January 2, 2025

Abstract

We introduce an ensemble learning method based on Gaussian Process Regression (GPR) for predicting conditional expected stock returns given stock-level and macro-economic information. Our ensemble learning approach significantly reduces the computational complexity inherent in GPR inference and lends itself to general online learning tasks. We conduct an empirical analysis on a large cross-section of US stocks from 1962 to 2016. We find that our method dominates existing machine learning models statistically and economically in terms of out-of-sample R -squared and Sharpe ratio of prediction-sorted portfolios. Exploiting the Bayesian nature of GPR, we introduce the mean-variance optimal portfolio with respect to the prediction uncertainty distribution of the expected stock returns. It appeals to an uncertainty averse investor and significantly dominates the equal- and value-weighted prediction-sorted portfolios, which outperform the S&P 500.

Keywords: empirical asset pricing, Gaussian process regression, portfolio selection, ensemble learning, machine learning, firm characteristics

1 Introduction

A central problem of empirical asset pricing is the prediction of conditional expected stock returns given the information set of market participants.¹ Conditional expected returns are notoriously hard to predict, for a number of reasons. First, financial markets are very noisy and exhibit a low signal-to-noise ratio when compared to other domains such as computer vision, which is arguably due to the efficiency of the markets. Second, the full information set is not observable and likely too complex to model. The literature has accumulated a non-exhaustive list of predictive stock-level characteristics and macro-economic variables, which continuously increase. Third, the relation between predictors and returns is evidently non-linear and time-varying due to the dynamically evolving economic conditions, which further complicates the problem.

Over the years, a wide range of methods have been proposed to improve the prediction performance, from traditional statistical methods (Welch and Goyal [2008], Koijen, Moskowitz, Pedersen, and Vrugt [2018] etc.) to the modern machine learning methods (Gu, Kelly, and Xiu [2020], Chen, Pelger, and Zhu [2022], Gu, Kelly, and Xiu [2021] etc.). Interest in machine learning methods for empirical asset pricing has grown tremendously in academic finance and the industry. The leading example in this vein is Gu et al. [2020], who outline a new research agenda marrying machine learning with empirical asset pricing. They compare several machine learning methods for predicting stock returns, namely linear regression, generalized linear models with penalization, random forests, and neural networks. Other recent studies, such as Chen et al. [2022], Gu et al. [2021], further explore machine learning methods for empirical asset pricing, which are primarily based on neural networks. These articles provide empirical evidence that neural networks can significantly improve the predictive performance over traditional statistical methods and thus improve our empirical understanding of stock returns. However, focusing exclusively on prediction performance often overlooks an equally important aspect, the uncertainty inherent in these predictions. Quantifying uncertainty plays a significant role in finance when it comes to making decisions. Capturing uncertainties is crucial and has significant implications because the quality of our predictions directly impacts the quality of applications we build upon these predictions, for example, portfolio selection, hedging, or speculation.

This paper adopts a broader perspective, stepping back from the traditional “horse race” to improve prediction accuracy. Instead, it leverages kernel methods in machine learning, particularly Gaussian process regression (GPR), for predicting conditional expected stock returns given observable stock-level characteristics and macroeconomic variables. As a Bayesian non-parametric method, the predictions from a GPR model naturally come along with a predictive distribution. In particular, it gives confidence intervals for the predicted conditional expected returns. As a novel application, we harness these uncertainty estimates by incorporating in portfolio construction, showcasing the methodological advantages of GPR over conventional machine learning models, which often give point estimates of return without any quantification of uncertainty.²

¹Conditional expected returns in excess of the risk-free rate are also referred to as risk premium.

²The standard error estimates of some of the machine learning algorithms are available in the literature. For

Our paper makes several methodological and empirical contributions. First, while Gu et al. [2020] study generalized linear models with nonlinear transformations of the original features, they restrict these transformations to second order splines. As such they miss the full range of kernel ridge regression, which comes with a strong mathematical framework and constitutes a powerful machine learning method that works well on medium data sizes. Gaussian processes provide an alternative view on kernel ridge regression, by modeling a distribution over functions and performing inference directly in function space.³ We bridge the gap in Gu et al. [2020] and establish a link between two significant and growing research areas, kernel methods in machine learning and empirical asset pricing in financial economics. Thus, we contribute to the emerging literature on machine learning for empirical asset pricing.

Second, as mentioned earlier, being a Bayesian method, the predictions from a GPR model come along with a predictive distribution. As a novel application, we harness these uncertainty estimates. We find that incorporating uncertainty in portfolio construction leads to substantial statistical and economic improvements in terms of out-of-sample R -squared and Sharpe ratio of prediction-sorted portfolios, respectively. More precisely, we first use the predictive covariance matrix to construct a minimum uncertainty-weighted (UW) decile portfolio in the spirit of a global minimum variance portfolio. We find that the UW portfolio delivers a significantly high out-of-sample predictive pooled R -squared, R_{pool}^2 , that outperforms the two traditional portfolios, namely, equal-weighted (EW) and value-weighted (VW). Motivated by this finding, we further exploit the predictive covariance matrix and introduce two new portfolios. The first is a prediction-weighted portfolio, originally proposed by Kaniel, Lin, Pelger, and Van Nieuwerburgh [2022], which takes advantage of the ranking (to form decile portfolios) and the relative strengths of the predictions. The second is a prediction-uncertainty-weighted (PUW) portfolio in the spirit of the mean-variance optimal portfolio that gives more weight to stocks with higher predicted returns and minimizes uncertainty at the same time, which appeals to an uncertainty averse investor. We find that PW and PUW portfolios generate large economic gains, in terms of Sharpe ratio, compared to EW and VW portfolios.

Third, a well-known issue with implementing GPR is the need to invert the kernel matrix repeatedly for the computation of the marginal log-likelihood function, which has a fundamental time complexity of the order $O(N^3)$, where N is the size of the training sample. This limitation prohibits, both in time and memory space, using GPR for large datasets. To tackle this computational

instance, Giordano, Rocca, and Perna [2002] investigate using the AR-Sieve bootstrap method to estimate the standard error of the sampling distribution of the neural network predictive values in a regression model with dependent errors. Farrell, Liang, and Misra [2021] use a semi-parametric framework to provide non-asymptotic high-probability bounds for neural network predictions. The estimates of standard error predictions from random forests and LASSO are obtained by Wager, Hastie, and Efron [2014], and Casella, Ghosh, Gill, and Kyung [2010] respectively. Although, these articles attempt to estimate prediction uncertainties, they are either computationally expensive or lack the theoretical rigor of GPR.

³Gaussian processes are powerful mathematical objects that have enjoyed success in many practical applications. Gaussian processes have very close connections to other regression techniques, such as kernel ridge regression, support vector machines and linear regression with radial basis functions. Gaussian process provide a mathematical framework for many well-known models, including Bayesian linear models, spline models, and large neural networks (under suitable conditions), see Williams and Rasmussen [2006].

bottleneck of GPR, we introduce an easy-to-implement ensemble learning method in the spirit of the mixture-of-experts approach. Specifically, we partition the large training sample into subsets, apply individual GPRs on all subsets in parallel, and obtain a predictive distribution conditional on the full training data by mixing the predictive distributions over the subsets. This also addresses one of the concerns associated with neural networks in financial applications. Neural networks thrive in data-rich environments. With so many parameters to learn, they require massive training data and are computationally costly to train. Much of the literature on neural networks in empirical asset pricing focuses on monthly returns of a large cross-section of stocks spanning several decades. It is questionable whether neural networks would perform reasonably when restricted to smaller training sets, such as single industry sectors, or the S&P 500. Such samples only have a few thousand data points, which seems unsuitable for neural networks. What’s more, neural networks hardly adapt to online learning, so one has to retrain the whole network when new data arrives.⁴ In other words, neural networks are computationally intensive and hence not scalable in scenarios where data comes in sequentially, as with financial data. In contrast, our ensemble learning approach offers several benefits: (i) it allows a straightforward parallel implementation of GPR on small training subsets, thus reducing the computational cost; (ii) it scales well with sample size and naturally lends itself to an online learning framework; and (iii) its data-driven mixing weight scheme takes into account the non-stationarity and heteroscedasticity present in the financial data.

Fourth, our empirical analysis confirms the insights from the growing literature that machine learning methods have excellent potential to predict conditional expected returns. In particular, we show that a simple GPR model with very few hyperparameters outperforms the benchmark models, both statistically and economically, in terms of the out-of-sample R -squared and Sharpe ratio of the prediction-sorted portfolios, respectively. Concretely, we conduct an extensive empirical analysis, investigating monthly returns of a large cross-section of US stocks from 1962 to 2016. Our features include 94 time-varying stock-specific characteristics. We compare the performance of our GPR model with a non-linear kernel against linear benchmark models. Specifically, ensemble GPR with an affine kernel, ensemble linear regression, and standard linear regression. We find that our model outperforms, out-of-sample, these benchmarks in predicting individual stock returns. In particular, our model generates an R_{pool}^2 of 0.96% compared to 0.74% for the ensemble GPR model with affine kernel, 0.61% for the ensemble linear regression model and 0.37% for the one-batch linear regression. We also evaluate the predictive performance of our model based on two alternative metrics. The first is the time average of the monthly R -squared, R_{avg}^2 , which gives equal weight to every month, in contrast to R_{pool}^2 , which places more weight on months with larger cross sections. The second is the information coefficient (IC), which quantifies the model’s ability to differentiate the relative performance among stocks disregarding the absolute levels of predictions. We find that R_{avg}^2 and IC are 0.58% and 7.3% for our model.

We also assess our model’s predictive performance at the portfolio level. In particular, we form decile portfolios (bottom $D1$ to top $D10$) sorted on out-of-sample stock return predictions from our

⁴Gu et al. [2020] re-fit the neural network once every year.

model. Our UW portfolios achieve a higher R -squared than EW and VW portfolios for each decile. Further, when assessed over the grand panel of all decile portfolios, UW generates a R_{pool}^2 of 12.8% compared to 8.17% and 2.94% for EW and VW. The more pronounced predictive power of the UW portfolio shows that reducing prediction uncertainty is economically significant. We also find that the economic gains from the decile portfolios constructed using our predictions are large in terms of Sharpe ratio. For example, the long-short portfolio from PUW with uncertainty aversion value 20 yields an annualized out-of-sample Sharpe ratio of 3.66, which compared to 3.68 from PW, however, at a significantly lower volatility. Moreover, it outperforms the Sharpe ratios of 3.18 (EW) and 1.12 (VW), which confirms that reducing prediction uncertainty matters economically. Further, our prediction uncertainty based portfolios outperform the corresponding portfolios from the linear benchmark models.

We find that the most important features are related to liquidity, which includes variables such as bid-ask spread (baspread), dollar volume (dolvol), turnover volatility (SD turn), Amihud illiquidity (ill), and recent price trends, including short-term reversal (mom1m and mom6m), stock momentum (mom12m), momentum change (chmom), and long-term reversal (mom36m). In general, we find that our model is inclusive and extracts predictive information from a wide range of features. We also investigate the cross-sectional heterogeneity in predicted returns and prediction uncertainty. We find that stocks with high predicted returns tend to be less liquid, and stocks with high prediction uncertainty are the ones with limits to arbitrage frictions and that exhibit extreme illiquidity. Stocks with higher predicted returns have a higher 6-month (mom6m) and 12-month (mom12m) momentum and a lower 1-month (mom1m) momentum, which suggests momentum over longer horizons and reversal over short horizons.

In sum, our paper confirms the great potential of machine learning for predicting conditional expected returns. We contribute to this understanding by adding prediction uncertainty, which greatly improves the performance of prediction-sorted portfolios.

Our paper contributes to the fast emerging literature on machine learning for empirical asset pricing.⁵ In their pioneering work, Gu et al. [2020] conduct a comparative study of several machine learning methods to predict the grand panel of individual stock returns from the US markets and demonstrated the advantages of machine learning methods over traditional approaches. Similar studies are performed for European stock markets, Drobetz and Otto [2021], and bond markets, Bianchi, Büchner, and Tamoni [2021]. Gu et al. [2021] use an autoencoder neural network to demonstrate that imposing economic structure on a machine learning algorithm can substantially improve the estimation. In the same spirit, Chen et al. [2022] use deep neural networks with the fundamental no-arbitrage condition as a criterion function to estimate an asset pricing model for individual stock returns. These articles, however, exclude the important class of kernel-based

⁵The literature on traditional empirical asset pricing can essentially be divided into two broad categories: time-series and cross-sectional prediction models. For the former see, e.g., Welch and Goyal [2008], Kojen et al. [2018] and references therein. Cross-sectional models aim at explaining differences in the cross-section of stock returns and do so by regressing returns on stock-level characteristics, e.g., past returns, turnover etc., and macro-economic variables. See, e.g., Fama and French [2008] and references therein. The main limitation of these traditional regression models is their incapability of incorporating a large number of features and non-linear dependencies.

models. We bridge this gap and show that our simple ensemble method based on GPR dominates the performance of their best benchmark models, which are based on neural networks. Our model leads to a better out-of-sample predictive R -squared, and further taking into account the estimates of the prediction accuracy leads to better portfolio performance in terms of Sharpe ratio.

The adoption of GPR in finance is only recent, albeit GPR has demonstrated much success outside of finance under the name of kriging. Williams and Rasmussen [2006] provide an extensive background on GPR models and highlight its applications in various fields. For instance, they emphasize that Gaussian processes can be viewed as a Bayesian non-parametric generalization of well-known econometrics techniques. In particular, a time series model, $AR(p)$, is a discrete-time equivalent of a Gaussian process model with Matérn covariance functions with an appropriate hyperparameter choice. Han, Zhang, and Wang [2016] combine Gaussian process state space models with stochastic volatility models and propose a GPR stochastic volatility (GPRSV) model to predict the volatility of the stocks returns. They also present an adjusted Markov Chain Monte Carlo to estimate their model and demonstrate, through empirical analysis, the superior predictive performance over the traditional GARCH and stochastic volatility models. De Spiegeleer, Madan, Reyners, and Schoutens [2018] show how GPR can be deployed to approximate the derivative pricing function, for instance, pricing of exotic options under advanced models. They also study the application of GPR in the fitting of sophisticated Greek curves and implied volatility surfaces. Their numerical findings suggest that GPR could deliver a speed-up of a factor of several magnitudes relative to other benchmark methods for respective problems. Cousin, Maatouk, and Rullière [2016] introduce shape-constrained Gaussian processes for yield-curve and credit default swaps (CDS) curve interpolation. Filipović, Pelger, and Ye [2022b] and Filipović, Pelger, and Ye [2022a] introduce an economically motivated kernel ridge regression method for estimating the yield and return curves of treasury bonds. Our paper seems to be the first that applies GPR to predicting conditional expected stock returns.

Our paper also contributes to the literature on scalable GPR. Our ensemble learning method complements existing approaches, such as inducing point methods Quinero-Candela and Rasmussen [2005] and subset of regressors (SoR) Silverman [1985], which approximate the kernel matrix using a reduced set of inducing points. Unlike inducing point methods, our ensemble learning approach does not rely on selecting a subset of points. Instead, it leverages the diversity of multiple Gaussian processes applied to different subsets of the data. Alternative approaches include Kronecker and Toeplitz methods, which exploit data structure to enable computationally efficient modeling for gridded or separable datasets (Wilson [2014]). These methods were further advanced in Wilson and Nickisch [2015], where the authors introduce Kernel Interpolation for Scalable Structured Gaussian Processes (KISS-GP), combining the inducing point framework with structure-exploiting techniques. This approach is extended in Wilson, Hu, Salakhutdinov, and Xing [2016] by integrating it with neural networks. More recently, Gardner, Pleiss, Weinberger, Bindel, and Wilson [2018] utilized GPU acceleration to perform efficient matrix computations for large-scale GPR. This GPU-based acceleration can also enhance our ensemble method, where each

individual Gaussian process model is implemented to take advantage of GPU computing.

The paper is organized as follows. Section 2 introduces the model framework and our ensemble learning approach. Section 3 contains our empirical analysis. Section 4 concludes. The appendix contains background material on Gaussian processes, on the kernel selection, and additional results.

2 Methodology

Consider a financial market consisting of assets i in discrete time $t = 0, 1, 2, \dots$, where t represents the end of a month. More specifically, we denote by \mathcal{I}_{t+1} the index set of assets i that exist during the period $[t, t + 1]$. At any time t , for any asset $i \in \mathcal{I}_{t+1}$, we observe the vector of predictor variables $x = x_{i,t}$ with values in a feature space \mathcal{X} consisting of asset i -specific characteristics and common macro-economic variables.

