

# Fundamentals of Perpetual Futures\*

Songrun He      Asaf Manela      Omri Ross      Victor von Wachter

First draft December 2022. This draft July 2024.

## Abstract

Perpetual futures are the most popular cryptocurrency derivatives. Perpetuals offer leveraged exposure to their underlying without rollover or direct ownership. Unlike fixed-maturity futures, perpetuals are not guaranteed to converge to the spot price. To minimize the gap between perpetual and spot prices, long investors periodically pay shorts a funding rate proportional to this difference. We derive no-arbitrage prices for perpetual futures in frictionless markets and bounds in markets with trading costs. Empirically, deviations from these prices in crypto are larger than in traditional currency markets, comove across currencies, and diminish over time. An implied arbitrage strategy yields high Sharpe ratios.

**JEL Classification:** G11, G12, G13

**Keywords:** Perpetual futures, crypto, random-maturity arbitrage, funding rate

# 1 Introduction

Perpetual futures are, by far, the most popular derivative traded in cryptocurrency markets, generating a daily volume of more than \$100 billion. Prior to the recent collapse of FTX, perpetual futures were among the most actively traded products on the exchange, with the now-bankrupt hedge fund Alameda Research taking the other side of many such leveraged trades. Despite their central role in crypto markets, there is relatively little work studying these derivatives. In this paper we ask: what are the theoretical fundamental values of perpetual futures, and how large are deviations from these fundamentals empirically?

Perpetuals are derivatives that allow investors to speculate on or hedge against cryptocurrency price fluctuations using high leverage, without needing to acquire the cryptocurrencies or to roll them over. Like traditional fixed-maturity futures, at initiation, a long and short counterparty agree on an initial futures price without exchanging any money, other than posting margin with the exchange. Both parties can enter or exit the contract at any time, with profits or losses continuously calculated and allocated to each side's margin account based on prevailing market prices.

Unlike fixed-maturity futures, perpetuals do not expire. This feature enhances the liquidity of the contract, as there is no staggering of contracts with different maturities traded on the exchange, and only a single perpetual futures contract per underlying asset is listed. Moreover, this instrument does not require market participants to roll over their futures positions and is traded 24/7.

Because they have no set expiration date, perpetuals are not guaranteed to converge to the spot price of their underlying asset at any given time, and the usual no-arbitrage prices for perpetuals are not applicable without additional restrictions. To minimize the gap between perpetual futures and spot prices, long position holders periodically pay short position holders a 'funding rate' proportional to this gap to incentivize trades that narrow

it. For example, when the futures price exceeds the spot price, arbitrageurs who borrow cash to long the spot and simultaneously short the futures would receive the funding rate. Their trades would tend to increase the spot price and decrease the futures price. A narrow gap means that perpetual futures offer effective exposure to variation in the spot price of the underlying asset to hedging and speculating investors. Typically, the funding rate is paid every eight hours and approximately equals the average futures-spot spread over the preceding eight hours. Note that the strategy just sketched, commonly referred to as 'funding rate arbitrage,' is not risk-free even disregarding margin requirements and trading costs, simply because there is no predetermined expiration date when the trade would be unwound at a profit.

We derive no-arbitrage prices for perpetual futures in frictionless markets and derive no-arbitrage bounds in markets with trading costs. The theoretical perpetual futures price is proportional to the spot price of the underlying, with a constant of proportionality that increases in the ratio of the interest rate to a constant that determines the intensity of the funding rate. The interest rate captures the cost of borrowing cash to finance holding the underlying, while the funding rate intensity captures the benefit of shorting the futures. Thus, intuitively, the future-spot spread is larger when the cash borrowing interest rate is large relative to the funding rate.

Our derivation relies on a weaker notion of arbitrage that we call *random-maturity arbitrage*. As its name suggests, unlike traditional riskless arbitrage, we allow the strategy's time-to-maturity to be random. At first glance, one might object that such prices are not truly based on riskless arbitrage. Note, however, that riskless no-arbitrage pricing is usually just a useful fiction (Pedersen, 2019). For example, in real-world futures markets, arbitrageurs must maintain a margin account during the entire period in which the arbitrage trade is open. Temporary worsening of apparent arbitrage opportunities can lead to liquidations and losses. As the saying goes, an arbitrageur must remain liquid longer than the market stays irrational. Thus, even arbitrage opportunities that appear to

be riskless in theory, may be risky in practice.

