_0 = 2.2 \times 10^{-9}$ s of ⁸⁷Rb atoms on Pyrex glass surfaces coated with OTS, estimated from the temperature dependence of the mean dwell time [16] and is five orders of magnitude larger than the typical period of thermal vibration. Therefore, this issue requires further investigation.

Equation (1) shows that the mean dwell time increases with cooling, which makes it easier to measure dwell times using time-resolved methods. If we assume that $\tau_0 = 2.4 \times 10^{-7}$ s (which is obtained by substituting $E_{\rm des} = 0.06$ eV [12, 13], $\tau_{\rm s} = 1.8 \times 10^{-6}$ s, and $T_{\rm s} = 345$ K [14]) is correct, then it can be seen from Eq. (1) that $\tau_{\rm s}$ will increase by 6.7×10^{-5} s with cooling of a sample from 305 to 123 K, which is sufficient time to detect using time-resolved methods. The spin relaxation probability with surface scattering is also expected to increase at low temperatures due to an increased dwell time.

In this study, we investigated the temperature dependence of the spin relaxation probability and dwell time of Rb atoms on tetracontane coatings. A beamscattering method and X-ray photoelectron spectroscopy (XPS) were employed to analyze the surface dwell time and surface chemical composition. Using an atomic beam and optical hyperfine pumping, the dwell time can be measured more directly compared to the methods used in earlier studies [14, 16]. The results show that the increase in mean dwell time (averaged over the majority of scattered atoms) with cooling from 305 to 123 K was shorter than 4.4×10^{-6} s, which is significantly shorter than the value of 6.7×10^{-5} s expected from the previously reported desorption energy $E_{\text{des}} = 0.06 \text{ eV} [12, 13]$ and the mean dwell time $\tau_{\rm s} = 1.8 \times 10^{-6}$ s at 345 K [14]. This indicates the existence of minor scattering components with dwell times at least three orders of magnitude

EXPERIMENTAL

Figure 1(a) shows the experimental setup. A114 89 tetracontane-coated quartz substrate was mounted in an¹¹⁵ 90 ultra-high vacuum (UHV) chamber with a base pressure¹¹⁶ 91 lower than 3×10^{-7} Pa. The tetracontane film was de-117 92 posited on the substrate in another high-vacuum cham-118 93 ber, the base pressure of which was 1.0×10^{-5} Pa. by₁₁₉ 94 evaporating tetracontane at 513 K for 10 min. The thick-120 95 ness and average roughness, Ra, of the film were mea-₁₂₁ 96 sured to be 0.93 ± 0.17 µm and 50 nm, respectively, using₁₂₂ 97 atomic force microscopy. The Rb beam was generated₁₂₃ 98 using a multi-channel effusive atomic beam source. The₁₂₄ 99 full width at half maximum of the atomic beam at the₁₂₅ 100 position of the sample was estimated to be $8.2 \text{ mm from}_{126}$ 101 a fluorescence image taken with a charge-coupled device₁₂₇ 102 (CCD) camera. 103

The two pump light beams were directed perpendicu-129 lar to the Rb beam. The pump and probe frequencies are130

FIG. 2. (a) Schematic diagram of the optical system for generating pump and probe light. AOM, EOM, BS, PBS, NPBS, RM, and QWP denote the acousto-optic modulator, electrooptic modulator, beam splitter, polarizing beam splitter, nonpolarizing beam splitter, removable mirror, and quarter-wave plate, respectively. (b) Schematic diagram of the signalprocessing system used for the delay-time measurements.

shown in Fig. 1(b). The optical system used to generate the pump and probe light is illustrated in Fig. 2(a). The frequency of the first pump light was tuned to the $F = 3 \rightarrow F' = 3$ transition frequency of the ⁸⁵Rb D_1 transition line using polarization spectroscopy [17, 18], where F and F' are the total angular momentum of atoms in the $5^2S_{1/2}$ and $5^2P_{1/2}$ states, respectively. The second pump light, the frequency of which was tuned to the $F = 2 \rightarrow F' = 3$ transition frequency of the D_1 line, was generated by blue-detuning the first pump light by 3,036 MHz [19, 20] using an electro-optic modulator (EOM) and an acousto-optic modulator (AOM), and was pulsed to 5×10^{-6} s by the AOM.