We denote by $r_{i,t+1}$ the excess log return (henceforth simply referred to as “return”, if there is no risk of confusion) of asset i over the period $[t, t + 1]$. Following Gu et al. [2020], we describe it as an additive prediction error model,

$$r_{i,t+1} = E_t(r_{i,t+1}) + \epsilon_{i,t+1}, \quad (1)$$

where E_t denotes the conditional expectation given the information available at time t . The errors $\epsilon_{i,t+1}$ are due to market imperfections and idiosyncratic noise. We assume that the conditional expected return is given by a common function $f : \mathcal{X} \rightarrow \mathbb{R}$,

$$E_t(r_{i,t+1}) = f(x_{i,t}), \quad \text{for all } i \in \mathcal{I}_{t+1} \text{ and } t. \quad (2)$$

At any given time t , our goal is to learn f from past data $\mathcal{D} = \{(x_{i,j-1}, r_{i,j}), i \in \mathcal{I}_j, j = 1, 2, \dots, t\}$, and then predict next period conditional expected returns, $\hat{r}_{i,t+1} = f(x_{i,t})$, for $i \in \mathcal{I}_{t+1}$. We assume that the function f does neither directly depend on the index i nor time t , so that it can be learned efficiently using all instances in the panel data set \mathcal{D} .

2.1 Ensemble learning method based on Gaussian process regression

We use Gaussian process regression (GPR) to learn the function f in (1) and (2). Thereto we assume that f is a Gaussian process with some pre-specified prior mean function $m(\cdot)$ and covariance function, or, kernel $k(\cdot, \cdot)$. We assume that the errors $\epsilon_{i,t+1}$ are i.i.d. Gaussian random variables with mean 0 and variance σ_ϵ^2 and independent of f . This means that the joint distribution of the past returns $\mathbf{r}_{1:t} = \{r_{i,j}, i \in \mathcal{I}_j, j = 1, 2, \dots, t\}$ and the conditional expected returns $f(\mathbf{x}_t) = \{f(x_{i,t}), i \in \mathcal{I}_{t+1}\}$ is Gaussian of the form

$$\begin{pmatrix} \mathbf{r}_{1:t} \\ f(\mathbf{x}_t) \end{pmatrix} \sim \mathcal{N} \left(\begin{pmatrix} m(\mathbf{x}_{0:t-1}) \\ m(\mathbf{x}_t) \end{pmatrix}, \begin{pmatrix} k(\mathbf{x}_{0:t-1}, \mathbf{x}_{0:t-1}) + \sigma_\epsilon^2 I & k(\mathbf{x}_{0:t-1}, \mathbf{x}_t) \\ k(\mathbf{x}_t, \mathbf{x}_{0:t-1}) & k(\mathbf{x}_t, \mathbf{x}_t) \end{pmatrix} \right), \quad (3)$$

where I is the identity matrix, and $\mathbf{x}_{0:t-1} = \{x_{i,j-1}, i \in \mathcal{I}_j, j = 1, 2, \dots, t\}$ and $\mathbf{x}_t = \{x_{i,t}, i \in \mathcal{I}_{t+1}\}$ denote the arrays of features observed by time $t - 1$ and at t , respectively. Here, for a function $g : \mathcal{X} \rightarrow \mathbb{R}$ and an array $\mathbf{x} = \{x_i\}$ of points in \mathcal{X} , we denote by $g(\mathbf{x}) = \{g(x_i)\}$ the corresponding array of function values. In particular, $k(\mathbf{x}_{0:t-1}, \mathbf{x}_{0:t-1})$ is the $N \times N$ matrix of the covariances evaluated at all pairs of the past features $\mathbf{x}_{0:t-1}$, where $N = \sum_{j=1}^t |\mathcal{I}_j|$ denotes the size of the sample. Similarly, $k(\mathbf{x}_{0:t-1}, \mathbf{x}_t)$ is the $N \times |\mathcal{I}_{t+1}|$ matrix of the covariances evaluated at all pairs of the past features $\mathbf{x}_{0:t-1}$ and current features \mathbf{x}_t .

The predictive (posterior) distribution of f given the data \mathcal{D} is again Gaussian with mean and covariance functions given by

$$\hat{m}(x) = m(x) + k(x, \mathbf{x}_{0:t-1}) (k(\mathbf{x}_{0:t-1}, \mathbf{x}_{0:t-1}) + \sigma_\epsilon^2 I)^{-1} (\mathbf{r}_{1:t} - m(\mathbf{x}_{0:t-1})), \quad (4)$$

$$\hat{k}(x, x') = k(x, x') - k(x, \mathbf{x}_{0:t-1}) (k(\mathbf{x}_{0:t-1}, \mathbf{x}_{0:t-1}) + \sigma_\epsilon^2 I)^{-1} k(\mathbf{x}_{0:t-1}, x'). \quad (5)$$

The mean $\hat{m}(\mathbf{x}_t)$ is then our prediction of the conditional expected return vector \mathbf{r}_{t+1} , and $\hat{k}(\mathbf{x}_t, \mathbf{x}_t)$ represents the covariance of the Bayesian uncertainty of our prediction.

In our empirical analysis, we assume that errors $\epsilon_{i,t+1}$ are economically non-significant with a small fixed variance of $\sigma_\epsilon^2 = 10^{-10}$. This may seem at odds with the anecdotal low signal-to-noise ratio of stock returns. But we can argue that the Bayesian uncertainty of our predictor also adds noise to the signal, which here is the true conditional expected returns. On the other hand, adding $\sigma_\epsilon^2 I$ to the kernel matrix $k(\mathbf{x}_{0:t-1}, \mathbf{x}_{0:t-1})$ has nevertheless a regularizing effect, as the latter may be ill-conditioned. We further set the prior mean function $m(\cdot)$ equal to zero. This is motivated by the empirical fact that zero predictions perform better than the historical mean of excess log returns, see Gu et al. [2020]. Moreover, it is well documented in the literature that a zero prior mean usually works well for GPR, see De Spiegeleer et al. [2018], Williams and Rasmussen [2006].

The kernel $k(\cdot, \cdot)$ of the prior distribution of f in (3) depends on hyperparameters, which are estimated from the training data by maximizing the marginal log-likelihood, given by

$$\log p(\mathbf{r}_{1:t} | \mathbf{x}_{0:t-1}) = -\frac{N \log(2\pi)}{2} - \frac{\mathbf{r}_{1:t}^\top (k(\mathbf{x}_{0:t-1}, \mathbf{x}_{0:t-1}) + \sigma_\epsilon^2 I)^{-1} \mathbf{r}_{1:t}}{2} - \frac{\log \det(k(\mathbf{x}_{0:t-1}, \mathbf{x}_{0:t-1}) + \sigma_\epsilon^2 I)}{2}. \quad (6)$$

A known challenge in GPR is that the computation of the log-likelihood function (6) involves repeated inversion of the regularized kernel matrix, which takes time of the order $O(N^3)$. This is only feasible for a small N (less than several thousand), which is not the case for the problem at hand for which N is of the order of millions.

We tackle the computational bottleneck of GPR and introduce an ensemble learning approach in the spirit of the mixture-of-experts method.⁶ Thereto, we partition the training data into subsets,

⁶Alternative ensemble learning approaches proposed in the literature include the product of GP experts in Ng and Deisenroth [2014], the generalised product of experts in Cao and Fleet [2014], the Bayesian Committee Machine in Tresp [2000], the robust Bayesian Committee Machine in Deisenroth and Ng [2015], and Distributed Kriging (DISK)

apply a GPR on each subset in parallel, and obtain a predictive distribution conditional on the full training data by mixing the predictive distributions over the subsets. In contrast to ad hoc partitioning schemes used in the literature, such as random or clustering based partitioning, we use that our training data is naturally divided into monthly subsets. That is, we treat data from each month $j = 1, 2, \dots, t$ as a training subset on which we train an individual Gaussian process $f^{(j)}$. Specifically, we estimate hyperparameters by maximizing the log-likelihood function (6), and obtain the predictive Gaussian distribution of $f^{(j)}$ with mean and covariance functions $\hat{m}^{(j)}(\cdot)$ and $\hat{k}^{(j)}(\cdot, \cdot)$ as in (4) and (5), with the training data $\{\mathbf{x}_{0:t-1}, \mathbf{r}_{1:t}\}$ replaced by $\{\mathbf{x}_{j-1}, \mathbf{r}_j\}$.

Finally, we obtain the predictive distribution conditional on the full training data by mixing the individual predictive Gaussian distributions of $f^{(j)}(\mathbf{x}_t)$ using some weights $w_j \geq 0$ with $\sum_j w_j = 1$. The mean vector and covariance matrix of this Gaussian mixture distribution are given by

$$\hat{\mathbf{r}}_{t+1} = \sum_j w_j \hat{m}^{(j)}(\mathbf{x}_t), \quad (7)$$

$$\hat{\Sigma}_{t+1} = \sum_j w_j \hat{\mathbf{M}}_{t+1}^{(j)} - \hat{\mathbf{r}}_{t+1} \hat{\mathbf{r}}_{t+1}^\top, \quad (8)$$

where $\hat{\mathbf{M}}_{t+1}^{(j)} = \hat{k}^{(j)}(\mathbf{x}_t, \mathbf{x}_t) + \hat{m}^{(j)}(\mathbf{x}_t) \hat{m}^{(j)}(\mathbf{x}_t)^\top$ denotes the second order moment matrix of $f^{(j)}(\mathbf{x}_t)$. The mean $\hat{\mathbf{r}}_{t+1}$ is our ensemble prediction of the conditional expected return vector \mathbf{r}_{t+1} , and $\hat{\Sigma}_{t+1}$ represents the covariance of the Bayesian uncertainty of our prediction.

For our empirical analysis, we implement the following two mixing weight schemes:

- (i) Equal weights: we select the $K_t \leq t$ most recent training months (more details on the choice of K_t follow in the next subsection), set $w_j = 0$ for $j \leq t - K_t$, and apply equal weights $w_j = 1/K_t$ to the GPR models $j = t - K_t + 1, \dots, t - 1, t$. The sums in (7) and (8) are effectively over $j = t - K_t + 1, \dots, t - 1, t$.
- (ii) MSE weights: as above we select the $K_t \leq t$ most recent training months and set $w_j = 0$ for $j \leq t - K_t$. We also hold out the most recent training month, $w_t = 0$, which we call *calibration* month, and define the weights for the remaining $K_t - 1$ months as proportional to the mean squared error

$$MSE_j = \frac{1}{|\mathcal{I}_t|} \sum_{i \in \mathcal{I}_t} (r_{i,t} - \hat{r}_{i,t}^{(j)})^2,$$

of GPR model j on the calibration month t with corresponding predicted returns $\hat{r}_{i,t}^{(j)} =$

in Guhaniyogi, Li, Savitsky, and Srivastava [2017]. The product of experts approach obtains the joint prediction by the product of all predictions from trained GPR models, while the generalized product of experts approach adds the flexibility by assigning weights to the contributions from independent GPR models thus increasing/reducing their importance. These approaches are further generalized in the Bayesian Committee Machine and the robust Bayesian Committee Machine, where the GP priors are explicitly incorporated when combining predictions. In contrast to these product of experts approaches, Distributed Kriging obtains the combined predictions as the Wasserstein barycenter of the subset posterior distributions.

$\hat{m}^{(j)}(x_{i,t-1})$. The MSE weights are thus given by

$$w_j = \frac{1/MSE_j}{\sum_{s=t-K_t+1}^{t-1} 1/MSE_s}, \quad j = t - K_t + 1, \dots, t - 2, t - 1.$$

That is, the smaller MSE_j the larger the weight w_j we give to GPR model j . The sums in (7) and (8) are effectively over $j = t - K_t + 1, \dots, t - 2, t - 1$.

Our ensemble learning approach has several advantages. First, it offers a substantial computational speed-up, due to a straightforward parallel implementation of the individual GPR models on subsets of the training data, compared to training a GPR model on the full training data. Second, the flexibility that each GPR model can have its own set of optimal hyperparameters (the parametric kernel is the same for each model) allows to account for the non-stationarity and heteroscedasticity present in the financial data. Third, our approach scales well with sample size and provides an online learning framework. This is in contrast to other sophisticated machine learning algorithms, which are hard to train recursively every month due to their high computational costs. Specifically, we only need to train one additional GPR model on the newly observed data from month $t + 1$ and combine it with the already trained GPR models on months $1, 2, \dots, t$ to obtain a mixed predictive distribution for the conditional expected returns \mathbf{r}_{t+2} .

2.2 Sample splitting: training, validation and test samples

The process of estimating hyperparameters, predicting, and evaluating the predictions requires the modeller to partition the full sample into training, validation and test samples. To achieve this goal, we conduct an empirical analysis of rolling and expanding schemes on the training and validation samples, and then use the scheme that performs best in terms of prediction accuracy on the validation sample, for our out-of-sample test data analysis.⁷

The underlying idea of the *rolling* scheme is to gradually shift the training and validation samples forward in time to include more recent data and exclude the oldest data points such that a fixed size of the rolling window is maintained. At each rolling step, one re-fits the model on the prevailing training and validation samples and obtains the predictions on the next test data, thus resulting in a sequence of performance measures, i.e., one corresponding to each window. Although this approach has the benefit that it can potentially leverage more recent data for predictions, it can significantly impact the performance of the model if the excluded data contains essential information, e.g., a financial crisis period. The *expanding* scheme also gradually includes more recent data points in the training and validation samples. But in contrast to the rolling scheme it retains the entire history in the training sample. In terms of the mixing weight schemes (i) and (ii),

⁷Another scheme, known as the fixed scheme, divides the sample into fixed training, validation, and test data, estimates the model once from the training and validation samples and makes predictions on the test sample. Although the fixed scheme is not very expensive in terms of the computation cost, it fails to capture the changes in the behaviour of data over time, thus affecting the model's performance.

we set $K_t = K$ for the rolling scheme, where K is a fixed constant, and $K_t = t$ for the expanding scheme.

2.3 Predictive performance evaluation

We evaluate the model performance in predicting conditional expected returns, using three measures. The first is the predictive out-of-sample pooled R -squared,

$$R_{pool}^2 = 1 - \frac{\sum_{t \in \mathcal{T}_3} \sum_{i \in \mathcal{I}_t} (r_{i,t} - \hat{r}_{i,t})^2}{\sum_{t \in \mathcal{T}_3} \sum_{i \in \mathcal{I}_t} r_{i,t}^2},$$

where \mathcal{T}_3 denotes the collection of test months. R_{pool}^2 provides a metric for the grand panel-level performance of the model by pooling the prediction errors across stocks and over time. Being a pooled performance measure, R_{pool}^2 places more weight on months with a comparatively larger cross-section of stocks. However, the size of the cross-section varies considerably across the sample, as shown in Figure 1. A monthly rebalancing portfolio manager is more concerned with the average monthly predictive performance.

Therefore, we also consider a second performance measure, the predictive out-of-sample average R -squared,

$$R_{avg}^2 = \frac{1}{|\mathcal{T}_3|} \sum_{t \in \mathcal{T}_3} R_t^2,$$

where R_t^2 denotes the R -squared for the predictions in month t ,

$$R_t^2 = 1 - \frac{\sum_{i \in \mathcal{I}_t} (r_{i,t} - \hat{r}_{i,t})^2}{\sum_{i \in \mathcal{I}_t} r_{i,t}^2}.$$

Both measures, R_{pool}^2 and R_{avg}^2 , compare our model predictions against the naive forecast of zero excess log returns and not against the historical mean excess log returns. This is because the latter are known to predict excess log returns worse than zero by a large margin, see Gu et al. [2020].