Our no-arbitrage prices provide a useful benchmark for perpetual futures and simultaneously prescribe a strategy to exploit divergence from these fundamental values. Motivated by the theoretical understanding, we study the empirical deviations of the perpetual futures price from the spot. We find that the mean deviation from our benchmark is modest and statistically insignificant, which suggests that it is a useful benchmark for futures prices.

Around this benchmark, however, perpetual futures often differ significantly from spot prices. The mean *absolute* deviation is about 60% to 90% per year across different cryptocurrencies, which is considerably larger than the deviations documented in traditional currency markets by [Du, Tepper, and Verdelhan \(2018\)](#). We find strong comovement of the futures-spot gap across different cryptocurrencies. This comovement can be due to commonality in funding and market liquidity faced by arbitrageurs who operate in multiple cryptocurrencies. Common sentiment could also drive the difference in futures demand relative to the spot. Overall, the deviation's magnitude is comparable to our theoretic no-arbitrage bound calibrated to actual trading fees.

Deviations decline on average about 11% a year, consistent with an increase in arbitrage capital and competition among arbitrageurs ([Kondor, 2009](#)). The narrowing gap provides an additional perspective on the downfall of Alameda Research and Three Arrows Capital. According to news reports and interviews, both hedge funds seem to have pivoted from such arbitrage activity around late 2021 to early 2022 and started taking more directional bets on cryptocurrencies, with both direct unhedged crypto holdings and investments in crypto startups. The large declines in crypto prices in 2022 subsequently exhausted their capital and led to their bankruptcies.<sup>1</sup>

---

<sup>1</sup>See, for example, Forbes, November 19, 2022, on [How Did Sam Bankman-Fried's Alameda Research Lose So Much Money?](#), Odd Lots, November 17, 2022, on [Understanding the Collapse of Sam Bankman-Fried's Crypto Empire](#), and Hugh Hendry's interview on December 3, 2022 of Kyle Davies on the [Collapse of Three Arrows Capital](#).

To understand the economics of the futures-spot spread, we consider a trading strategy motivated by the random-maturity arbitrage theory. Whenever the futures-spot spread exceeds the theoretical bound under certain trading cost tiers, we open the trading position and close it when the futures-spot spread returns to its theoretical relationship under no trading costs. We find that empirically, the random maturity arbitrage strategy generates a sizable Sharpe ratio even under high trading costs. For example, for Bitcoin perpetual futures, the strategy generates a Sharpe ratio of 1.8 under high trading costs typical of retail investors, and up to 3.5 for highly-active market makers who pay no such fees. The strategy's performance is even better for Ether and other cryptocurrencies and delivers significant alphas relative to the 3-factor model of [Liu, Tsyvinski, and Wu \(2022\)](#) and the 5-factor model of [Cong, Karolyi, Tang, and Zhao \(2022b\)](#).

The strong performance of our simple trading strategy, which exploits deviations from the random-maturity no-arbitrage bounds we derive, provides compelling evidence for the usefulness of these bounds as a benchmark for perpetual futures prices. The strategy generates high Sharpe ratios, even for investors subject to the highest trading costs on Binance. This indicates that the no-arbitrage prices serve as an effective anchor for perpetual futures, with profitable random maturity arbitrage opportunities arising when market prices diverge significantly from these fundamental values. Thus, the success of the trading strategy underscores the practical value and validity of our theoretical no-arbitrage results.

What explains these large no-arbitrage deviations? One natural explanation is that liquidity in crypto markets is insufficient for arbitrageurs to eliminate such violations. Our finding that the spreads decline over time is consistent with liquidity improving as these markets develop, and leaves open the possibility that they will narrow going forward. We also find, however, that past return momentum significantly explains the futures-spot gap with a time-series regression  $R^2$  of more than 50%. When past returns are high, futures tend to trade at a higher price relative to the spot. This indicates positive feedback or

momentum trading behavior in the perpetual futures market. This correlation may linger even as crypto markets become more efficient.