The probe light was used to selectively excite Rb atoms in the F = 3 state to the F'' = 4 state through the D_2 transition, resulting in fluorescence. Here, F'' is the total angular momentum of the atoms in the $5^2P_{3/2}$ state. The fluorescence was detected by a CCD camera and a photomultiplier tube (PMT), which were equipped with interference filters that were designed to transmit only the probe light and fluorescence. The frequency of the probe light could be tuned, which enabled selective excitation of the incident or scattered atoms. For probing scattered atoms, the probe light was blue-detuned from the $F = 3 \rightarrow F'' = 4$ transition frequency of the D_2

transition line by 160 MHz, such that it did not excite187 131 incident atoms. With this frequency, the probe light ex-188 132 cites Rb atoms whose velocity component along the probe189 133 light is 125 ± 5 m/s; these are abundant among scattered 134 atoms [21] but negligible among incident atoms. Here, 135 the natural line width of the Rb D_2 transition line (6.06) 136 MHz) [22] was used to calculate the uncertainty. When 137 probing the incident atoms, the direction of the probe 138 light beam was the same as that used to probe the scat-139 tered atoms; however, the frequency was red-detuned by₁₀₁ 140 60.3 MHz from the $F = 3 \rightarrow F'' = 4$ transition frequency. 141 With this frequency, the probe light excites atoms with 142 a velocity component along the probe light of -47 ± 5 143 m/s. Because atoms with this velocity component are 144 found among both incident and scattered atoms, the flu-145 orescence intensity of the incident atoms was estimated¹⁹⁴ 146 by subtracting the contribution of scattered atoms from¹⁹⁵ 147 the measured fluorescence intensity, as discussed below. ¹⁹⁶ 148

Mean dwell-time estimates were based on time-of-149 flight (TOF) measurements obtained using the pump and 150 probe light. The incident Rb atoms were first pumped 151 to the F = 2 state by the first pump light and subse-152 quently irradiated with the second pump light, which was 153 pulsed; atoms that were irradiated with the second pump 154 light were momentarily pumped to the F = 3 state. The ¹⁹⁸ 155 incident atoms pumped to the F = 3 state by the sec-¹⁹⁹ 156 ond pump light enhanced the fluorescence induced by the 200 157 probe light when they reached it. The delay time in the²⁰¹ 158 fluorescence enhancement induced by irradiation by the 159 second pump light is the sum of the TOF of the Rb atoms 160 (from the second pump light to the probe light via the 161 film surface) and the surface dwell time. The probe-light-202 162 induced fluorescence was detected by the PMT. The sig-203 163 nal from the PMT was processed using the system shown₂₀₄ 164 in Fig. 2(b). Delay-time spectra were acquired by $accu_{205}$ 165 mulating the time intervals between the irradiation of the $_{206}$ 166 second probe light and the detection of fluorescence by_{207} 167 PMT. The delay-time distribution can be treated as the₂₀₈ 168 distribution of the sum of the TOF and the dwell time₂₀₀ 169 only when the hyperfine relaxation by a single collision_{210} 170 is negligibly small. When the hyperfine relaxation by a_{211} 171 single collision is significant, hyperfine polarization of in-212 172 cident atoms is lost over the surface dwell time. In this $_{213}$ 173 case, a large percentage of the scattered atoms experi-174 ence spin relaxation while on the surface; as such, they 175 do not contribute to the delay-time spectra. Therefore, 176 the probability of spin relaxation resulting from $surface_{214}$ 177 scattering must be estimated prior to measurement of the $_{_{215}}$ 178 dwell time. 179 216