Investors can use our model to construct portfolios based on the predicted relative performance of the stocks. For example, a long-short investor will go long in top-ranked stocks and short in bottom-ranked stocks to earn the difference between the relative returns of the two buckets of stocks. The performance metrics, R_{pool}^2 and R_{avg}^2 , measure the extent to which the levels of predicted excess returns differ from realized excess returns and thus are not necessarily suitable for a long-short investor. Therefore, we consider a third performance measure, the information coefficient, defined as the average

$$IC = \frac{1}{|\mathcal{T}_3|} \sum_{t \in \mathcal{T}_3} \rho_t$$

of the cross-sectional Spearman's rank correlation coefficients between the realized excess returns

and predictions,

$$\rho_t = 1 - \frac{6 \sum_{i \in \mathcal{I}_t} d_i^2}{|\mathcal{I}_t|(|\mathcal{I}_t|^2 - 1)},$$

where d_i is the difference in ranks between the i th largest elements of $\{\hat{r}_{j,t}\}_{j \in \mathcal{I}_t}$ and $\{r_{j,t}\}_{j \in \mathcal{I}_t}$. The IC, originally proposed by Ambachtsheer [1974], is a widely used performance measure in investment management to measure predictive ability. It disregards the absolute levels, is less sensitive to outliers, and quantifies the model’s ability to differentiate the relative performance among stocks.

3 An empirical study of US equities

This section contains our empirical analysis. Section 3.1 describes the data and the steps we follow to prepare it for the empirical analysis. Section 3.2 discusses the model selection where we conduct a comparison study on the validation sample to select the model parameters for out-of-sample analysis, namely the sample splitting scheme, the mixing weight scheme to create an ensemble and the kernel. Section 3.3 contains the performance results of our model using statistical and economic criteria. Section 3.4 focuses on the cross-section insights of the model performance such as variable importance, the relationship between the features and the predicted returns, and the relationship between the features and the prediction uncertainty. Section 3.5 discusses residual analysis.

3.1 Data

We consider the monthly returns of approximately 30,000 individual stocks from the three major stock exchanges in the US, namely, NYSE, AMEX and NASDAQ. The data is collected from CRSP over a period spanning 55 years from February 1962 to December 2016. We use the monthly Treasury bill rate as a proxy for the risk-free rate to determine the excess simple return of a stock.

The literature on empirical asset pricing has constructed a large collection of features that help predict future stock returns. The conditioning information we use includes 94 stock-specific characteristics that is considered in Gu et al. [2020] and Gu et al. [2021].⁸ The stock-level characteristics pertain to several categories, including past returns, investment profitability, value, trading frictions etc. Thereof, 61 characteristics are updated annually, 13 are updated quarterly, and 20 are updated on a monthly basis. Since most characteristics are lagged in the sense that there is a delay in their release to the public, we follow the common conventions concerning the usage of these characteristics to avoid a forward-looking bias. More precisely, we assume that there is a lag of at most one month, four months and six months in the monthly, quarterly and annually reported characteristics respectively. Consequently, we predict the returns r_{t+1} over the period $[t, t + 1]$ as a function of the most recent publicly available characteristics at t . That is, we use the most

⁸Data is available on the homepage of Dacheng Xiu (<https://dachxiu.chicagobooth.edu/>).

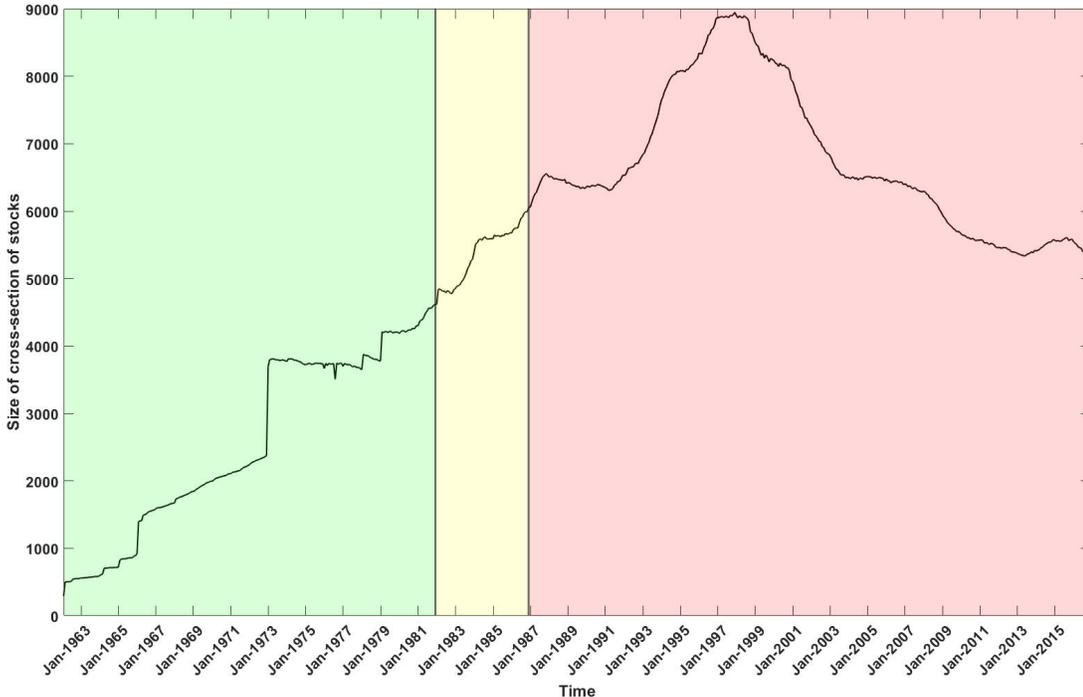

Figure 1: This figure shows the size of the cross-section of stocks in each month of the sample. The full sample is split into training sample (green), Feb 1962 to Dec 1981, validation sample (yellow), Jan 1982 to Dec 1986, and test sample (red), Jan 1987 to Dec 2016.

recent monthly, quarterly and annual characteristics at the end of the months $t - 1$, $t - 4$ and $t - 6$, respectively.

To prepare the data for empirical analysis, we apply transformations to the stock-specific characteristics. This is a common practice in machine learning since different features have different absolute scales, and some of them are highly skewed and leptokurtic. To address the difference in scale and remove the influence of outliers, at any time t , we standardize the non-missing values across any specific characteristic by subtracting the cross-sectional mean and dividing by the cross-sectional standard-deviation. We then replace the missing observations by zero.

3.2 Model selection

We divide the data into three consecutive non-overlapping samples while maintaining the temporal ordering of the data, as shown in Figure 1. The training sample, Feb 1962 to Dec 1981, is used to estimate the hyperparameters of the Gaussian process. The validation sample, Jan 1982 to Dec 1986, is used for model selection, that is, the kernel function, the mixing weight scheme, the sample splitting scheme (rolling or expanding), and the size of the rolling window if we adopt a rolling scheme. The test sample, Jan 1987 to Dec 2016, is then used to evaluate the performance of the selected model.

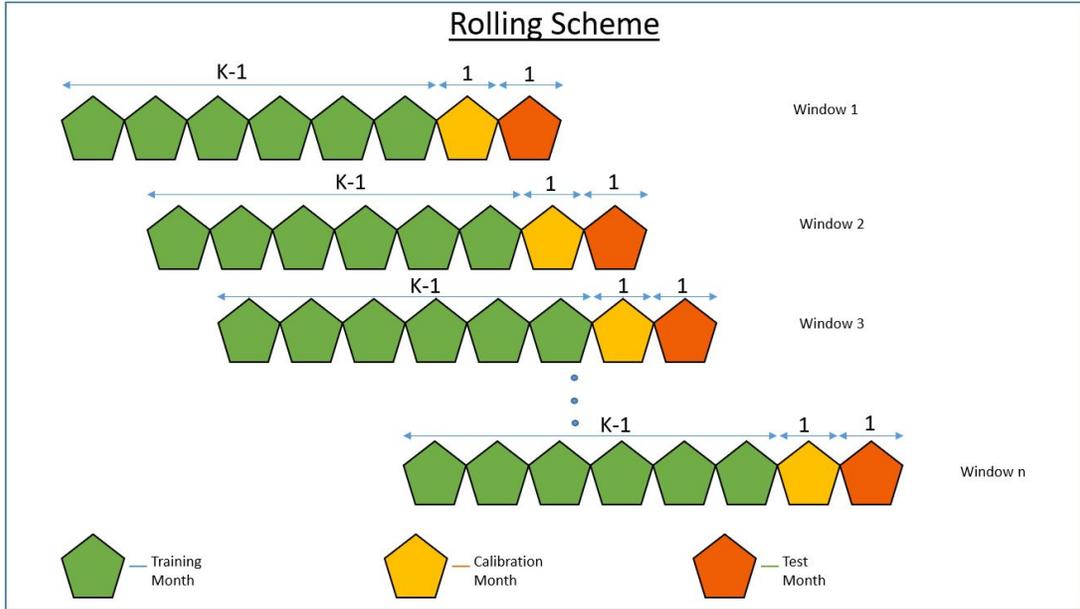

Figure 2: This figure describes the mechanism of the rolling scheme with training window, including a calibration month, of length K .

For model selection, we follow a data-driven approach and select the configuration, among all possible combinations, that performs best on the validation sample in terms of prediction accuracy, as measured by R_{pool}^2 . More specifically, we implement our ensemble method for both, rolling and expanding, schemes. In more detail, we apply the rolling scheme for different possible training window lengths $K = 2, \dots, 239$. That is, for the MSE weighting scheme (ii) and $K = 2$, we use Nov 1981 and Dec 1981 as training and calibration months, respectively, for the first test month, Jan 1982.⁹ Likewise, we choose Oct 1986 and Nov 1986, respectively, for the last test month, Dec 1986. Similarly, for the maximal possible $K = 239$, we use Feb 1962 to Nov 1981 as training months and Dec 1981 as calibration month for the test month Jan 1982, and shift each by one month for the next test month. This is illustrated in Figure 2. We also apply the expanding scheme, using the full training sample available for each test month. More specifically, we use Feb 1962 to Nov 1981 as training months and Dec 1981 as a calibration month for the test month Jan 1982, while we use Feb 1962 to Oct 1986 as training months and Nov 1986 as calibration month for the last test month Dec 1986. We follow a similar procedure for the equal weighting scheme (i) but without holding out a calibration month.

In preliminary experiments reported in the appendix with various kernels in predicting excess log returns over the validation period, we observe that the following three kernels outperformed

⁹For $K = 2$, as there is only one training month, the role of the calibration month is effectively redundant.

the others in terms of R_{pool}^2 ,

$$K_5(x, x') = \sigma^2 \left(1 + \frac{\|x - x'\|^2}{2\alpha\ell^2} \right)^{-\alpha}, \quad K_8(x, x') = \sigma^2 \left(1 + \frac{\|x - x'\|^2}{2\alpha\ell^2} \right)^{-\alpha},$$

$$K_{10}(x, x') = \sigma^2 \exp \left\{ - \left(\frac{\|x - x'\|}{\ell} \right)^\gamma \right\},$$

where $\sigma, \alpha, \ell > 0, \gamma \in (0, 2]$ are hyperparameters.¹⁰ We therefore report the validation analysis only for these kernels on simple excess returns. We note that σ is not relevant for the predictive mean in (4) but it is significant in quantifying the Bayesian uncertainty of our predictions, see (5).

Figure 3 shows R_{pool}^2 over the validation sample for MSE- and equal-weighting schemes against varying lengths K of the training window for the three kernels selected in the preliminary studies. The solid lines correspond to the rolling scheme, while the dotted lines represent R_{pool}^2 for the expanding scheme, which does not depend on K . There are several findings. First, we observe that both sample splitting and mixing weight schemes generate positive R_{pool}^2 for K large enough ($K > 30$). Second, the MSE weighted ensemble yields a larger R_{pool}^2 than the equal weighted. A possible explanation is the temporal non-stationarity of financial data. There are non-observable changing regimes such that the regime prevailing at any given month j is not explicitly captured by the observable features \mathbf{x}_{j-1} . But it is implicitly captured by the trained Gaussian process $f^{(j)}$ through its fitted hyperparameters and predictive distribution, given data $\{\mathbf{x}_{j-1}, \mathbf{r}_j\}$. The MSE-weighting scheme in turn gives more weight to a training month j the closer its regime is to the current regime prevailing in the calibration month. This results in a more accurate prediction than for equal weighting. Third, it is striking that incorporating the full available training sample, which is the expanding scheme, worsens the predictive performance; as the dotted lines are below the solid lines for both mixing weight schemes. This finding is in line with the bias-variance trade-off in machine learning, as our ensemble model complexity grows with the size of the training window. Fourth, for the rolling scheme, R_{pool}^2 is relatively more volatile for small K ($K < 50$) and becomes stable and provides considerably more consistent performance for large K ($K > 50$). Further, for $K > 50$, we observe a peak around $K = 100$, which motivates us to choose $K = 96$ as the window length for the rolling scheme.¹¹ Finally, the performance of the three kernels is similar to each other. We select K_{10} as the best kernel to do out-of-sample test. To conclude, based on the performance in the validation sample, we select the rolling scheme with training window length $K = 96$, the MSE-weighting scheme and the gamma exponential kernel for the out-of-sample test.

¹⁰The kernels K_8 and K_{10} are rational quadratic and γ -exponential kernels, the standard kernels from the literature. The kernel K_5 is a modified version of rational quadratic, we call it linear quadratic kernel.

¹¹The NBER's business cycle dating committee maintains a chronology of US business cycles, available on <https://www.nber.org/research/data/us-business-cycle-expansions-and-contractions>. During our sample period, the average length of a business cycle is around eight years, which is in line with our choice of $K = 96$.

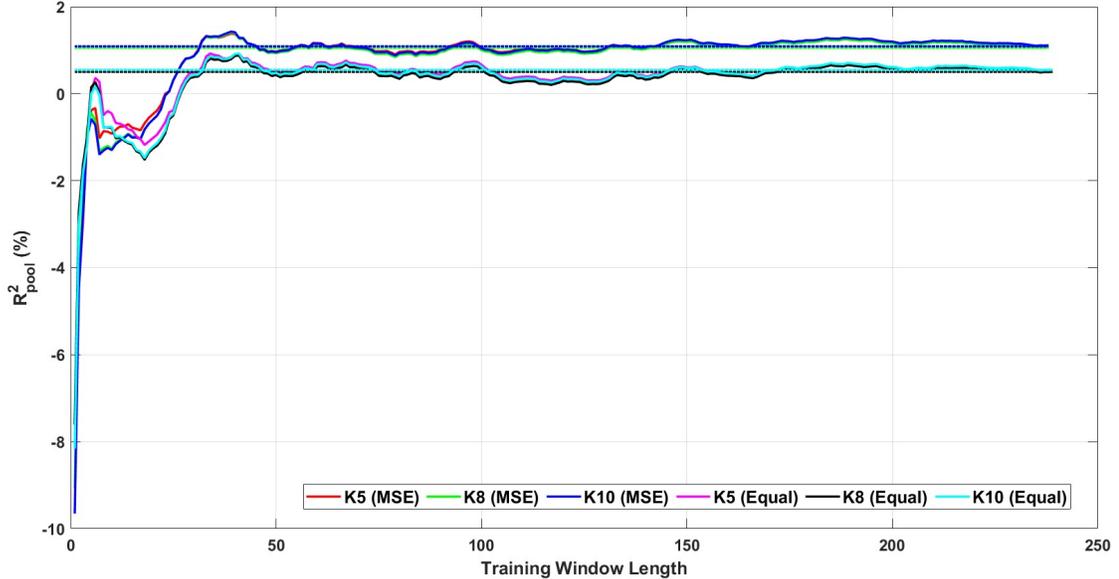

Figure 3: This figure presents R_{pool}^2 over the validation sample, Jan 1982 to Dec 1986 for MSE- and Equal- weighting scheme against the length of the training window.

3.3 Model performance

Having selected the model configuration, we now conduct our empirical analysis over the test sample. We first train $K - 1 = 95$ individual monthly GPR models, Jan 1979 to Nov 1986, compute MSE weights on the first calibration month, Dec 1986, and use these weights to get the predictive distribution for the returns in the first test month, Jan 1987. We proceed by induction and train one additional GPR model on Dec 1986, combine it with the already trained GPR models on the previous 94 months, Feb 1979 to Nov 1986, compute MSE weights on the next calibration month, Jan 1987, and predict returns on Feb 1987. We repeat this online learning procedure until the full test sample is exhausted, consisting of 360 test months until Dec 2016. We evaluate the predictive performance, both statistically and economically, in the following subsections.