The existing literature on perpetual futures mainly focuses on empirical evidence. See e.g. [Alexander, Choi, Park, and Sohn \(2020\)](#), [De Blasis and Webb \(2022\)](#), [Ferko, Moin, Onur, and Penick \(2022\)](#), and [Streltsov and Ruan \(2022\)](#). [Christin, Routledge, Soska, and Zetlin-Jones \(2022\)](#) present a novel study on the strategy of longing the spot and shorting the perpetual futures to understand the demand pressure in the market. They document a significant return to this trading strategy and attribute the profits to differences of opinion and leverage constraints in the market. Our paper provides a general explanation for their findings as perpetual futures are more expensive relative to the theoretical no-arbitrage price for most of the recent sample period across major cryptocurrencies. Therefore, longing the spot and shorting the futures would be consistent with arbitrage trading directions. [Angeris, Chitra, Evans, and Lorig \(2022\)](#) provide a theoretical no-arbitrage analysis of perpetuals, which relies on a strong assumption that the payoff from the perpetual is a fixed function of the underlying spot price. [Ackerer et al. \(2023\)](#) derive no-arbitrage prices for various perpetual contracts in both discrete and continuous-time by assuming the existence of an equivalent martingale measure. We further relate our work to both papers below. Overall, compared to the existing literature, we illustrate the fundamental mechanism behind the perpetual design and derive theoretical no-arbitrage prices and bounds for this instrument in the presence of trading costs.

Also related is a recent literature on fixed maturity futures in the crypto market. [Schmeling, Schrimpf, and Todorov \(2022\)](#) provide a comprehensive analysis of the carry of fixed-maturity crypto futures, with the carry defined following the general definition of [Kojien, Moskowitz, Pedersen, and Vrugt \(2018\)](#). They document volatile convenience yields for fixed-maturity crypto futures and attribute this to trend-chasing small investors and the relative scarcity of arbitrage capital. [Cong, He, and Tang \(2022a\)](#) provide a novel link of the volatile convenience yield to the staking, service flow, and transaction

convenience of the underlying tokens. They show that the large deviation from uncovered interest rate parity can be reconciled with transaction convenience. Our paper focuses on perpetual futures rather than fixed maturity futures and extends fixed-maturity to random-maturity no-arbitrage pricing.

More broadly, our paper contributes to the understanding of frictions and arbitrage in cryptocurrency markets. [Makarov and Schoar \(2020\)](#) study price deviations across exchanges. They find large gaps across countries, highlighting the important role played by capital controls and slow-moving arbitrage capital as in [Duffie \(2010\)](#). Our analysis focuses on the price wedge between the spot and the futures market. We find that even within an exchange, futures prices deviate from their theoretical arbitrage-free values. These results indicate there are significant limits to arbitrage as in [Gromb and Vayanos \(2018\)](#) for cryptocurrencies in the early years. Finally, our finding that deviations from the no-arbitrage benchmark in crypto markets are highly correlated across currencies suggests that a common risk factor drives this variation as documented by [Lustig, Roussanov, and Verdelhan \(2011\)](#) in traditional currency markets.

The rest of the paper is organized as follows: Section 2 provides the institutional details and history of perpetual futures. Section 3 presents the no-arbitrage analysis of the perpetual futures market and derives the theoretical price of perpetual futures. Section 4 demonstrates the empirical futures-spot deviation and presents the simple theory-motivated trading strategy that can exploit the arbitrage opportunity. Section 5 provides some explanation for the deviation between futures and the spot. Section 6 concludes.

## 2 An Introduction to Perpetual Futures

The idea of perpetual futures was first introduced by [Shiller \(1993\)](#). The goal was to set up a perpetual claim on the cash flows of an illiquid asset. For example, the underlying

illiquid asset could be a house that generates rents as cash flows. The purpose of the perpetual futures is to enable price discovery for the underlying with an illiquid or hard-to-measure price. Perpetual futures have no expiration date but cash is exchanged between the long and the short side: after buying the perpetual futures, the long side is entitled to receive the flow cash flow from the short side and they settle the price difference when exiting the position.