To evaluate the spin relaxation resulting from a single collision, we used the first pump light and the probe light. The first pump light polarizes incident Rb atoms in the beam to the F = 2 state. Given that the probe-lightinduced fluorescence of the incident and scattered atoms reflects the number of atoms in the F = 3 state, the²¹⁷ fluorescence intensity decreases when the first pump light²¹⁸ is introduced. The population fraction f_i of the F = 2 state of the incident atoms pumped by the first pump light can be written as

$$f_{\rm i} = \frac{N_2}{N_2 + N_3} \tag{2}$$

$$=1-\frac{N_3}{N},\tag{3}$$

where N_2 and N_3 are the numbers of atoms in the F = 2and F = 3 states in the incident atoms, respectively, and $N = N_2 + N_3$. Because the fluorescence intensity is proportional to the number of atoms in the F = 3 state,

$$N_3 = CI_{i,p},\tag{4}$$

where C is a constant and $I_{i,p}$ is the intensity of the fluorescence of incident atoms induced by the first pump light. $I_{i,p}$ can be obtained by

$$I_{i,p} = i_{-60.3 \text{ MHz,p}} - i_{160 \text{ MHz,p}} \times \frac{M(-47 \text{ m/s}, T_{s})}{M(125 \text{ m/s}, T_{s})}$$
(5)

where $i_{\delta,p}$ is the fluorescence intensity measured with the first pump light introduced with the probe light bluedetuned by δ from the $F = 3 \rightarrow F'' = 4$ transition frequency, and $M(v, T_s)$ is the Maxwell distribution given by

$$M(v, T_{\rm s}) = \sqrt{\frac{2m}{\pi k_{\rm B} T_{\rm s}}} \exp\left(-\frac{mv^2}{2k_{\rm B} T_{\rm s}}\right),\tag{6}$$

where m is the mass of an ⁸⁵Rb atom. The first term in Eq. (5) includes contributions from both incident and scattered atoms. To subtract the latter, the second term is introduced. The second term is the fluorescence intensity of the scattered atoms excited by the probe light red-detuned by 60.3 MHz estimated from the fluorescence intensity measured with the probe light blue-detuned by 160 MHz (based on the fact that the velocity distribution of the scattered atoms can be expressed as a Maxwell distribution [21]).

Because F = 2 and F = 3 states have five- and sevenfold degeneracy, N_3 and N can be written as

$$N = \frac{12}{7} C I_{\rm i,np}.\tag{7}$$

Here, $I_{i,np}$ is the intensity of the fluorescence of incident atoms without the first pump light, which can be obtained by

$$I_{\rm i,np} = i_{-60.3 \text{ MHz,np}} - i_{160 \text{ MHz,np}} \times \frac{M(47 \text{ m/s}, T_{\rm s})}{M(125 \text{ m/s}, T_{\rm s})}, \qquad (8)$$

where $i_{\delta,np}$ is the intensity of fluorescence measured with the probe light blue-detuned by δ with the first pump ²¹⁹ light blocked. Therefore, we can experimentally deter-²²⁰ mine f_i as

$$f_{\rm i} = 1 - \frac{7}{12} \frac{I_{\rm i,p}}{I_{\rm i,np}}.$$
 (9)

Similarly, the population fraction $f_{\rm s}$ of the F = 2 state of the scattered atoms is written as

$$f_{\rm s} = 1 - \frac{7}{12} \cdot \frac{I_{\rm s,p}}{I_{\rm s,np}},$$
 (10)

where $I_{s,p}$ and $I_{s,np}$ are the intensities of the fluorescence 223 of the scattered atoms measured with the probe light 224 blue-detuned by 160 MHz with and without the pump 225 light, respectively. The fluorescence of the incident atoms 226 is negligible when the probe laser is blue-detuned by 160 227 MHz, which was confirmed by the fluorescence intensity 228 being lower than the detection limit when the sample was 229 removed from the atomic beam position. By comparing 230 $f_{\rm i}$ and $f_{\rm s}$, the proportion of atoms whose total angular 231 momentum is changed by scattering at the surface can 232 be estimated. 233

The delay-time and spin-relaxation measurements were conducted using different samples prepared by the same procedure, to minimize aggregation of Rb atoms, which may contaminate the surface. The aggregation of Rb on the surface resulting from atomic Rb beam irradiation was checked by XPS using Al k α radiation with a photon energy of 1486.6 eV.