3.3.1 Predictive performance across all stocks

We first evaluate the predictive performance of our ensemble GPR model, henceforth referred to as E-GPR (γ -exp), across all stocks and benchmark it against three linear models. The first benchmark, *E-GPR (affine)*, is an *ensemble GPR model with an affine kernel function*, defined as

$$K(x, y) = c_0 + c_1 x^\top y,$$

where $c_0, c_1 > 0$ are hyperparameters. The second benchmark, *ensemble linear regression (E-LR)*, adopts the ensemble GPR framework by fitting a separate linear regression for each training month. The third benchmark is *standard linear regression (LR)*, fitted using all available training data for

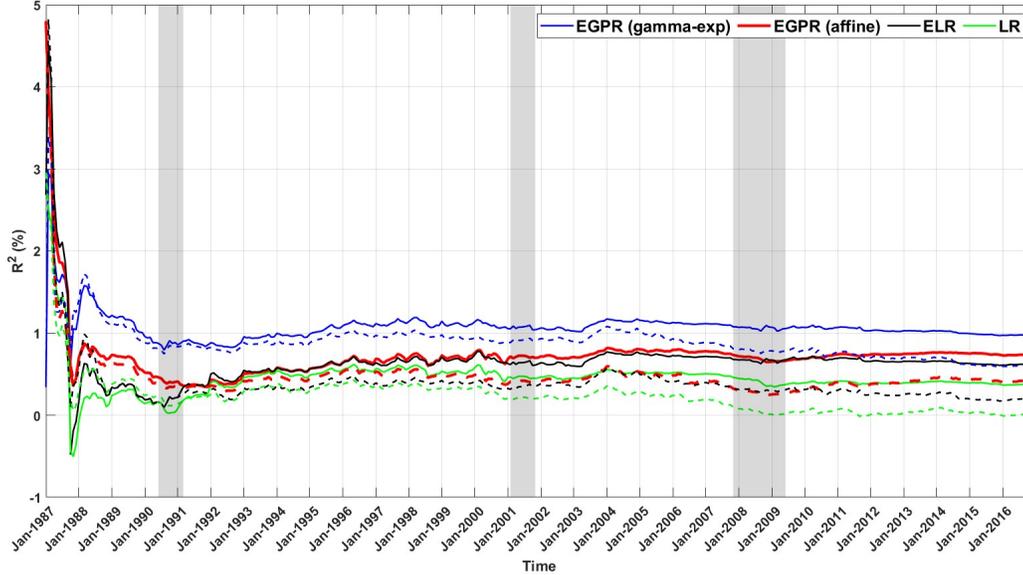

Figure 4: This figure shows the evolution of R^2_{pool} (solid lines) and R^2_{avg} (dotted lines) over an expanding test subsample for our model, E-GPR (γ -exp), against the linear benchmark models, E-GPR (affine), E-LR and LR. The shaded periods indicate NBER recessions.

Model	R^2_{pool} (%)	R^2_{avg} (%)
E-GPR (γ -exp)	0.96	0.58
E-GPR (affine)	0.74	0.42
E-LR	0.61	0.18
LR	0.37	0.003

Table 1: Comparison of predictive performance across all stocks, i.e., $R^2(\%)$, among various models each test month.

Figure 4 shows the out-of-sample performance in predicting the returns across time. It illustrates the evolution of R^2_{pool} (solid lines) and R^2_{avg} (dotted lines) across an expanding test sample for our model and the linear benchmark models.¹² For example, R^2_{pool} (R^2_{avg}) in Jan 2000 is the pooled R -squared (average R -squared) evaluated on the test sample, Jan 1987 to Jan 2000.

Further, Table 1 presents the final values of R^2_{pool} and R^2_{avg} for each model over the entire test sample. These final values correspond to the endpoints of the curves depicted in Figure 4.

There are several observations. The positive values of R^2_{pool} and R^2_{avg} over the expanding test subsample indicates that our model outperforms the zero predictions consistently over time. Moreover, our model achieves $R^2_{pool} = 0.96\%$ over the full test sample.¹³ The value $R^2_{avg} = 0.58\%$ over the full test sample further confirms the superior performance of our model. To assure that small stocks do not drive this unprecedented predictive performance, i.e., that our model is not

¹²We also plot the time series of monthly R -squared, R^2_t , from our model in Figure A.3 in the appendix.

¹³This is substantially greater than the corresponding numbers, 0.4% and 0.58%, for the neural network models in Gu et al. [2020] (Table 1 on Page 2250) and Gu et al. [2021] (Table 2 on Page 11), respectively.

simply picking up small-scale inefficiencies driven by illiquidity, we also measured R_{pool}^2 on two test subsamples. The first consists of the top-1,000 stocks and the second of the bottom-1,000 stocks by market capitalization each month. The values of R_{pool}^2 for the two subsamples are 0.73% and 1.34%, respectively. This is indicative that our model is capable of capturing the systematic structure in the large-cap as well as small-cap stocks, although the performance is slightly better for the small-cap stocks.

Compared to the linear benchmark models, we observe a significant improvement in prediction accuracy when employing the non-linear kernel instead of the affine kernel. Our model, E-GPR (γ -exp), consistently outperforms the linear benchmarks in terms of both R_{pool}^2 and R_{avg}^2 . Figure 4 also illustrates the temporal evolution of the contribution of non-linearity to predictive performance, highlighting that the ranking of model performance presented in Table 1 remains consistent throughout the sample period. This consistency reinforces the robustness of our model across different time horizons. Additionally, the improved R^2 of ensemble linear regression (E-LR) compared to standard linear regression (LR) underscores the benefits of our proposed ensemble learning approach.

Figure 5 shows the time series of monthly Spearman’s rank correlations ρ_t between the predicted and realized returns. The flat line gives the information coefficient, IC , our third performance measure. It is evident that there is a substantial variation over time in the ability of our model to differentiate relative performance between stocks, as can be seen by correlation coefficients ranging from -23.2% to 31.61%. The information coefficient equals 7.3% and is significantly greater than zero at the 95% confidence level. Remarkably, we observe that our model performs equally well during the NBER recession months, as shown in the shaded periods.

3.3.2 Predictive performance across sorted portfolios

So far, our model’s predictive performance assessment has been based on individual stock returns. Next, we analyze the predictive ability of our model at the portfolio level. Why should we assess the portfolio-level predictions when our model is optimized for predicting individual stock returns? We know that one of the main applications of predicting stock returns is to construct portfolios. A model performing better at predicting stock returns need not provide accurate predictions at the portfolio level. Therefore, assessing portfolio forecasts give an additional measure to evaluate the predictive ability of our model.

Given our predictions at the beginning of each test month, we sort stocks into deciles, which we denote by $D1, D2, \dots, D10$, where $D1$ corresponds to the lowest predicted returns and $D10$ corresponds to the largest predicted returns. Within each decile, we then construct three different portfolios. The first is *equal weighted (EW)*, and the second is *value weighted (VW)* by market capitalization. These are the standard portfolios in the empirical asset pricing literature. For the third portfolio, we minimize the variance of the Bayesian uncertainty of our predictions by solving the following optimization problem,

$$\min_{\mathbf{w} \in \mathcal{W}} \mathbf{w}^\top \hat{\Sigma}_{t+1} \mathbf{w}, \quad (9)$$

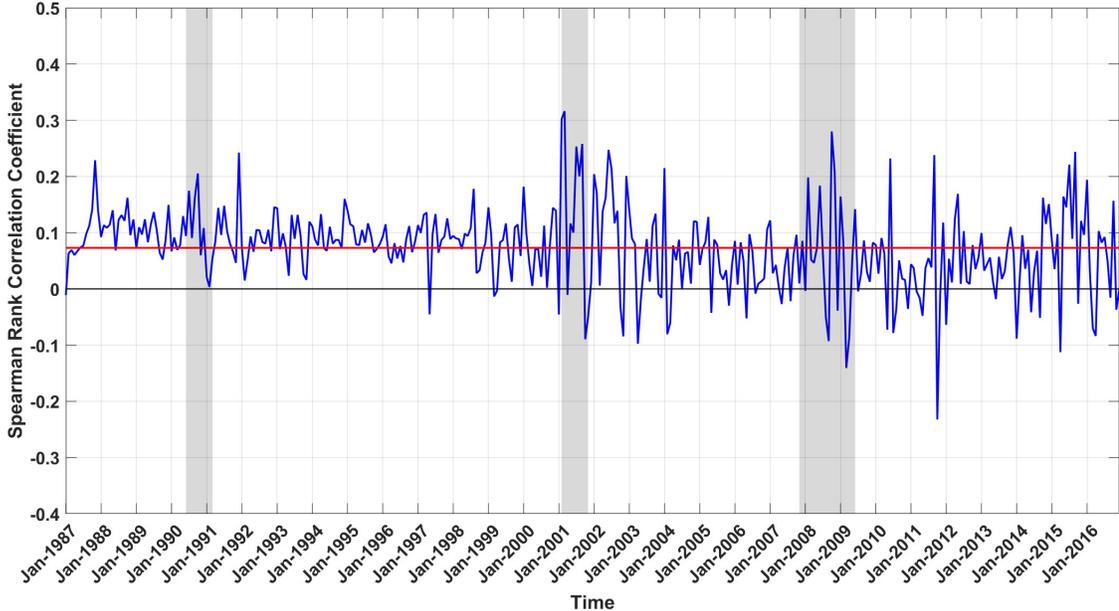

Figure 5: This figure shows the evolution of Spearman’s rank correlation ρ_t between the realized and predicted returns over the test sample. The flat line gives the information coefficient. The shaded periods indicate NBER recessions.

for the predictive covariance matrix $\hat{\Sigma}_{t+1}$, and where $\mathcal{W} = \{\mathbf{w}; \sum_{j \in D} w_j = 1, w_j \geq 0, j \in D\}$ denotes the feasible set of portfolio weights, for the respective decile D . We call it the *uncertainty-weighted (UW) portfolio*. The goal of studying the predictive performance of the UW portfolio is to examine the role of accuracy estimates in portfolio selection and finally, study its economic contribution when we construct a risk-adjusted portfolio below.

Table 2 shows the out-of-sample predictive performance of EW and VW portfolios from our ensemble GPR model with γ -exponential kernel. We also compare to the performance of EW and VW portfolios from the benchmark models. We report the R^2_{pool} between the predicted excess returns and realized excess returns of the decile portfolios over the test sample, along with R^2_{pool} , pooled over all deciles, for each of the two portfolio strategies. It provides a grand portfolio-level assessment of portfolio predictions against the realized portfolio returns.

Table 3 compares the same measures for UW portfolios from our ensemble GPR model with γ -exponential kernel to that from the ensemble GPR model with affine kernel. Note that UW portfolios are a unique feature of GPR models and thus are not available for E-LR and LR. It is evident from Table 2 that the out-of-sample predictive performance at the portfolio level aligns very closely with the results on the prediction performance at the individual stocks level reported earlier. That is, GPR based models outperform both the variants of the linear regression model (E-LR and LR) across all the portfolio strategies. Remarkably, the UW portfolios significantly outperform the EW and VW portfolios in terms of predictive performance across all the deciles. Further, the UW portfolio yields a positive grand panel R^2_{pool} of 12.80% in contrast to EW and

Table 3: In this table, we report the out-of-sample predictive performance, measured by R_{pool}^2 in percentage points, across the sorted portfolios obtained using uncertainty-weighted strategy. We compare the performance of our ensemble GPR model with γ -exponential kernel to ensemble GPR model with affine kernel. The first ten columns (*D1* to *D10*) report R_{pool}^2 for each decile while the last column (*All*) reports R_{pool}^2 calculated over the grand panel of all deciles.

VW portfolios that generate a grand panel R_{pool}^2 of 8.17% and 2.94%, respectively. These findings reveal that prediction uncertainties matter.

3.3.3 Economic performance of sorted portfolios

Next, we assess whether the improved statistical performance of our prediction-sorted portfolios translates into better economic performance. On top of the EW and VW portfolios discussed in the previous subsection, we introduce two additional portfolios.

First, for the *prediction-weighted (PW)* portfolio we assign weights, within each decile, to the stocks based on their predicted returns. The goal is to take advantage of the relative strength of the prediction signal in addition to the rankings. Specifically, for each of the top five deciles (*D6* to *D10*), we subtract the smallest predicted return within the decile to aim at maximal predicted return. Similarly, for each of the bottom five deciles (*D1* to *D5*), we subtract each predicted return from the largest predicted return within that decile to aim at the minimal predicted return. We

then normalized the level-adjusted predicted returns such that they sum up to 1 within each decile. More specifically, for any stock i we define the level-adjusted predicted return

$$\hat{s}_{i,t+1} = \begin{cases} \hat{r}_{i,t+1} - \min_{j \in D_i} \hat{r}_{j,t+1}, & \text{if } i \text{ lies in the top 5 deciles, } D6 \text{ to } D10, \\ \max_{j \in D_i} \hat{r}_{j,t+1} - \hat{r}_{i,t+1}, & \text{if } i \text{ lies in the bottom 5 deciles, } D1 \text{ to } D5, \end{cases} \quad (10)$$

where $\hat{r}_{j,t+1}$ are the predicted returns in decile D_i corresponding to stock i . These level-adjusted predicted returns are then normalized to obtain portfolio weights,

$$w_i = \frac{\hat{s}_{i,t+1}}{\sum_{j \in D_i} \hat{s}_{j,t+1}}.$$

Second, the *prediction-uncertainty-weighted (PUW)* portfolio is motivated by the findings of the previous subsection that the UW portfolio yields a substantially higher R_{pool}^2 (for each decile) than the EW and VW portfolios. We utilize the predictive covariance matrix and the predicted returns to construct a mean-variance type portfolio for a uncertainty averse investor. We aim at maximizing the portfolio return by investing in stocks with high predicted returns with high accuracy at the same time. More precisely, we combine (9) and (10) by solving the following optimization problem,

$$\max_{\mathbf{w} \in \mathcal{W}} \mathbf{w}^\top \hat{\mathbf{s}}_{t+1} - \frac{\zeta}{2} \mathbf{w}^\top \hat{\Sigma}_{t+1} \mathbf{w}, \quad (11)$$

where $\hat{\mathbf{s}}_{t+1} = \{\hat{s}_{j,t+1}, j \in D\}$ is the vector of level-adjusted predicted returns in the respective decile D , and ζ is the uncertainty-aversion parameter.

Figure 6 shows the cumulative excess log returns of the VW decile portfolios $D1$ to $D10$. It also shows the cumulative excess log returns of the S&P 500 for comparison. A clear pattern emerges. First, realized returns of the decile portfolios essentially increase monotonically from $D1$ to $D10$. Portfolios based on higher predictions have higher subsequent returns. In particular, the $D1$ portfolio and $D10$ portfolio clearly separate. Second, the $D10$ portfolio outperforms the S&P 500 by a large margin. Similar patterns emerge for the EW, PW, and PUW20 decile portfolios, as shown in Figures A.4 to A.7 in the appendix. These findings indicate that our sorted portfolio strategies can consistently dissect the market into high- and low-performing stocks.