**Figure 1** Total trading volumes of perpetual futures across exchanges

The figure displays the 7-day moving average daily traded volume for perpetual futures across all exchanges in blue. The median daily volume is \$17.8 bn. (2020), \$132.0 bn. (2021) and \$101.9 bn. (2022). This translates to a yearly volume of \$8,551 bn. (2020), \$51,989 bn. (2021) and \$39,306 bn. (2022) respectively. Additionally, the grey line depicts the ratio between the traded volume in perpetuals and spot markets. In 2022 the Perpetual markets are consistently trading between 2x or 3.5x the spot volume. The data is obtained from CoinGecko, a crypto data specialist. We exclude exchanges that are known for misrepresenting data (e.g. forms of wash trading).

Perpetual futures in crypto markets similarly have no expiration date and cash is exchanged between the long and the short side, but their purpose is different from Shiller’s original idea. First, unlike, e.g. real estate market, crypto has no inherent dividend or cash flow. Second, the price discovery argument of Shiller is most applicable to settings where spot prices are difficult to measure. Crypto spot prices, however, can be measured from active trading on different exchanges, and decentralized exchanges such as Bancor (Hertzog et al., 2017) or Uniswap (Adams et al., 2021) offer price discovery for assets

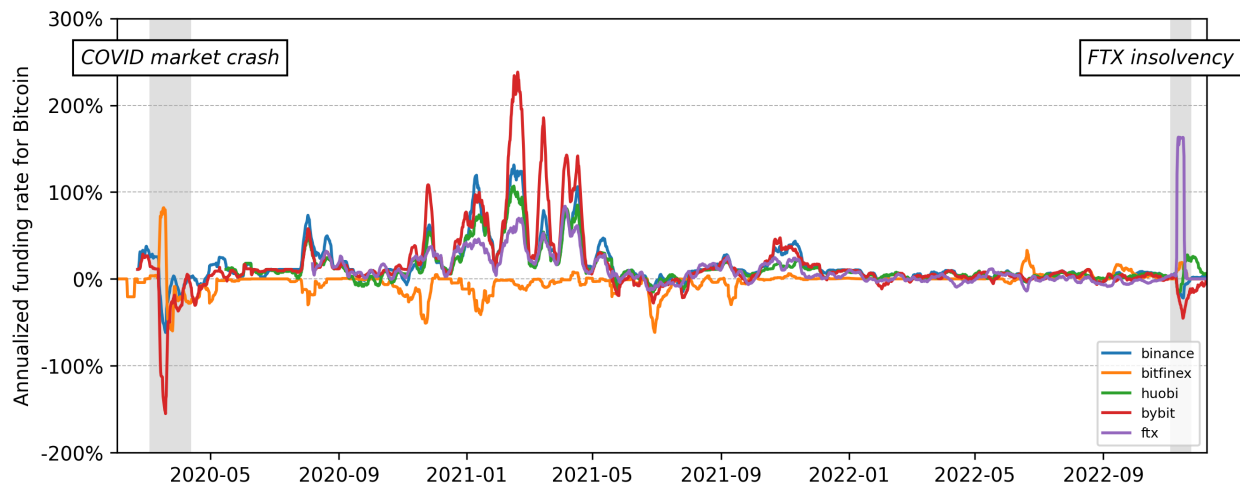

with minimal liquidity. The major role perpetual futures play in the crypto space is to offer an effective leveraged trading vehicle to hedge or speculate the underlying spot price movement, which makes the market more complete. It also serves as an effective tax payment optimization tool for investors.

Crypto perpetual futures were first introduced by BitMEX in 2016, which has gained great popularity in the crypto space since its inception. It initially served as an effective hedging tool for crypto miners. It was later adopted by crypto speculators interested in leveraged exposure. Nowadays, based on data from CoinGecko, the median total daily trading volume of perpetual futures across all exchanges is 101.9 billion in the year 2022 which is about  $2\times$  to  $3\times$  the total spot trading volume across these exchanges. Figure 1 presents the 7-day moving average of the total trading volume of perpetual futures across all exchanges. We see a significant rise in trading of perpetual futures around January 2021 and the total volume stabilizes at a level above \$100 billion per day following the rise.