241 RESULTS AND DISCUSSION

242

X-ray photoelectron spectroscopy

Aggregation of Rb atoms on the surface was investi-243 gated by XPS. The temperature at which aggregation 244 was noticeable was approximately 123 K; this varied 245 slightly among samples. Figure 3 shows the XPS spectra 246 of the as-prepared sample and the spectra taken after ex-247 posing the sample to an atomic Rb beam with a flux of 248 $10^{11}\text{--}10^{12}~\mathrm{s}^{-1}$ at 153 K for 2 h and 123 K for 2 h. The 249 spectrum of the as-prepared sample displayed a strong 250 peak at $E - E_{\rm F} = -285$ eV, which was assigned to the 251 C 1s state. After exposure to the Rb beam at low tem-252 perature, new peaks appeared at $E - E_{\rm F} = -531, -246,$ 253 -238, and -109 eV; these were assigned to the O 2p, 254 Rb $3p_{1/2}$, Rb $3p_{3/2}$, and Rb 3d states, respectively. The 255 existence of the O 2p peak indicates that some of the 256 adsorbed Rb atoms had become oxidized by the residual 257 O_2 or H_2O in the UHV chamber. 258

²⁵⁹ Spin relaxation resulting from surface scattering

The spin relaxation caused by surface scattering was evaluated at 305, 153, and 123 K. The temperature of the

FIG. 3. X-ray photoelectron spectroscopy spectra of the clean sample and the sample exposed to an Rb beam at 153 K for 2 h and 123 K for 2 h.

FIG. 4. (a)Temperature dependence of the F = 2 population fraction of the incident and scattered atoms, f_i and f_s , respectively and (b) the temperature dependence of the ratio f_s/f_i of the incident and scattered atoms.

Rb oven of the Rb beam source was set to 393 K. Under 262 these conditions, the flux intensity was estimated to be 263 $10^{11} - 10^{12}$ atoms per second based on the designed value 264 and the fluorescence induced by the probe light. Below 265 123 K, the number of scattered atoms was significantly 266 smaller than at above 123 K, indicating the initiation of 267 Rb atom adsorption at around 123 K, which is consistent 268 with the XPS results. Figure 4(a) shows the population 269 fractions of the F = 2 state for the incident and scat-270 tered atoms. Uncertainties in the population fractions 271 were estimated by repeating the measurements three to 272 five times. Because the spin relaxation induced by a sin-273 gle scattering process is negligibly small at room tem-274 perature [8], the difference between $f_{\rm s}$ and $f_{\rm i}$ at 305 K 275 is attributed to the incident atoms away from the beam 276 center, as opposed to relaxation due to scattering. When 277 measuring the population fraction of the F = 2 state of 278 incident atoms, atoms that pass the edge of the atomic 279 beam are difficult to pump or detect due to the large 280 deviation in velocity direction with respect to the major 281 component of the incident atoms, which the pump and 282 probe light frequencies are tuned to excite. However, 283 when the probe light is blue-detuned to detect only the 284 scattered atoms, atoms that were not pumped can be 285 detected, as surface scattering changes the direction of 286 the translational movement of atoms. The temperature 287 dependence of the ratio of the population fraction of the 288 incident and scattered atoms f_s/f_i is shown in Fig. 4(b); 289 no increase in spin relaxation probability induced by cool-290 ing was observed above 123 K within the experimental 291 error. Given that Rb atoms experience 10^4 collisions be-292 fore their spins relax [8] in paraffin-coated cells at room 293 temperature, the low spin relaxation probability at 123 294 K means that the mean dwell time at 123 K is smaller₃₁₄ 295 than 10^4 times the mean dwell time at 300 K. Thus, from₃₁₅ 296 Eq. (1), $\tau_0 \exp\left(\frac{E_{\text{des}}}{k_{\text{B}} \cdot 123 \text{ K}}\right) \le 10^4 \cdot \tau_0 \exp\left(\frac{E_{\text{des}}}{k_{\text{B}} \cdot 305 \text{ K}}\right)$. By₃₁₆ solving this, we obtain $E_{\text{des}} \le 0.16 \text{ eV}$, which agrees with³¹⁷ 297 298 318 $E_{\text{des}} = 0.06 \text{ eV}$ from previous reports [12, 13]. 299 319