In Figure 7, we plot the cumulative excess log returns of the top ($D10$) and bottom ($D1$) decile portfolios for EW, VW, UW, PW, PUW20, and the S&P 500. The PUW $D10$ portfolio yields a cumulative excess log return of 10.63. The PUW $D1$ portfolio, on other side, yields a cumulative excess log return of -7.08. The corresponding numbers for PW portfolio are 20.14 and -8.67, and for EW portfolio are 11.73 and -8.67 respectively. The large difference in cumulative returns from PW portfolios shows that our model is not only good at dissecting the stock market into deciles but also at predicting the relative return levels within a decile. Further, the uncertainty averse PUW portfolio dominates the performance of the VW by a large margin in both directions, top and bottom and compares favorably to that of EW. These findings show that exploiting the Bayesian nature of GPR by incorporating uncertainty in the predictions can significantly improve

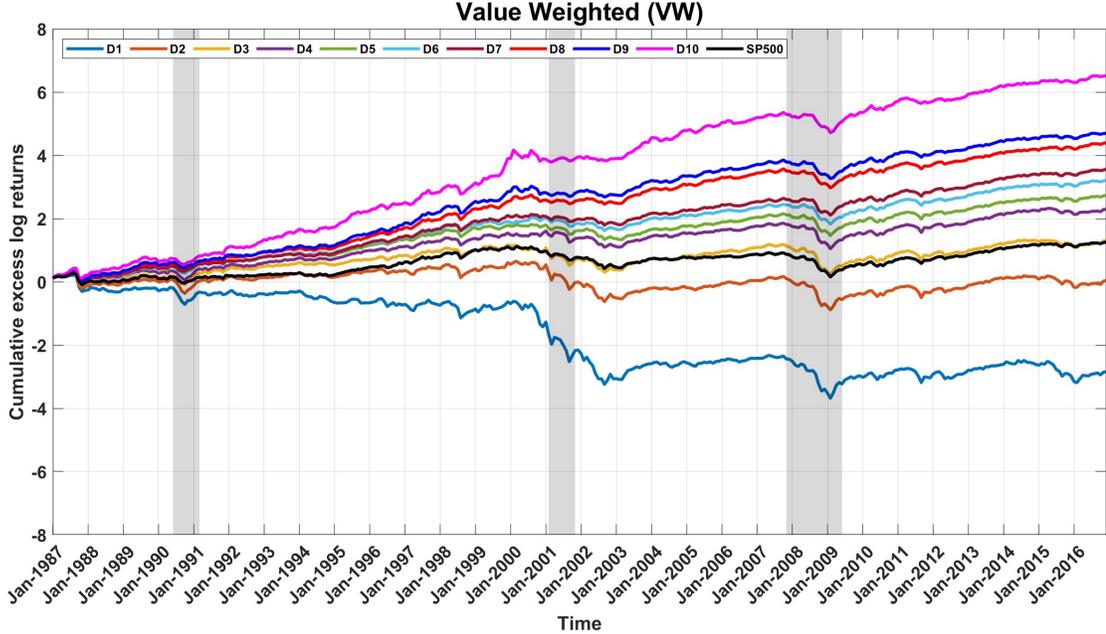

Figure 6: This figure shows the out-of-sample cumulative excess log returns of the VW decile portfolios sorted based on our predicted returns. It also shows the S&P 500. The shaded periods indicate NBER recessions.

portfolio performance. Interestingly, the bottom decile portfolio performance is essentially flat in the post-2000 sample, except for PUW. This observation has also been reported in Gu et al. [2020].

We also construct a zero-net-investment portfolio that is long D_{10} and short D_1 for all the five portfolio strategies. Figure 8 shows their cumulative excess log returns. The qualitative conclusions are identical to what we observed in Figure 7.

We evaluate the performance of decile portfolios, D_1 to D_{10} , and the long-short portfolio LS from our five portfolio strategies, namely EW, VW, PW, UW and PUW, in terms of their predicted monthly returns, the average realized monthly returns, their standard deviations, and Sharpe ratios. These metrics are annualized and are calculated based on simple excess returns, and are collected in Table 4. We observe that realized portfolio returns generally increase monotonically with our model’s predictions. The average realized monthly returns, their standard deviations, and Sharpe ratios for S&P 500 are 0.054, 0.150 and 0.360 respectively. It is evident that each of our portfolios generate a higher Sharpe ratio in comparison to the S&P 500 index. The Sharpe ratio of 3.18 of the LS portfolio from EW outperforms Sharpe ratio of 1.12 of the corresponding portfolio from the VW strategy, an observation coinciding with the findings of Gu et al. [2020]. Further, taking into account the levels of predictions, the PW portfolio outperforms the EW portfolio in terms of Sharpe ratio, but it exhibits a higher standard deviation of 25% compared to 16% from the EW. This reconfirms that our model is good at predicting the ranks of stock returns as well as their levels relative to other stocks within the same decile. The best long-short strategy comes from the PUW20 portfolio, which gives on average 53% annualized return with annualized volatility of 15%,

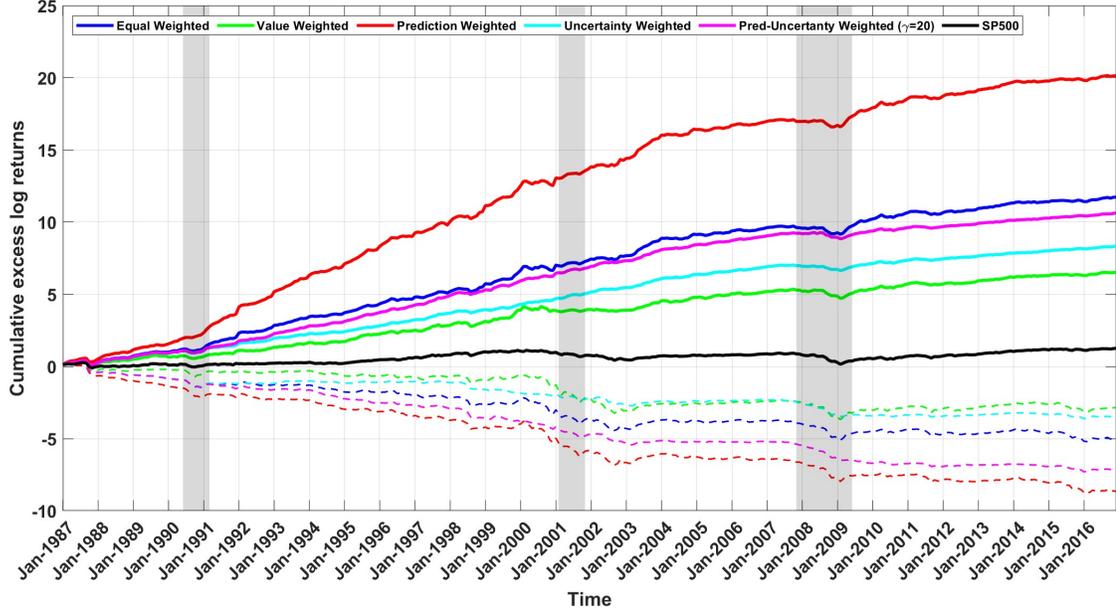

Figure 7: This figure shows the out-of-sample cumulative excess log returns of the $D10$ (solid lines) and $D1$ (dashed lined) portfolios for EW, VW, PW, UW and PUW ($\gamma = 20$), sorted based on our predicted returns. It also shows the S&P 500. The shaded periods indicate NBER recessions.

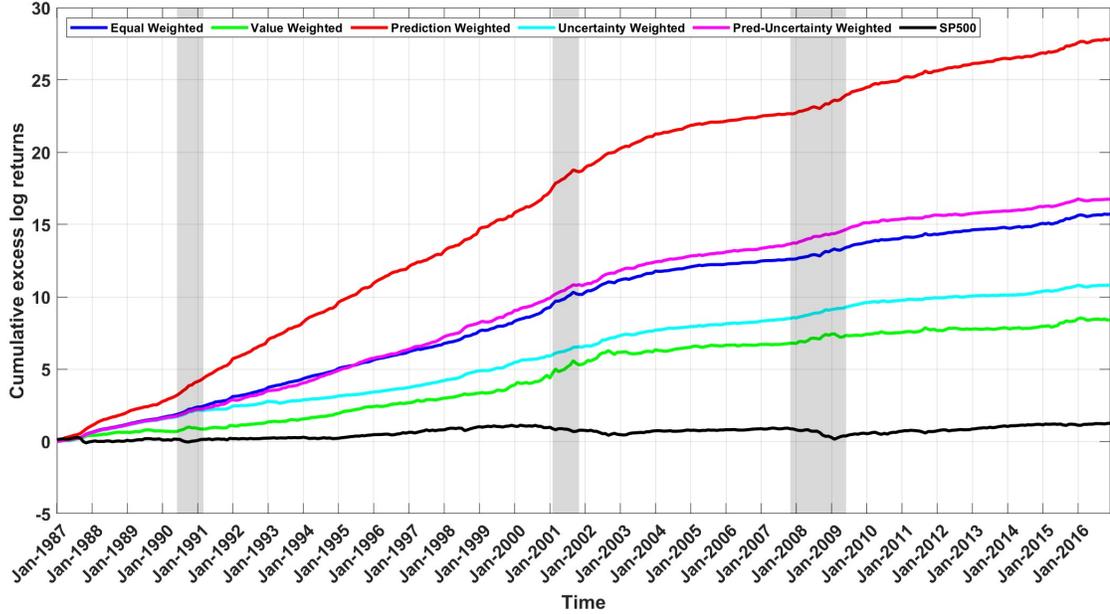

Figure 8: This figure shows the cumulative excess log returns of the long-short portfolios for EW, VW, PW and PUW, obtained by taking a long position in the $D10$ and short position in $D1$ portfolios. It also shows the S&P 500. The shaded periods indicate NBER recessions.

amounting to an annualized Sharpe ratio of 3.66. The annualized Sharpe ratio of the LS portfolio from the PW strategy is 3.68, slightly higher than that from PUW20 but it comes at the expense of a high standard deviation of 25%. Nonetheless, PW could potentially be a suitable choice for a risk-seeking investor. The UW portfolio also generates a high Sharpe ratio of 2.97, with an annualized standard deviation of just 11%. The UW portfolio is an ideal choice for a risk-averse investor who by taking least risk can still beat the market. As we increase ζ in the PUW portfolios, we approach the performance of the UW portfolios, which is as expected. These findings suggest that taking into account the uncertainty estimates of the predictions significantly improves the performance of the EW and VW portfolios, typically studied in the literature.¹⁴

Next, we investigate the factors contributing to the improved performance of our portfolios, aiming to identify whether this enhancement stems from the non-linearity of the Gaussian process regression or from the ensemble learning approach. For that, we compare the performance of the portfolios from our ensemble GPR model with γ -exponential kernel to the corresponding portfolios from the ensemble GPR model with affine kernel, the ensemble linear regression model, and the standard linear regression model. The results for the benchmark models are reported in Tables 5 and 6. An important implication emerges from a comparison of the portfolio performance in Table 5, with that in Table 4. It demonstrates that the non-linear kernel outperforms the affine kernel in several aspects: dissecting the cross-section (EW and VW portfolios), accurately predicting stock return levels (PW portfolios), and achieving high precision in return predictions (UW and PUW portfolios). While the performance of the PW portfolio with affine kernel is comparable to that with γ -exponential kernel, the uncertainty-based portfolios, UW and PUW, exhibit significant improvements when using the non-linear kernel over the affine kernel. Thus, it suggests that the affine kernel is not able to deliver good estimates of the prediction uncertainty, as is also evident from the performance of the UW portfolio in Table 5 where the annualized standard deviation of the *LS* portfolio is 43%, much higher than 11% of the corresponding portfolio resulting from the γ -exponential kernel. Furthermore, the performance of the EW, VW and PW portfolios of the GPR with affine kernel (Table 5) is similar to the corresponding portfolios from linear regression (Table 6). The performance of the ensemble linear regression is similar to that of the standard regression model. In summary, these observations suggest that the improved portfolio performance of our ensemble GPR model with γ -exponential kernel stems from several aspects: the non-linearity, the ensemble learning approach, and the prediction uncertainty estimates.

We also examine how the contributions from these factors, the non-linearity, the ensemble learning approach, and the prediction uncertainty estimates, change over time. To this end, we plot the cumulative excess log-return of long-short portfolios from these models in Figures A.8 to A.10 in the appendix. In Figure A.8 for EW long-short portfolios, E-GPR (γ -exp) consistently outperforms the linear benchmark models, demonstrating the significant contribution of non-linearity in improved portfolio performance. Additionally, E-GPR (affine) and E-LR perform comparably,

¹⁴Our performance compares favorably to Gu et al. [2020], who report Sharpe ratios of 1.0 and 0.8 for EW and VW *D10* portfolios, -0.4 and -0.19 for EW and VW *D1* portfolios, and 2.36 (2.63) and 1.2 (1.53) for EW and VW long-short portfolios (in Gu et al. [2021]).

Table 4: In this table, we compare the economic performance of prediction sorted portfolios over the 30-year out-of-sample testing period for the ensemble GPR model with γ -exponential kernel. We compare the performance of the decile portfolios corresponding to EW, VW, PW, UW and PUW strategies. We report the performance of PUW portfolios for different values, $\{1, 1020, 100, 250\}$ of ζ , the uncertainty-aversion parameter. We also compare the long-short portfolios. For each portfolio, we report the predicted monthly returns (“Pred”), the average realized monthly returns (“Avg”), their standard deviations (“Std”), and Sharpe ratios (“SR”). We calculate these measures using realized simple excess returns of the portfolios over the test sample. The values of “Avg”, “Std” and “SR” for the S&P 500 are 0.054, 0.150 and 0.360 respectively. All measures are annualized.

Table 6: In this table, we compare the economic performance of prediction sorted portfolios over the 30-year out-of-sample testing period for the standard linear regression model (LR) and ensemble linear regression model (E-LR). We compare the performance of the decile portfolios corresponding to EW, VW, and PW strategies. We also compare the long-short portfolios. For each portfolio, we report the predicted monthly returns (“Pred”), the average realized monthly returns (“Avg”), their standard deviations (“Std”), and Sharpe ratios (“SR”). We calculate these measures using realized simple excess returns of the portfolios over the test sample. The values of “Avg”, “Std” and “SR” for the S&P 500 are 0.054, 0.150 and 0.360 respectively. All measures are annualized.

with both achieving slightly better results than LR. A similar pattern is observed for VW long-short portfolios underscoring the robustness of non-linear approaches. Moreover, ensemble models exhibit considerably better performance than LR, further confirming the importance of adopting an ensemble learning approach. When incorporating uncertainty, PUW from our model surpasses PUW from E-GPR (affine) for both levels of uncertainty aversion ($\zeta = 1$ and $\zeta = 20$) and the PW portfolios from linear benchmark models, in Figure A.10.¹⁵

We end this section by a disclaimer noting that the performance of the above portfolios does not take into account any transaction costs, which, when considered, could offset the gains.¹⁶ Importantly, our dataset contains highly illiquid stocks with extremely small market capitalization. These stocks are thus unlikely to be accessible to investors and may incur significant transaction costs due to high bid-ask spreads and low liquidity. Hence, an investor could not potentially exploit the higher gains by shorting the *D1* portfolio. But this applies to the benchmarks in the literature as well.

3.4 Cross-sectional insights

This section focuses on cross-sectional insights of the model performance. Section 3.4.1 analyzes the contribution of individual features to the model’s performance. Section 3.4.2 examines the relationship between the features and the return predictions, while Section 3.4.3 examines how the features relate to the prediction uncertainty.

3.4.1 Variable importance

We analyze the relative importance of individual features based on their contribution to the performance of our model. Following the approach in Gu et al. [2020], we rank the features based on a variable importance metric, denoted as VI_j for any feature j . VI_j is defined as the reduction in pooled R -squared resulting from assigning all values of feature j to zero, while keeping the estimates of the remaining model parameters unchanged. Specifically, we re-obtain the predictions for each test month using the pre-trained GPR models from the training period, utilizing all but the j th feature, which is set to zero. Figure 9 reports the resultant importance of the top twenty features, normalized to sum to one.¹⁷ Beyond these, variable importance hovers near zero. The total contribution by the top twenty features is 96.89%.

Following Gu et al. [2020], we have grouped the features into four categories. The first category is based on recent price trends, which includes variables such as short-term reversal (mom1m and mom6m), stock momentum (mom12m), momentum change (chmom), long-term reversal (mom36m), recent maximum return (maxret) and industry momentum (indmom). The second category consists of liquidity variables, which include bid-ask spread (baspread), dollar volume (dolvol), turnover

¹⁵These levels of uncertainty aversion were chosen based on their superior Sharpe ratios.

¹⁶Avramov, Cheng, and Metzker [2020] pointed out that transaction costs could significantly deteriorate the performance of machine learning portfolios due to high turnover or extreme positions.

¹⁷There were features for which the reduction in R_{pooled}^2 (%) was negative but negligibly close to zero. We replaced the variable importance for such features with zero.