[Cong, Li, Tang, and Yang \(2022c\)](#) document significant wash trading behavior among crypto exchanges because of competition, the ranking mechanism, and lack of regulation. They estimate that over 70% of crypto trading volume is not real. [Amiram, Lyandres, and Rabetti \(2021\)](#) confirm this conclusion using new data and an extended methodology. Therefore, in calculating trading volume, we exclude exchanges that are known to misrepresent data.

A key feature of crypto perpetual futures is the funding rate, which is the cash exchanged between the long and short counterparties. Its goal is to keep the futures price close to the underlying spot so that the futures can be an effective hedging tool for spot price movement. The funding rate is typically paid every 8 hours. Its value is approximately a weighted average of the prior 8 hours' price gap of the futures and the spot. If the futures price is above the spot, the funding rate will be positive, meaning the long side of the futures needs to pay the short side. This incentivizes traders to short the

**Figure 2** Bitcoin annualized funding rate across exchanges

The figure presents the 7-day moving average annualized funding rate for Bitcoin (BTC) across exchanges. The data is obtained from Glassnode, an analytics platform. The data covers two major market turbulences: the COVID stock market crash from February to April 2020 and the FTX insolvency in November 2022. The FTX collapse led to significant negative funding rates on all solvent exchanges. Thus, the perpetual future prices were lower than the spot prices on the solvent exchanges. Vice versa on the insolvent FTX. The funding rates become more volatile after the event, indicating increased uncertainty for the market participants.

futures, and in doing so, to move its price back in line with the spot. On the other hand, when the futures price is below the spot, the funding rate turns negative, which means the short side needs to pay the long side. Therefore, the funding rate is the key mechanism keeping the futures price close to the spot price.<sup>2</sup> Note that perpetual futures cannot be replicated by rolling over 8-hour maturity futures. For the latter, every 8 hours, the price is guaranteed to converge to the underlying spot, while for the perpetual futures this is not the case.

Figure 2 presents the annualized 7-day moving average of Bitcoin perpetual funding rates across leading exchanges from January 2020 to December 2022. The funding rate is positive when the futures-to-spot spread is positive, and negative otherwise. Funding rates tend to be similar across exchanges due to cross-exchange arbitrage activity, but

<sup>2</sup><https://www.binance.com/en/support/faq/360033525031> provides a detailed explanation of how the funding rate is calculated. We summarize the mechanism in Appendix B.

can diverge during extreme liquidity episodes. During March 2020, as COVID-19 started to spread and liquidity evaporated, funding rates turned substantially negative in most exchanges. Funding rates turned highly positive during the crypto bull run of early 2021. The last episode highlighted is the collapse of FTX, which was the 4th largest crypto exchange at the time. The figure shows that Bitcoin futures prices were substantially higher than spot prices at FTX, but the opposite was true on other exchanges. This pattern is consistent with FTX investors liquidating their short futures positions quickly, either voluntarily to reduce their exposure to the failing exchange, or involuntarily as the exchange liquidated their underfunded positions.

### 3 Arbitrage in Perpetual Futures

We next derive no-arbitrage prices for perpetual futures prices relative to spot prices. Unlike traditional futures, perpetual futures have no expiration date. To analyze arbitrage in this market, we extend the traditional notion of risk-free arbitrage, where arbitrageurs have a guaranteed positive payoff at a certain time in the future. We first describe the payoff structure of perpetual futures. We then introduce a generalized notion of an arbitrage opportunity with a certain positive payoff but at an uncertain future time.

**Definition 1** (Perpetual futures). *A perpetual futures contract with price  $\{F_t\}_{t=0}^\infty$  written on an underlying asset with spot price  $\{S_t\}_{t=0}^\infty$  is a swap agreement between the long and the short side. There is no cost to open the position. Once open, both the long side and the short side can terminate their position at any time  $t$ . To stay in the contract, both sides have to meet two requirements. (1) For each unit of the perpetual, the long and short sides must exchange an  $\mathcal{F}_s$ -adapted cash-flow  $\kappa(F_s - S_s)ds$ ,  $s \in (0, t)$ , referred to as the funding payment.  $\kappa$  is a scaling parameter determining the magnitude of the funding rate relative to the price gap. If the value is positive, the long pays the short, and vice versa. (2) Both sides need to post mark-to-market margins to cover any losses in their margin accounts.*