300

Delay-time spectra

320

321

322

323

Figure 5(a) shows the delay-time spectrum at $T_{\rm s} = 303_{324}$ 301 K. The intervals of the second pump light pulses were₃₂₅ 302 2.00×10^{-4} s. During the measurement, spectra with and 326 303 without the second pump light were acquired by switch-327 304 ing the second pump light repeatedly using a shutter.328 305 The delay-time spectrum was obtained by subtracting₃₂₉ 306 the latter from the former. For this measurement, the₃₃₀ 307 temperature of the Rb oven of the beam source was set_{331} 308 to 453 K, which was 60 K higher than that used for the₃₃₂ 309 low-temperature measurement, to achieve higher signal₃₃₃ 310 intensity. As a result, the signal intensity was enhanced₃₃₄ 311 by a factor of ~ 20 . The feature at $0-1.0 \times 10^{-5}$ s is at-335 312 tributed to the second pump light, which partially pene-336 313

FIG. 5. Delay-time spectra (a) at 303 K taken with a highintensity Rb beam and long repetition period (b) at 305, 153, and 123 K. Dots with error bars represent the experimental data and solid lines represent the simulation results.

trated the interference filter, and the fluorescence of the incident atoms; this is excluded from the intensity integration discussed below. The time origin was defined by the rising edge of the second pump light-derived feature. The feature peaking at around 2×10^{-5} s was attributed to the enhanced fluorescence of scattered atoms caused by the second pump light. The peak area obtained by integrating the intensity in the region 1.0×10^{-5} - 1.89×10^{-4} s and subtracting the average level of the region 1.89×10^{-4} - 1.94×10^{-4} s as the base level, which corresponds to the sum of the area of the regions represented by α and β in Fig. 5 (a), accounted for $91 \pm 5\%$ of the total signal intensity. Here, the total signal intensity is the sum of regions α , β , and γ . If we adopt the average level of the region $9.3 \times 10^{-5} - 9.8 \times 10^{-5}$ s as the base level, the integrated intensity in the region 1.0×10^{-5} - 9.3×10^{-5} s, which corresponds to the area of region α , accounts for $79 \pm 2\%$ of the total intensity. This implies that $79 \pm 2\%$ of the scattered atoms will contribute to the peak intensity in the delay-time spectra, if we regard the sum of the region $t < 9.3 \times 10^{-5}$ s as the peak intensity and adopt the average level of the region 9.3×10^{-5} -9.8×10^{-5} s as the base level. For the temperature-

dependence measurement, we used 1.00×10^{-4} s as the₃₈₁ 337 second pump light interval and subtracted the average of₃₈₂ 338 the region near the back edge of the time window from 339 the whole spectra, instead of subtracting the background 340 spectra taken without the second pump light. This dra-341 matically reduced the measurement time, which was es-342 sential to prevent Rb aggregation during measurements 343 at low temperatures. 344

Figure 5 (b) shows the delay-time spectra taken at 305, 153, and 123 K. The temperature of the Rb oven of the Rb beam source was set to 393 K. By cooling the tetra-₃₈₃ contane film from 305 to 123 K, the delay-time spectrum₃₈₄ shifted to the longer side and the mean delay time $\tau_{\rm M}$ in-₃₈₅ creased by $(7.0 \pm 3.2) \times 10^{-6}$ s from $(2.54 \pm 0.21) \times 10^{-5}_{386}$ to $(3.24 \pm 0.24) \times 10^{-5}$ s. Here, $\tau_{\rm M}$ is defined by