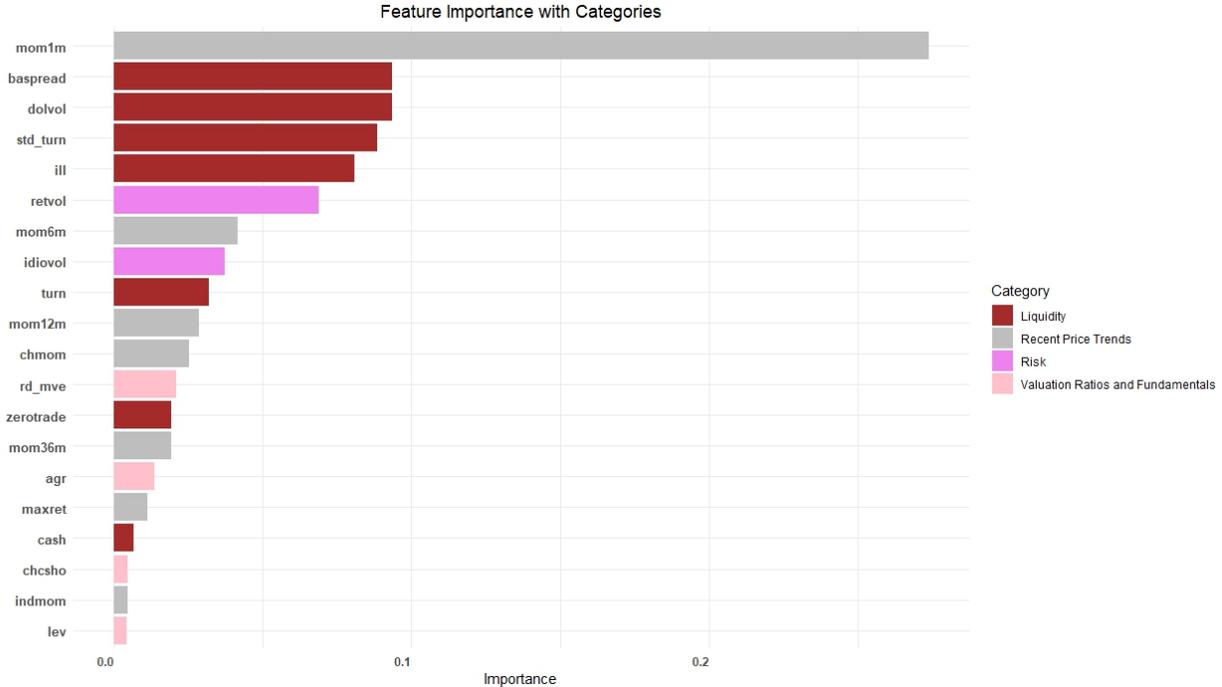

Figure 9: Top twenty features by variable importance, averaged over all training samples. The variable importance of these twenty features is normalized to sum to one.

Category	Importance (%)
Liquidity Variables	41.78
Recent Price Trends	41.02
Risk Measures	10.91
Valuation Ratios and Fundamental Signals	6.29

Table 7: Variable Importance by Categories

volatility (SD.turn), Amihud illiquidity (ill), turnover (turn) and cash. The third category consists of risk measures, which include total and idiosyncratic return volatility (retvol, idiovol). The fourth category includes valuation ratios and fundamental signals consisting of features such as R&D to market capitalization (rd_mev), asset growth (agr), change in shares outstanding (chcshe) and leverage (lev). We also report the category-wise contributions of these features in Table 7, which shows that our model is inclusive and extracts predictive information from a wide range of features in the sense that it assigns significant importance to features across all the four categories, rather than being dependent on any single category.

3.4.2 Association between features and predicted returns

Next, we investigate the cross-sectional heterogeneity in predicted returns and prediction uncertainty, and relate them to the above top twenty features.

To analyze the relation between predicted returns and the features, in each of the test months,

we divide the cross-section into deciles based on the predicted returns. That is, given our predictions in each of the test month, we sort stocks into deciles, which we denote by $D1, D2, \dots, D10$, where $D1$ corresponds to the stocks with lowest predicted returns and $D10$ corresponds to the stocks with highest predicted returns. Within each decile, we find the mean of each of the top twenty features resulting into a vector of length 360 (number of test months) for each feature. Since the cross-sectional mean of each feature is standardized to zero, we also conduct t -tests to determine whether the mean feature values within each decile are significantly different from zero. We report the results of the t -test in Table A.1 in the appendix.

Figure 10 presents the mean values of the top twenty features, categorized into four groups, averaged across the testing period for each decile. In the panel on liquidity variables, we observe that stocks with the highest predicted returns tend to be less liquid, as indicated by higher values of the bid-ask spread (*baspread*) and illiquidity (*ill*). Additionally, higher predicted returns are associated with lower values of turnover (*turn*) and dollar volume (*dolvol*), further reinforcing the observation that less liquid stocks are linked to higher predicted returns. For momentum variables, we observe an increasing trend in 6-month (*mom6m*) and 12-month (*mom12m*) momentum, coupled with a declining trend in 1-month (*mom1m*) momentum. This pattern suggests a positive momentum effect over longer horizons and a reversal effect over shorter horizons. Further, the stocks in deciles $D1$ and $D10$ tend to carry higher levels of risk as depicted by a U-shaped pattern for risk measures, *retvol* and *idivol*, a finding that aligns with the risk-return trade-off: the stocks with higher expected returns, positive or negative, have high values of risk levels. The bottom right panel, valuation ratios and fundamentals, shows that our models predict higher returns for growth-oriented and R&D-intensive firms as depicted by rising trend in *rd_mve* and *agr*. In contrast, *chcsho* exhibits a declining trend, suggesting higher predicted returns for firms with less equity dilution.

In essence, the above findings also give insights into the shape of the predictive function as they reveal how our model translates features to predictions. That is, analyzing the behavior of features across deciles based on predicted returns offers an understanding of the structural relationship and feature interactions that govern the model’s predictive behavior. In conclusion, we observe significant heterogeneity in the features across deciles, suggesting that predicted returns are influenced by a diverse set of factors.

3.4.3 Association between features and prediction uncertainty

To analyze the relation between prediction uncertainty and the features, we repeat the above exercise. Given our prediction uncertainty in each of the test month, we sort stocks into deciles, which we denote by $D1, D2, \dots, D10$, where $D1$ corresponds to the stocks with lowest prediction uncertainty and $D10$ corresponds to the stocks with highest prediction uncertainty.

Figure 11 shows the mean value of each of the top twenty features, categorized into four groups, averaged over the testing period for each decile. We report the results of the t -test in Table A.2 in the appendix. There are several interesting observations. We observe that the stocks with high prediction uncertainty are indeed the ones with limits to arbitrage frictions and that exhibit

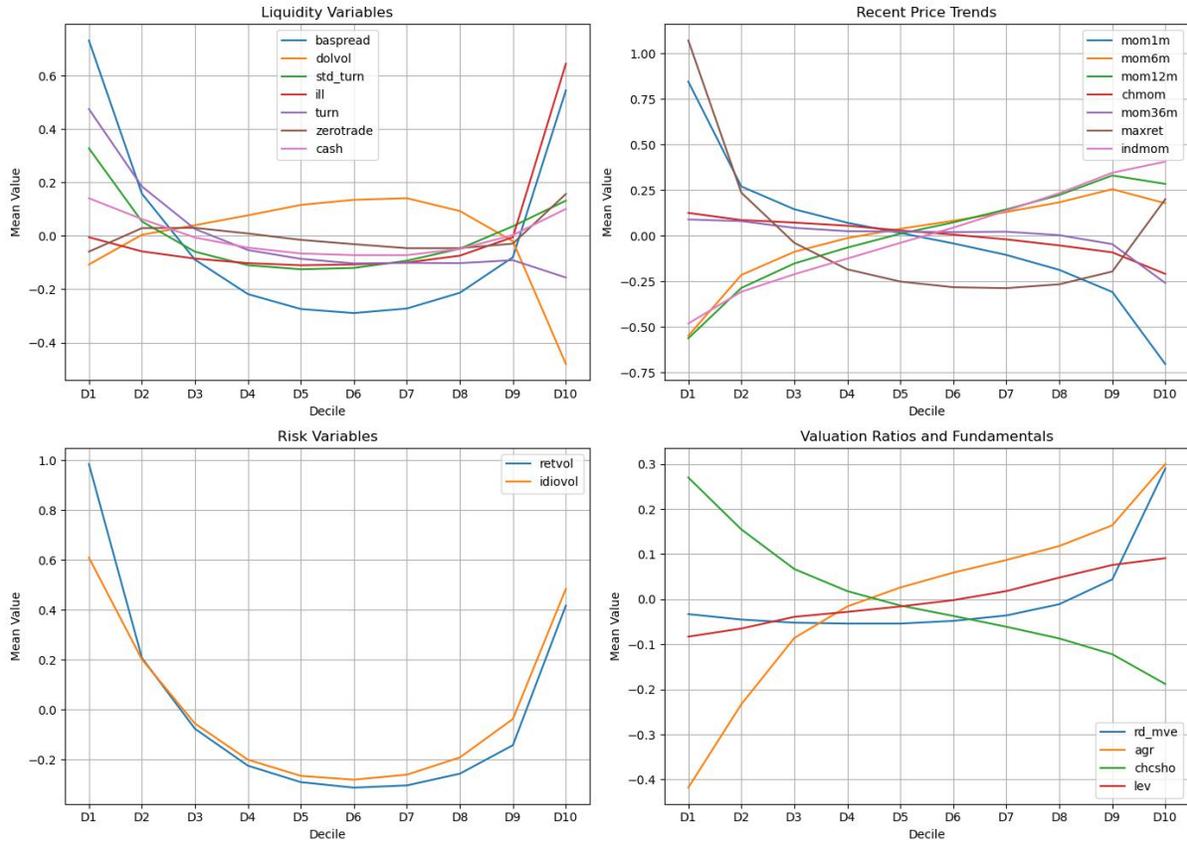

Figure 10: This figure shows the relationship between the features and predicted returns. Horizontal axes show cross-sectional deciles of predicted returns ($D1$ is lowest, $D10$ is highest). Vertical axes show time averages of conditional means of feature values given deciles.

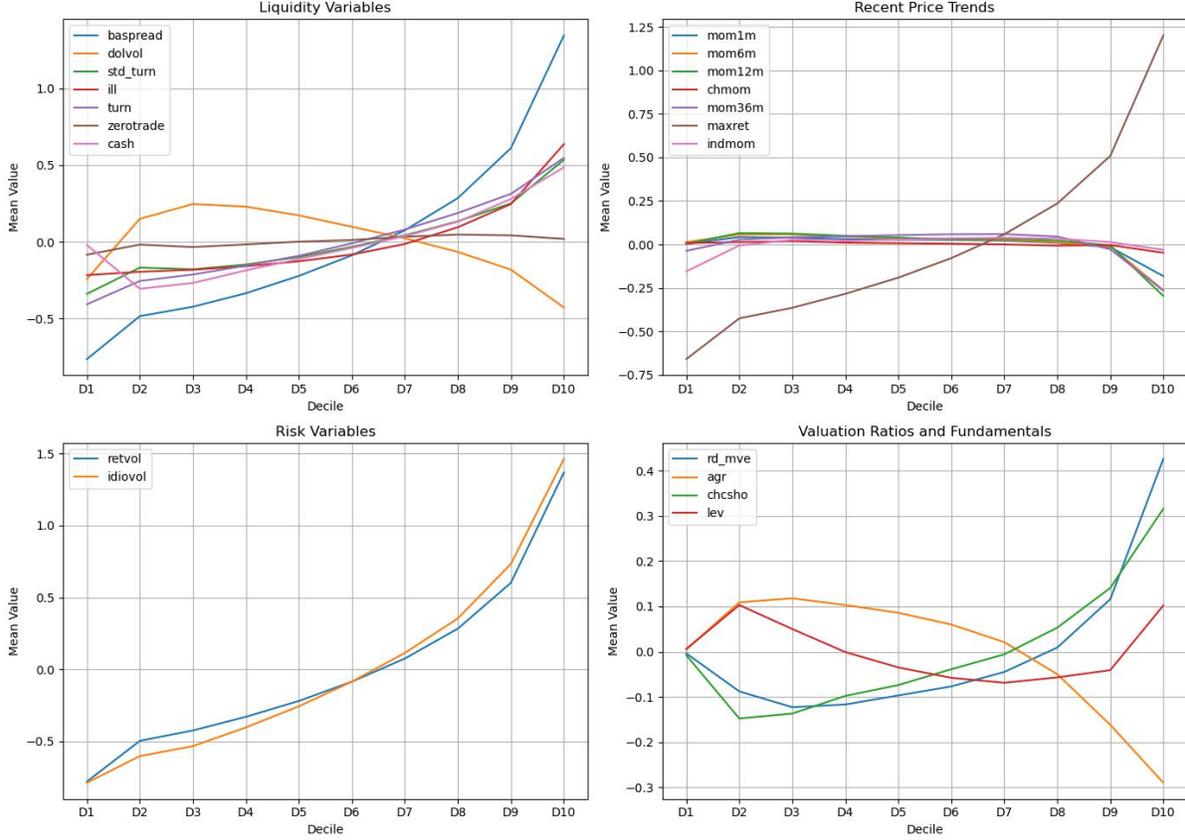

Figure 11: This figure shows the relationship between the features and prediction uncertainty. Horizontal axes show cross-sectional deciles of prediction uncertainty ($D1$ is lowest, $D10$ is highest). Vertical axes show time averages of conditional means of feature values given deciles.

extreme illiquidity as depicted by high value of bid-ask spread, a high value of illiquidity (ill) and a low value of dollar volume (dolvol). Further, the stocks with high uncertainty have high values of risk measures, namely return volatility (retvol) and idiosyncratic volatility (idiovol), low value of asset growth (agr), a relatively higher leverage and high value of maximum return (maxret). In contrast, other recent price trends exhibit no clear association with prediction uncertainty.

3.5 Residual diagnostics

Leveraging the inherent ability of the GPR model to quantify prediction uncertainty, we present another use case. Following Gu et al. [2021], we consider a set of pre-specified portfolios, defined as

$$\mathbf{w}_t^\top = (\mathbf{Z}_t^\top \mathbf{Z}_t)^{-1} \mathbf{Z}_t^\top,$$

where \mathbf{Z}_t is the $|\mathcal{I}_t| \times 94$ matrix whose i th row consists of 94 features corresponding to the i th asset at time t . Given the portfolio weights \mathbf{w}_t at the beginning of each test month, we obtain the

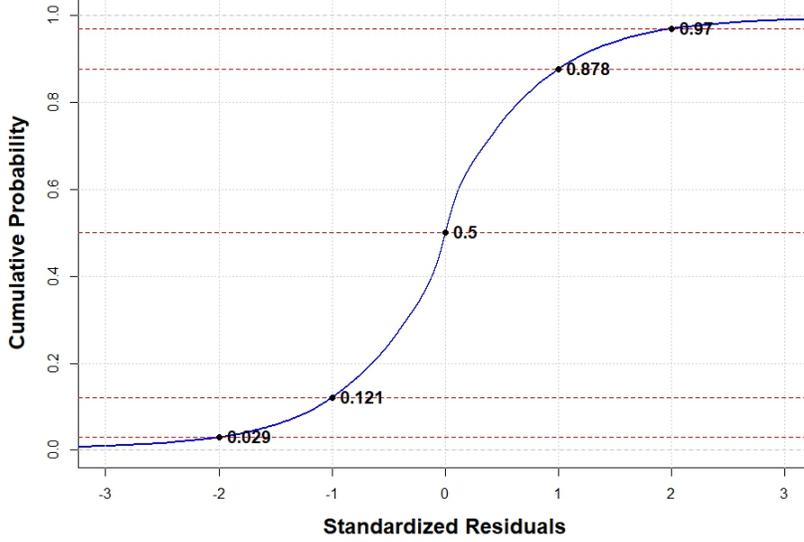

Figure 12: Empirical cumulative distribution function of the standardized residuals of the pre-specified feature sorted portfolios.

realized portfolio returns

$$\mathbf{R}_{t+1} = \mathbf{w}_t^\top \mathbf{r}_{t+1}.$$

The vector \mathbf{R}_{t+1} represents a collection of portfolios that are dynamically rebalanced based on features. We also obtain the predicted portfolio returns, $\mathbf{w}_t^\top \hat{\mathbf{r}}_{t+1}$ and the prediction uncertainty in terms of the variance, $\mathbf{w}_t^\top \hat{\Sigma}_{t+1} \mathbf{w}_t$, thanks to our posterior uncertainty estimates that allow us to calculate portfolio variances. For each of the 360 test months and the 94 portfolios, we compute the standardized residuals

$$\boldsymbol{\eta}_{t+1} = \frac{\mathbf{R}_{t+1} - \mathbf{w}_t^\top \hat{\mathbf{r}}_{t+1}}{\sqrt{\mathbf{w}_t^\top \hat{\Sigma}_{t+1} \mathbf{w}_t}},$$

resulting in a balanced panel of size 94×360 . According to standard GPR model assumptions, the standardized residuals, $\boldsymbol{\eta}_{t+1}$, should follow a standard normal distribution. But a normality test leads to rejection of this hypothesis. However, this is due to the heavy tails of the residuals. In fact, Figure 12 presents the empirical cumulative distribution function (ECDF) of the grand panel of standardized residuals. Remarkably, the empirical median is exactly zero. Approximately 75% of the residuals fall within one standard deviation, and 94.1% lie within two standard deviations, which aligns with the two-sigma rule.