This definition is an approximation of real-world perpetual futures.<sup>3</sup> In most exchanges, the funding payment for perpetual futures is paid every 8 hours and approximately equals the average difference between the futures price and the spot over the 8 hours (480 minutes or  $\frac{1}{1095}$  years). If we measure time units in years, the cumulative funding rate payment during an 8-hour period is:

$$\int_t^{t+1/1095} \kappa(F_s - S_s) ds.$$

Consider the case when  $F_t - S_t = G$ , which is constant over the 8-hour interval. In the real world, the funding rate payment would equal  $G$  while in our model, the number is  $\frac{\kappa G}{1095}$ . To equalize the two, we have  $\kappa = 1095$ .

The traditional notions of arbitrage typically consider a guaranteed positive payoff at a certain future date.

**Definition 2** (Riskless arbitrage). *A riskless arbitrage opportunity is defined with respect to a payoff  $x$  at a certain future time  $\tau$  and its price  $p(x)$ . If the following conditions are satisfied: (1)  $x \geq 0$  almost surely, (2)  $x > 0$  with some positive probability, and (3) its price satisfies  $p(x) \leq 0$ , then this payoff is an arbitrage opportunity (Cochrane, 2009).*

There is no certain future time, however, when a perpetual futures expires and its price is guaranteed to converge to some fixed function of the spot price. Therefore, a generalized notion of arbitrage is required. Suppose the risk-free rate is constant. We define *random-maturity arbitrage* opportunities as zero-cost strategies with a guaranteed positive payoff at a bounded uncertain future time. Stated formally:

**Definition 3** (Random-maturity arbitrage). *A random-maturity arbitrage opportunity is defined with respect to a random payoff  $x$  at a bounded future random time  $\tilde{\tau} < \bar{T}$ , and its price*

---

<sup>3</sup>To avoid price manipulation and volatile funding payments, Binance applies a clamp function to funding rate payments when the deviation is small. We provide a thorough discussion of the funding rate mechanism in Appendix B.

$p(x)$ . If the following conditions are satisfied: (1)  $x \geq 0$  almost surely, (2)  $x > 0$  with some positive probability, and (3) its price satisfies  $p(x) \leq 0$ , then this payoff is a random-maturity arbitrage opportunity.

Definition 3 generalizes traditional arbitrage in the sense that there is a guaranteed positive payoff but at an uncertain future time. The following corollary specializes this definition for perpetual futures:

**Corollary 1.** *In the perpetual futures market, if a strategy (1) has 0 cost at time 0, and (2) for any price path of the futures and the spot,  $\{F_t\}_{t=0}^{\infty}$  and  $\{S_t\}_{t=0}^{\infty}$ , there exists a bounded unwinding time  $\tilde{\tau}$  such that the strategy's discounted payoff is positive, then this strategy is a random-maturity arbitrage.*

We next show that when there is no random-maturity arbitrage, the futures price is a fixed constant times the spot price under the two following assumptions:

**Assumption 1.** *The risk-free short rate  $r$  in the cash market and the instantaneous interest rate on the underlying asset  $r'$  are constant.*

**Assumption 2.** *The gap between the perpetual futures and its fundamental price is bounded:  $\sup_t |F_t(\omega) - \lambda S_t(\omega)| < M, \forall \omega$ , where  $\lambda$  is a proportionality constant implied by Equation (1).*

**Assumption 3.** *The funding rate is larger than the short rate in the cash market:  $\kappa > r$ .*

Assumption 1 guarantees that there is no roll-over risk for the arbitrageurs. Assumption 2 is a no-bubble condition, which says that the largest deviation of perpetual futures from its no-arbitrage price can be bounded by  $M$ . Assumption 3 states that the design of the contract needs to guarantee that the reward for convergence trade is larger than deploying the capital to the risk-free asset. With these three assumptions, we can state our result as follows.

**Proposition 1** (No-arbitrage price). *Under Assumptions 1, 2, and 3, there is an absence of random-maturity arbitrage opportunities if and only if*

$$F_t = \frac{\kappa}{\kappa - (r - r')} S_t. \quad (1)$$

*Proof.* We first show when there are no random maturity arbitrage opportunities, the perpetual futures price must be given by Equation (1). We establish this using the conjecture and verify approach.