$$\tau_{\rm M} = \frac{\sum_i t_i I_i}{\sum_i I_i},\tag{11}$$

where t_i and I_i are the delay time and the intensity at the₃₈₇ 352 *i*th point, respectively. The uncertainty in $\tau_{\rm M}$ originates 353 from the uncertainty in I_i at each point, which is $\sqrt{I_i}$. 354 Data points in the region $6 \times 10^{-6} \le t_i < 9.3 \times 10^{-5}$ 355 s were included in the summation. The average of the 356 region 9.5×10^{-5} s $\leq t_i < 9.9 \times 10^{-5}$ s was adopted 357 as the base level. Intensities between 0 and 6×10^{-6} s, 358 which include the peak originating from the second pump 359 light, were not included in the summation. Because the 360 velocity distribution of the scattered beam also depends³⁸⁸ 361 on the film temperature [21], we cannot simply attribute³⁸⁹ 362 the increase in $\tau_{\rm M}$ to the increase in mean dwell time.³⁹⁰ 363 To evaluate the increase in TOF due to the change in³⁹¹ 364 velocity distribution, we simulated TOF spectra without³⁹² 365 taking the dwell time into account. 366 393

The simulation considered the TOF from the second³⁹⁴ pump light to the surface, and from the surface to the³⁹⁵ probe light. The velocity distribution $d_{\rm b}(v)$ of the inci-³⁹⁶ dent atoms, and the TOF distribution from the second³⁹⁷ pump light to the surface $D_{\rm b}(t, L_1)$, were calculated us-³⁹⁸ ing equations [21]

$$d_{\rm b}(v) = \frac{m^2}{2k_{\rm B}^2 T_{\rm b}^2} v^3 \exp\left(-\frac{mv^2}{2k_{\rm B}T_{\rm b}}\right),\qquad(12)_{_{402}}^{_{401}}$$

$$D_{\rm b}(t, L_1) = d_{\rm b}\left(\frac{L_1}{t}\right) \frac{\mathrm{d}}{\mathrm{dt}}\left(\frac{L_1}{t}\right) \tag{13}_{40}^{40}$$

$$= \frac{m^2 L_1^4}{2k_{\rm B}^2 T_{\rm b}^2 t^5} \exp\left(-\frac{m}{2k_{\rm B} T_{\rm b}} \left(\frac{L_1}{t}\right)^2\right), \ (14)_{406}^{405}$$

where $T_{\rm b}$ is the temperature of the incident beam deter-373 mined by the temperature of the capillary of the beam_{410} 374 source, v is the velocity of atoms, L_1 is the distance be-₄₁₁ 375 tween the second pump light and the surface along $\text{the}_{_{412}}$ 376 atomic beam direction, and t is the time. $T_{\rm b}$ was $453_{_{413}}$ 377 K, and L_1 was roughly estimated to be 1.8×10^{-3} m. 378 The distribution $d_{\rm s}(v_{\perp s})$ of the velocity component of 379 the scattered atoms perpendicular to the surface, which 380

are in thermal equilibrium with the film, and the TOF distribution $D_{\rm s}(t, L_2)$ are given by

$$d_{\rm s}(v_{\perp \rm s}) = \sqrt{\frac{2m}{\pi k_{\rm B} T_{\rm s}}} \exp\left(-\frac{m v_{\perp \rm s}^2}{2k_{\rm B} T_{\rm s}}\right),\tag{15}$$

$$D_{\rm s}(t, L_2) = d_{\rm s}\left(\frac{L_2}{t}\right) \frac{\rm d}{\rm dt}\left(\frac{L_2}{t}\right) \tag{16}$$

$$=\sqrt{\frac{2m}{\pi k_{\rm B}T_{\rm s}}}\frac{L_2}{t^2}\exp\left(-\frac{m}{2k_{\rm B}T_{\rm s}}\left(\frac{L_2}{t}\right)^2\right)$$
(17)

where $v_{\perp s}$ is the velocity component perpendicular to the film surface, and L_2 , which was estimated to be 1.42×10^{-3} m, is the height of the probe light from the film surface [21]. The total TOF spectrum S(t) is given by

$$S(t) = \frac{1}{w} \int_{t-w}^{t} dr \int_{0}^{r} ds \ u_{\rm b}(s, L_1) \\ \times u_{\rm s}(r-s, L_{\rm s}),$$
(18)