We also conduct statistical tests to determine whether the mean and variance of the standardized residuals are 0 and 1, respectively. To this end, for each portfolio, we calculate the empirical mean and variance of the residuals over the 360 months. Subsequently, we perform t -tests to assess whether the average of the portfolio means and the average of the portfolio variances significantly deviate from 0 and 1, respectively. This approach allows us to evaluate the consistency of the

Mean of	Min	1st Qu.	Median	Mean	3rd Qu.	Max	p -value
Portfolio Means	-0.244	-0.026	0.002	0.001	0.031	0.187	0.910
Portfolio Variances	0.592	0.816	0.908	1.025	1.113	3.344	0.537
Grand Panel of Residuals	-30.352	-0.479	-0.001	0.001	0.482	20.191	0.898

Table 8: Summary statistics of the means and variances of the standardized residuals of the 94 portfolios

residuals with the expected properties under the normal assumption. The first two rows in Table 8 present the summary statistics of the means and variances of the standardized residuals of the 94 portfolios, and the p -values of the corresponding t -tests, which clearly shows that we fail to reject the null hypothesis of mean 0 and variance 1. We also test whether the mean of the grand panel of the standardized residuals is significantly different from 0, the third row in Table 8 presents the corresponding results. A p -value of 0.898 shows that this is not the case. These findings highlight our model’s capability to reliably predict portfolio returns as well as quantify prediction uncertainties up to a two-sigma level.

4 Conclusion

The out-of-sample prediction of conditional expected stock returns remains a central challenge in empirical asset pricing. In this paper, we introduce a novel ensemble GPR method to predict conditional expected returns. While we do not claim that our simple method is the best approach for all situations, we find that it outperforms the benchmarks by significant margins in terms of R -squared. Exploiting the Bayesian nature of GPR, we also model and quantify the prediction uncertainty, which leads to significant economic gains in terms of the performance of uncertainty-weighted prediction-sorted portfolios. Our ensemble learning approach reduces the computational complexity inherent in GPR and addresses the non-stationarity and heteroscedasticity in financial data. As such, it lends itself to a variety of online learning tasks to be explored in future research. Another direction of future research consists of exploiting kernel methods beyond Gaussian processes for the modeling of statistical financial risk, such as in Filipović and Pasricha [2022].

A Gaussian Process Regression

In this appendix we give an introduction to Gaussian process regression. For more background and theory we refer the reader to Williams and Rasmussen [2006].

A.1 Gaussian Processes

A Gaussian process is a collection of random variables, any finite number of which have a joint Gaussian distribution. More specifically, let \mathcal{X} be a non-empty set. A random function $f : \mathcal{X} \rightarrow \mathbb{R}$ is a *Gaussian process (GP)* with mean function $m(\cdot)$ and covariance function, or, kernel $k(\cdot, \cdot)$, if for any finite set $\mathbf{x} = (x_1, x_2, \dots, x_n) \subset \mathcal{X}$ the random vector

$$f(\mathbf{x}) = (f(x_1), f(x_2), \dots, f(x_n))^{\top}$$

follows multivariate normal distribution $\mathcal{N}(m(\mathbf{x}), k(\mathbf{x}, \mathbf{x}^\top))$ with mean vector

$$m(\mathbf{x}) = (m(x_1), m(x_2), \dots, m(x_n))^\top$$

and covariance matrix

$$k(\mathbf{x}, \mathbf{x}^\top) = (k(x_i, x_j))_{i,j=1}^n.$$

A.2 Training GPR

To fit the hyperparameters by maximum likelihood, we compute the partial derivatives of the marginal likelihood function (6) w.r.t. the hyperparameters,

$$\begin{aligned} \frac{\partial}{\partial \theta_j} \log p(\mathbf{y} | \mathbf{X}, \theta) &= -\frac{\mathbf{y}^\top K_y^{-1} \frac{\partial K_y}{\partial \theta_j} K_y^{-1} \mathbf{y}}{2} - \frac{1}{2} \text{tr} \left(K_y^{-1} \frac{\partial K_y}{\partial \theta_j} \right) \\ &= \frac{1}{2} \text{tr} \left((K_y^{-1} \mathbf{y} \mathbf{y}^\top K_y^{-1} - K_y^{-1}) \frac{\partial K_y}{\partial \theta_j} \right) \end{aligned} \quad (12)$$

where we write $K_y = \mathbf{K} + \sigma_\epsilon^2 I$. We then find the optimal hyperparameters $\hat{\theta}$ by any gradient based optimizer and gradient given in (12).

B Choice of kernel

A critical ingredient in the success of Gaussian process regression is the choice of kernel as it defines our prior assumptions about the function being modeled. It also drives the model's potential to capture the relationship between input features and the output variable by governing the flexibility, smoothness and the generalization ability of the model. In preliminary experiments, we tried with various kernels in predicting excess log returns in the validation period for a guided choice on the optimal kernel. We experimented with the following ten kernels,

$$(i) \quad K_1(x, x') = \sigma^2 (1 + \alpha \|x\|)(1 + \alpha \|x'\|) \left(1 + \frac{\|x-x'\|^2}{2\alpha\ell^2} \right)^{-\alpha}$$

$$(ii) \quad K_2(x, x') = \sigma^2 \sqrt{(1 + \alpha \|x\|^2)} \sqrt{(1 + \alpha \|x'\|^2)} \left(1 + \frac{\|x-x'\|^2}{2\alpha\ell^2} \right)^{-\alpha}$$

$$(iii) \quad K_3(x, x') = \sigma^2 \sqrt{(1 + \alpha \|x\|^2)} \sqrt{(1 + \alpha \|x'\|^2)} \exp \left\{ -\frac{\|x-x'\|^2}{2\ell^2} \right\}$$

$$(iv) \quad K_4(x, x') = \sigma^2 (1 + \alpha \|x\|)(1 + \alpha \|x'\|) \exp \left\{ -\frac{\|x-x'\|}{\ell} \right\}$$

$$(v) \quad K_5(x, x') = \sigma^2 \left(1 + \frac{\|x-x'\|}{2\alpha\ell^2} \right)^{-\alpha}$$

$$(vi) \quad K_6(x, x') = \sigma^2 (1 + \alpha \|x\|)(1 + \alpha \|x'\|) \left(1 + \frac{\|x-x'\|}{\beta} \right)^{-1}$$

$$(vii) \quad K_7(x, x') = \sigma^2 \exp \left\{ -\frac{\|x-x'\|^2}{2\ell^2} \right\}$$

$$(viii) \quad K_8(x, x') = \sigma^2 \left(1 + \frac{\|x-x'\|^2}{2\alpha\ell^2} \right)^{-\alpha}$$

$$(ix) \quad K_9(x, x') = \sigma^2 \exp \left\{ -\frac{\|x-x'\|}{\ell} \right\}$$

$$(x) \quad K_{10}(x, x') = \sigma^2 \exp \left\{ -\left(\frac{\|x-x'\|}{\ell} \right)^\gamma \right\}$$

where $\sigma, \alpha, \ell > 0, \gamma \in (0, 2]$. Here, the kernels K_7 to K_{10} are the standard kernels: squared exponential kernel, rational quadratic kernel, exponential kernel and the γ -exponential kernel respectively. The kernels K_1 to K_6 are variations of the four standard kernels defined with an aim to introduce feature dependent variance function and utilizing the fact that any non-degenerate covariance kernel can be factorized as $k(x, x') = \sqrt{v(x)v(x')}\rho(x, x')$ where $v : \mathcal{X} \rightarrow (0, \infty)$ is a function and ρ a kernel on \mathcal{X} with $\rho(x, x) = 1$. This factorization can always be achieved by setting $v(x) = k(x, x)$ and $\rho(x, x') = k(x, x')/\sqrt{v(x)v(x')}$, so that $v(x)$ is the variance of $f(x)$, and $\rho(x, x')$ the linear correlation of $f(x)$ and $f(x')$.

Figures A.1 and A.2 show R_{pool}^2 over the validation sample for MSE- and equal-weighting schemes against varying lengths K of the training window in predicting log-excess returns. It is evident from both the plots that both the weighting schemes generate positive R_{pool}^2 for K large enough ($K > 50$) with K_2 being an exception in equal-weighting scheme. Further, the best performing kernels are K_5, K_8 and K_{10} . To conclude, based on the performance in validation sample on log-excess returns, we select these three kernels for further analysis.

C Additional results

This appendix includes supplementary figures and tables referenced in the main text.

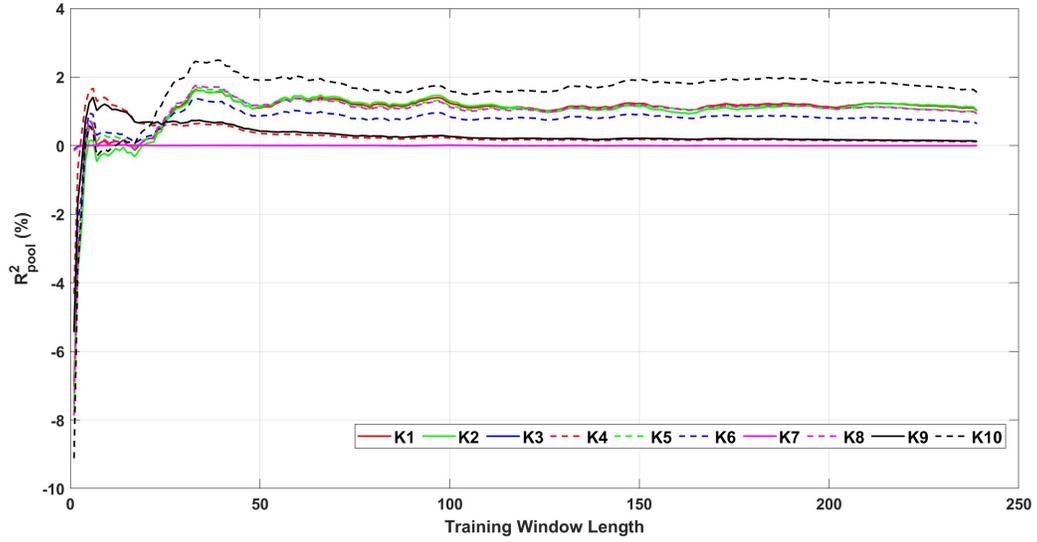

Figure A.1: This figure presents R^2_{pool} over the validation sample, Jan 1982 to Dec 1986 for MSE-weighting scheme against the length of the training window for ten kernels under consideration.

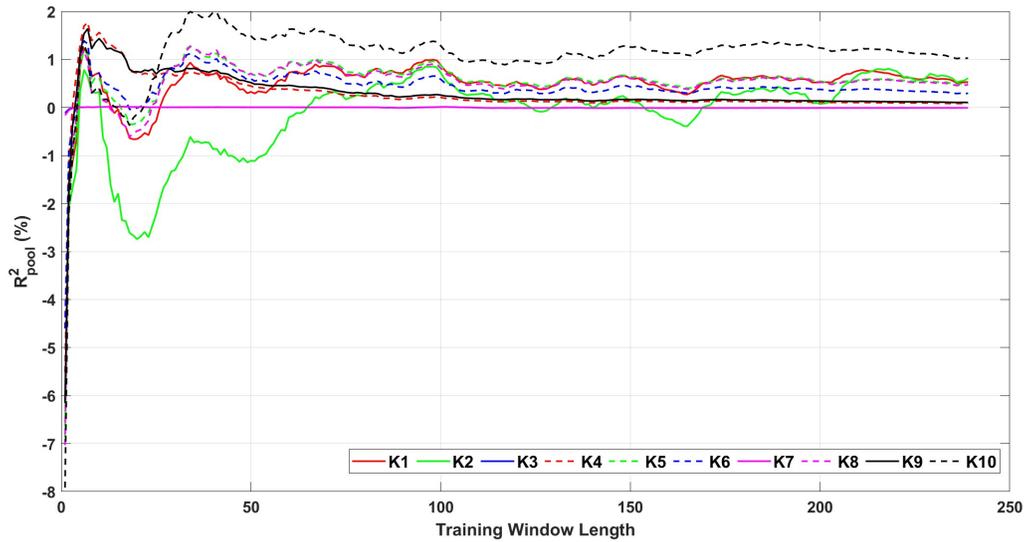

Figure A.2: This figure presents R^2_{pool} over the validation sample, Jan 1982 to Dec 1986 for equal-weighting scheme against the length of the training window for ten kernels under consideration.

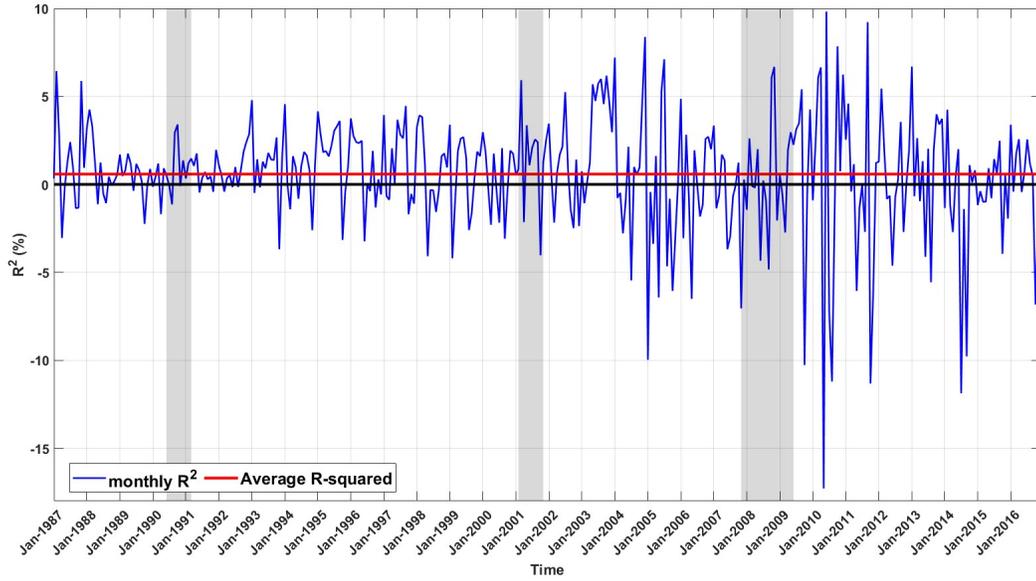

Figure A.3: This figure shows the evolution of R_t^2 over the test sample. The shaded periods indicate NBER recessions.

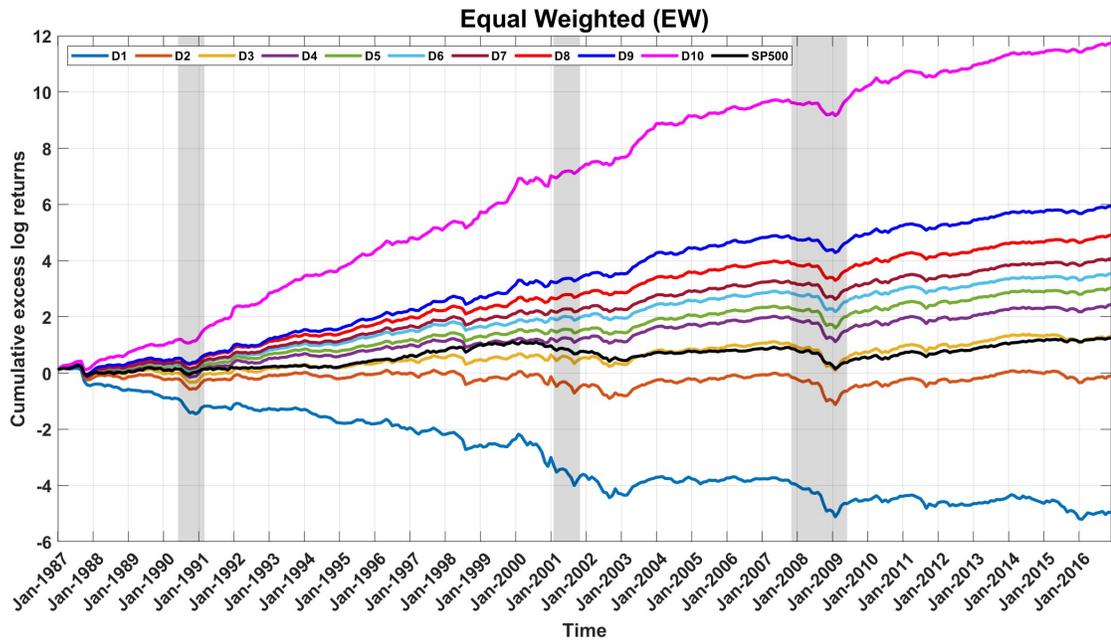

Figure A.4: This figure shows the cumulative excess log returns of equal weighted (EW) decile portfolios sorted based on our predicted returns. It also shows the S&P 500. The shaded periods indicate NBER recessions.