Firstly, conjecture that the equilibrium futures price is a linear function of the spot:  $F_t = \lambda S_t$ , where  $\lambda$  is the parameter to be determined. Consider the following two scenarios in Table 1. (1)  $F_0 > \lambda S_0$ ; (2)  $F_0 < \lambda S_0$ . We show in the first case that arbitrageurs would long the spot and short the futures because this is a random-maturity arbitrage opportunity. We then show that the opposite strategy is optimal in the second case.

For the payoff given in Table 1, it is worth noting that the mark-to-market margin requirements indicate any interim futures price changes will affect the payoff of the trader since she needs to post enough margin to cover losses or can invest the surplus in margin account in risk-free assets. Moreover, in the cash market, the trader needs to roll over the short-term debt to finance the position in the spot market. The interest paid from holding the underlying asset depends on the spot price.

To start off, we need to fix  $\lambda$ . Given our conjecture, if  $F_t = \lambda S_t$ , both the first and second strategies in Table 1 should have 0 payoff. This condition gives us the following equation:

$$\lambda = 1 + \frac{(r - r')\lambda}{\kappa} \implies \lambda = \frac{\kappa}{\kappa - (r - r')}.$$

Next, given this  $\lambda$ , we verify that the deviation shown in Table 1 implies the existence

		$F_0 > \lambda S_0$	$F_0 < \lambda S_0$
Actions		Long $\lambda$ spot, short 1 futures	Long 1 futures, short $\lambda$ spot
Time 0	Futures	0	0
	Spot	$-\lambda S_0$	$+\lambda S_0$
	Cash	$+\lambda S_0$	$-\lambda S_0$
Time $t$	Futures	$-\int_0^t e^{-rs} dF_s$	$\int_0^t e^{-rs} dF_s$
	Funding	$\kappa \int_0^t (F_s - S_s) e^{-rs} ds$	$-\kappa \int_0^t (F_s - S_s) e^{-rs} ds$
	Spot	$\lambda \int_0^t e^{-rs} (dS_s + r' S_s ds)$	$-\lambda \int_0^t e^{-rs} (dS_s + r' S_s ds)$
	Cash	$-\lambda \int_0^t e^{-rs} r S_s ds$	$\lambda \int_0^t e^{-rs} r S_s ds$
Payoff		$-\int_0^t e^{-rs} d(F_s - \lambda S_s) + \kappa \int_0^t e^{-rs} \left( F_s - \left( 1 + \frac{(r-r')\lambda}{\kappa} \right) S_s \right) ds$	$\int_0^t e^{-rs} d(F_s - \lambda S_s) - \kappa \int_0^t e^{-rs} \left( F_s - \left( 1 + \frac{(r-r')\lambda}{\kappa} \right) S_s \right) ds$

**Table 1** Discounted payoffs to arbitrage strategies in perpetual futures and spot markets

This table presents the costs and benefits of two arbitrage trading strategies: (1) when  $F_0 > \lambda S_0$ , long  $\lambda$  spot and short 1 futures; (2) when  $F_0 < \lambda S_0$ , long 1 futures and short  $\lambda$  spot. In the last row, the payoff from exiting the position is the discounted payoff from futures and spot price changes, proceeds from the cash market, and the funding rate.

of random maturity arbitrage opportunities. In what follows, we denote the deviation by:

$$u_s \equiv F_s - \frac{\kappa}{\kappa - (r - r')} S_s.$$

We can then write the payoffs of the two strategies in Table 1 respectively as:

$$\begin{aligned} -\int_0^t e^{-rs} du_s + \kappa \int_0^t e^{-rs} u_s ds &= -e^{-rt} u_t + u_0 + (\kappa - r) \int_0^t u_s e^{-rs} ds, \\ \int_0^t e^{-rs} du_s - \kappa \int_0^t e^{-rs} u_s ds &= e^{-rt} u_t - u_0 - (\kappa - r) \int_0^t u_s e^{-rs} ds, \end{aligned}$$

where the equality follows from integration by parts.