where

400

$$u_{\rm b}(t, L_1) = \int_0^\infty \frac{1}{\sqrt{2\pi\sigma_1^2}} \exp\left(-\frac{(x-L_1)^2}{2\sigma_1^2}\right) \times D_{\rm b}(t, x) dx,$$
(19)

$$u_{\rm s}(t, L_2) = \int_0^\infty \frac{1}{\sqrt{2\pi\sigma_2^2}} \exp\left(-\frac{(x-L_2)^2}{2\sigma_2^2}\right) \\ \times g_{\rm s}(t, x) dx,$$
(20)

where w is the duration of the second pump light and σ_1 and σ_2 are the $1/\sqrt{e}$ half width of the second pump light and probe light, respectively. σ_1 and σ_2 were 2.4×10^{-4} and 1.7×10^{-4} m, respectively.

The simulation results are indicated by solid lines in Fig. 5. The intensities of the simulation results were adjusted to fit the experimental results. The simulated TOF spectra are in good agreement with the experimental results. According to the simulation results at 305 K, the peak area calculated by integrating the spectral intensity between 1.0×10^{-5} and 9.3×10^{-5} s and subtracting the average of the region 9.3×10^{-5} - 9.8×10^{-5} s accounts for 81% of the total intensity, which is in good agreement with the experimental results shown in Fig. 5(a). The simulated mean TOF calculated from the region 0-9.3 $\times 10^{-5}$ s increased by 5.8×10^{-6} s from 2.48×10^{-5} to 3.06×10^{-5} s with cooling from 305 to 123 K. Here, the average of the region 9.5×10^{-5} s $< t_i < 9.9 \times 10^{-5}$ s was adopted as the base level. The experimentally observed shift of $\tau_{\rm M}$, which is $(7.0 \pm 3.2) \times 10^{-6}$ s, is the sum of the increase in mean dwell time and mean TOF. Therefore, the increase in mean dwell time induced by cooling can be obtained by subtracting the increase in the simulated mean TOF from the experimentally obtained increase in the mean delay time. Therefore, we can see from the experimental and simulation results that

$$\tau_{\rm s,t < 93 \ \mu s}(123 \ {\rm K}) - \tau_{\rm s,t < 93 \ \mu s}(305 \ {\rm K}) = (1.2 \pm 3.2) \times 10^{-6} \ {\rm s}, \qquad (21)$$

414 which means

418

$$\begin{aligned} \tau_{\rm s,t < 93 \ \mu s}(123 \ {\rm K}) &- \tau_{\rm s,t < 93 \ \mu s}(305 \ {\rm K}) \\ &\leq 4.4 \times 10^{-6} \ {\rm s.} \end{aligned} \qquad \begin{aligned} & \overset{460}{}_{461} \\ \end{aligned}$$

459

467

⁴¹⁵ Here, $\tau_{s,t < t_{max}}(T_s)$ is the mean dwell time of the scatter-⁴⁶³ ⁴¹⁶ ing component, with a delay time of less than t_{max} at a ⁴⁶⁴ ⁴⁶⁵ surface temperature of T_s .

Discussion

The discrepancy between our result ($\tau_{\rm s}(123 \text{ K})$ – 419 $\tau_{\rm s}(305~{\rm K}) \leq 4.4 \times 10^{-6}~{\rm s}$) and the value ($\tau_{\rm s}(123~{\rm K}) -$ 420 $\tau_{\rm s}(305~{\rm K}) = 6.7 \times 10^{-5}~{\rm s})$ obtained by substituting the⁴⁶⁹ 421 desorption energy $E_{\rm des} = 0.06$ eV [12, 13] and mean⁴⁷⁰ 422 dwell time $\tau_{\rm s} = 1.8 \times 10^{-6}$ s at T = 345 K [14] into⁴⁷¹ 423 Eq. (1) may be explained by assuming multiple scatter-⁴⁷² 424 ing components with different mean dwell times. Using473 425 the method described in this study, the scattering com-474 426 ponents with dwell times larger than 9.3×10^{-5} s is not⁴⁷⁵ 427 detected. In Ref. [14], on the other hand, the mean dwell⁴⁷⁶ 428 time was estimated based on the Larmor frequency shift⁴⁷⁷ 429 caused by the interaction with the surface and evanescent⁴⁷⁸ 430 pump light. 431