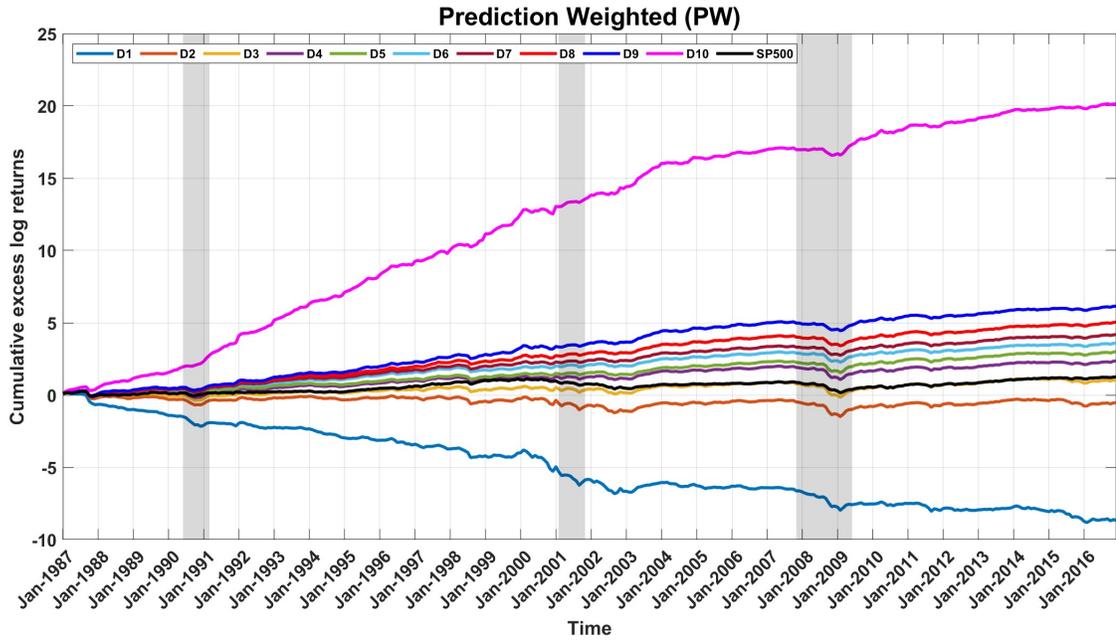

Figure A.5: This figure shows the cumulative excess log returns of prediction weighted (PW) decile portfolios sorted based on our predicted returns. It also shows the S&P 500. The shaded periods indicate NBER recessions.

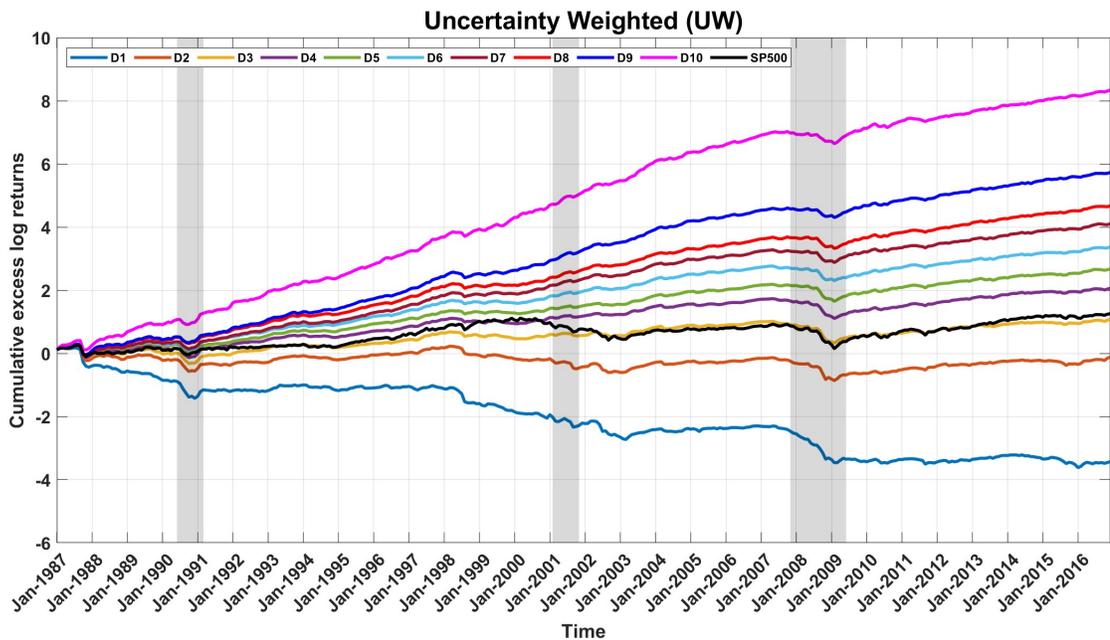

Figure A.6: This figure shows the cumulative excess log returns of uncertainty-weighted (UW) decile portfolios sorted based on our predicted returns. It also shows the S&P 500. The shaded periods indicate NBER recessions.

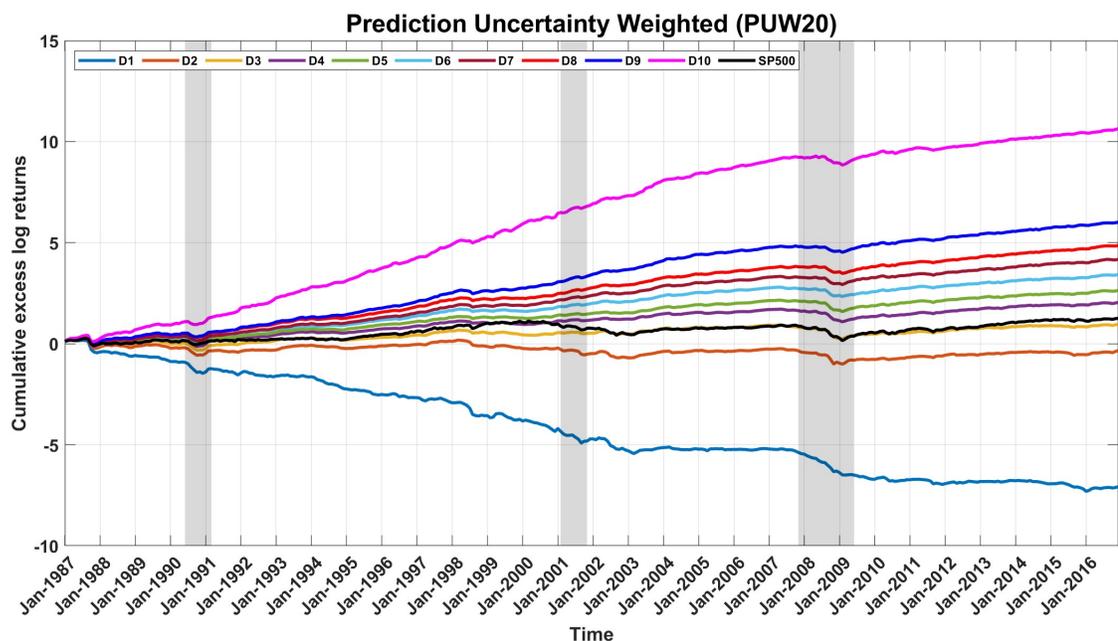

Figure A.7: This figure shows the cumulative excess log returns of prediction-uncertainty-weighted (PUW), with $\gamma = 20$, decile portfolios sorted based on our predicted returns. It also shows the S&P 500. The shaded periods indicate NBER recessions.

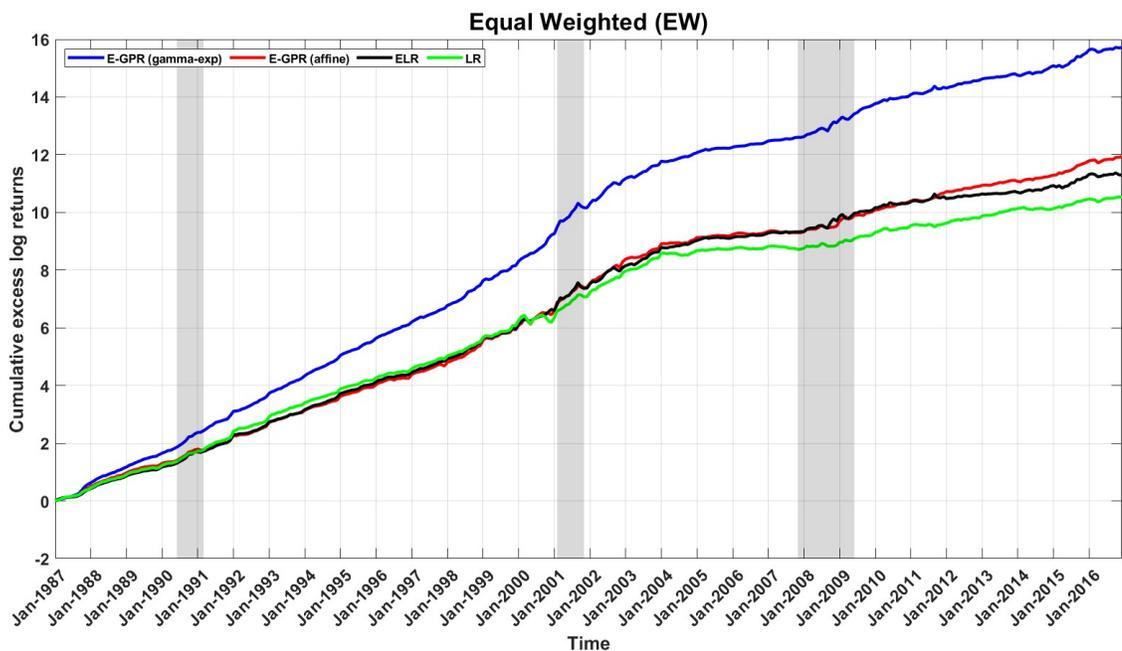

Figure A.8: This figure shows the cumulative excess log returns of equal-weighted (EW) long-short portfolio sorted based on the predicted returns from our GPR model (E-GPR (γ -exp)) and linear benchmark models (E-GPR (affine), E-LR and LR). The shaded periods indicate NBER recessions.

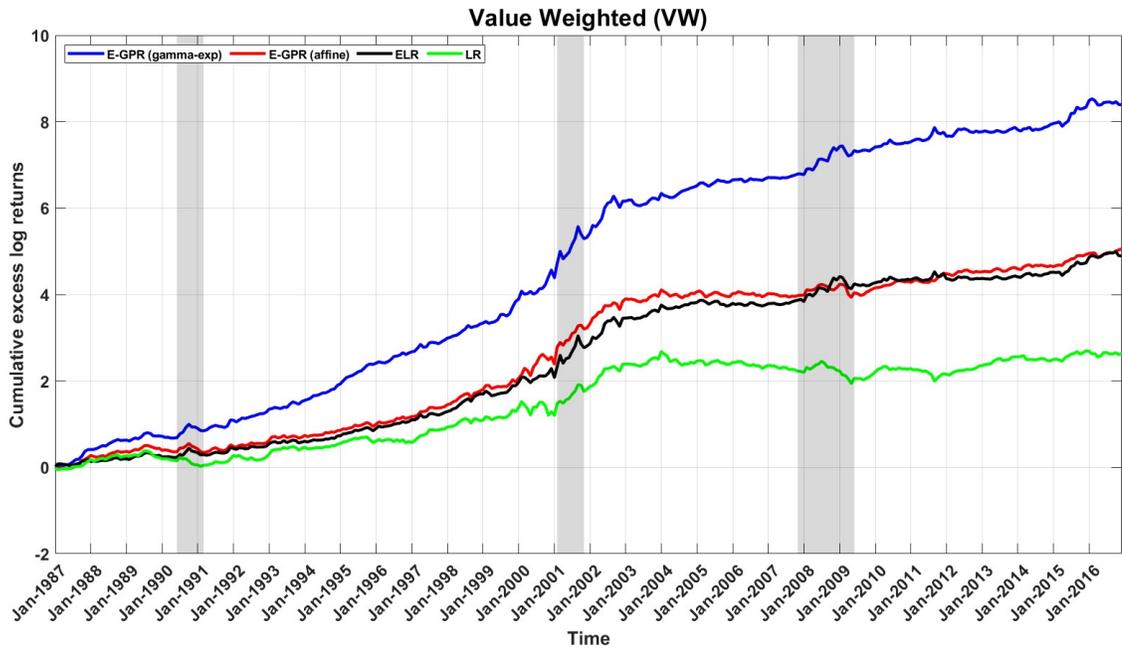

Figure A.9: This figure shows the cumulative excess log returns of value-weighted (VW) long-short portfolio sorted based on the predicted returns from our GPR model (E-GPR (γ -exp)) and linear benchmark models (E-GPR (affine), E-LR and LR). The shaded periods indicate NBER recessions.

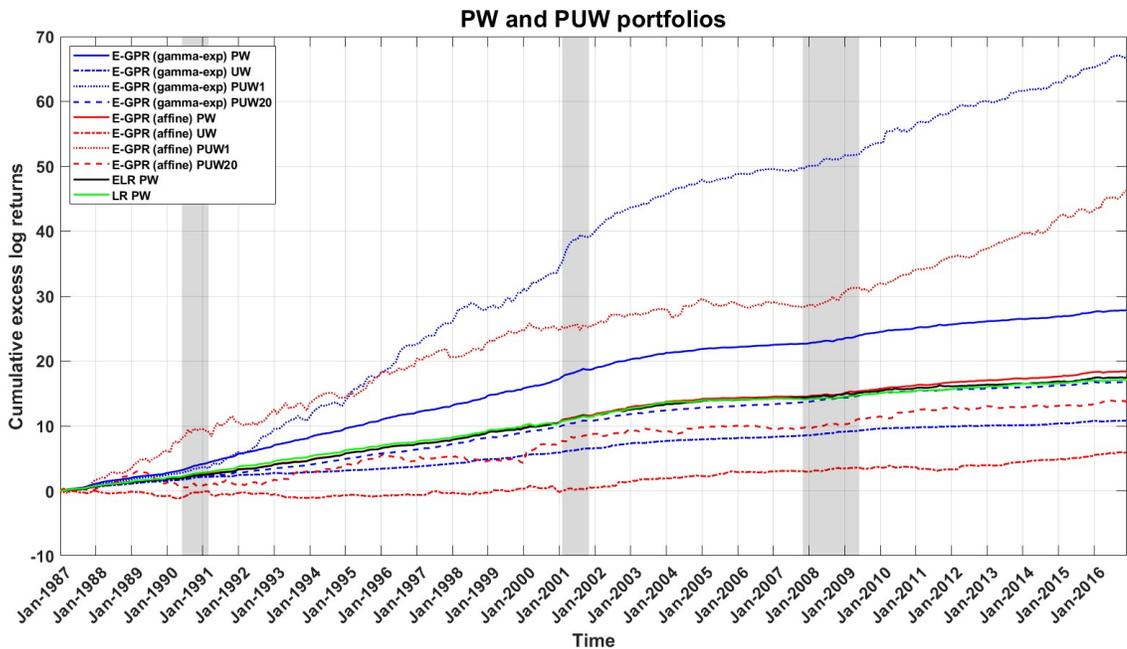

Figure A.10: This figure shows the cumulative excess log returns of prediction-weighted (PW) and prediction-uncertainty-weighted (PUW) long-short portfolio sorted based on the predicted returns from our GPR model (E-GPR (γ -exp)) and linear benchmark models (E-GPR (affine), E-LR and LR). The shaded periods indicate NBER recessions.