The reason for the difference in mean dwell times be-480 432 tween the scattering components can be attributed to⁴⁸¹ 433 differences in pre-exponential factors. It has been re-434 ported that a certain proportion of the incident atoms 435 penetrate the PDMS film, diffuse into the bulk, and des-482 436 orb from the surface [15], which makes the mean dwell 437 time about a million times larger than that calculated 438 from the desorption energy and film temperature. If the $_{asa}$ 439 diffusion barrier in the bulk is significantly smaller than 440 the desorption energy, the temperature dependence of the 441 diffusion time can be neglected so that the temperature 442 dependence of the mean dwell time is almost entirely de-443 termined by the desorption energy. By assuming that two⁴⁸⁵ 444 scattering components with different mean dwell times⁴⁸⁶ 445 exist, we can approximate the temperature dependence $^{\scriptscriptstyle 487}$ 446 of the mean dwell time as 447 489

$$\tau_{\rm s} = (1-p)\tau_1 \exp\left(\frac{E_{\rm des}}{k_{\rm B}T_{\rm s}}\right) + p\tau_2 \exp\left(\frac{E_{\rm des}}{k_{\rm B}T_{\rm s}}\right), \ (23)_{_{491}}^{_{490}}$$

where p is the proportion of scattering events with⁴⁹³ 448 longer mean dwell times, and τ_1 and τ_2 are the pre-449 exponential factors for the scattering events with shorter 450 and longer mean dwell times, respectively. We sup-497 451 pose that $\tau_2 \exp\left(\frac{E_{\rm des}}{k_{\rm B}T_{\rm s}}\right)$ is significantly larger than the⁴⁹⁸ 452 time window of 9.3×10^{-5} s and only the component₅₀₀ 453 with a shorter mean dwell time, which corresponds to_{501} 454 the first term in Eq. (23), contributes to the delay-502 455 time spectra. By substituting Eq. (1) into our re-503 456 sults $(\tau_{\rm s}(123 \text{ K}) - \tau_{\rm s}(305 \text{ K}) \le 4.4 \times 10^{-6} \text{ s})$, we obtain⁵⁰⁴ $0 < \tau_1 \le 1.6 \times 10^{-8} \text{ s}$. From $\tau_2 \exp\left(\frac{E_{\rm des}}{k_{\rm B}T_{\rm s}}\right) \gg 9.3 \times 10^{-5}{}^{505}_{506}$ 457 458

s at $T_{\rm s} \leq 305$ K, we get $\tau_2 \gg 9.47 \times 10^{-6}$ s. By substituting $\tau_{\rm s} = 1.8 \times 10^{-6}$ s at 345 K [14] and $E_{\rm des} = 0.06$ eV [12, 13] into Eq. (23), $p = \frac{2.4 \times 10^{-7} \rm s - \tau_1}{\tau_2 - \tau_1}$. From $0 < \tau_1$ and $\tau_2 \gg 9.47 \times 10^{-6}$ s, p < 0.025, which means that the component with a shorter mean dwell time is the major component. This is consistent with the fact that the observed 79 ± 2 % fraction within 9.3×10^{-5} s is nearly the same as the 81 % fraction obtained from the simulation without dwell times.

CONCLUSIONS

Scattering of Rb atoms on tetracontane surfaces was investigated. No significant spin relaxation was observed with a single scattering process down to 123 K. The temperature evolution of delay time showed that the increase in mean surface dwell time induced by cooling from 305 to 123 K was less than 4.4×10^{-6} s. Taken together, the results indicate the existence of multiple scattering sites. The pre-exponential factor τ_0 of the minor components is at least three orders of magnitude larger than that of the major component, which means that the mean dwell time of the minor scattering components is at least three orders of magnitude larger than that of the major component.