**Scenario 1:** If  $F_0 > \lambda S_0$ , consider the first strategy of longing  $\lambda$  spot and shorting 1 futures. We want to show that for any price path of the perpetual futures and the spot, there exists a bounded future unwinding time  $t$  such that the strategy's payoff is positive, which would mean this is a random-maturity arbitrage. To prevent the arbitrageur from

making a profit, the payoff must be nonpositive at all times  $t$ :

$$\underbrace{-e^{-rt}u_t}_{\text{spread at unwinding}} + \underbrace{u_0}_{\text{initial spread}} + \underbrace{(\kappa - r) \int_0^t u_s e^{-rs} ds}_{\text{funding payments}} \leq 0. \quad (2)$$

Consider the first time period when the deviation is positive. That is,  $u_s > 0$ ,  $s \in (0, \min\{t > 0, u_t = 0\})$ . Rearrange the terms, the inequality becomes:

$$e^{-rt}u_t \geq u_0 + (\kappa - r) \int_0^t u_s e^{-rs} ds. \quad (3)$$

Let  $\underline{u}_t$  denote a process, implicitly defined by  $e^{-rt}\underline{u}_t = u_0 + (\kappa - r) \int_0^t \underline{u}_s e^{-rs} ds$ , which provides a lower bound for all processes  $u_t$  satisfying inequality (3). Solving this integral equation, we have:

$$\underline{u}_t = e^{\kappa t} u_0.$$

From the above expression, there exists a time  $\bar{T} = \frac{\log(M) - \log(u_0)}{\kappa}$ , such that  $\underline{u}_t \geq M$  when  $t \geq \bar{T}$ . This implies that  $u_t \geq M$  when  $t \geq \bar{T}$ , which violates Assumption 2.

Therefore,  $u_t$  cannot stay positive in  $(0, \bar{T})$ . However, if the deviation ever hits 0 during  $t \in (0, \bar{T})$ , this would also make positive profit for the arbitrageur. Consider the first time the deviation hits 0. The payoff in Equation (2) is positive. In sum, if  $F_0 > \lambda S_0$ , the proposed strategy is a random maturity arbitrage.

**Scenario 2:** Next, if  $F_0 < \lambda S_0$ , i.e.  $u_0 < 0$ , consider the second strategy of longing 1 futures and shorting  $\lambda$  spot. As before, we want to show that for this strategy under any price path of the perpetual futures and the spot, there always exists a bounded future time  $t$  such that the strategy payoff is positive, i.e. this is a random maturity arbitrage. Similarly, to prevent the arbitrageur from making a profit, the payoff needs to satisfy:

$$e^{-rt}u_t \leq u_0 + (\kappa - r) \int_0^t u_s e^{-rs} ds.$$

Consider the first time period when the deviation is negative, i.e.  $u_s < 0$ ,  $s \in (0, \min\{t > 0, u_t = 0\})$ .  $e^{-rt}\bar{u}_t = u_0 + (\kappa - r) \int_0^t \bar{u}_s e^{-rs} ds$  provides an upper bound for all processes satisfying the inequality. This is the same integral equation as we see in the first case. We have:

$$\bar{u}_t = e^{\kappa t} u_0.$$

From the above expression, there exists  $\bar{T} = \frac{\log(M) - \log(-u_0)}{\kappa}$  such that  $\bar{u}_t < -M$  when  $t \geq \bar{T}$ . This implies that  $u_t \leq -M$  when  $t \geq \bar{T}$ , which breaks Assumption 2.

Similar to scenario 1,  $u_t$  cannot stay negative in  $(0, \bar{T})$ . However, if it ever hits 0 in the period, exiting the position the first time the deviation hits 0 would be a profitable strategy for the arbitrageur. Therefore, if  $F_0 < \lambda S_0$ , the proposed strategy is a random maturity arbitrage.

In sum, when there is an absence of random maturity arbitrage strategies, the price of perpetual futures is a fixed constant times the spot price given in Equation (1).

For the opposite direction of proof, when the futures and spot prices satisfy Equation 1, we need to prove that there is no random maturity arbitrage opportunity in the market. This can be seen easily as any long-short trading strategies would be exposed to the risk in the spot market as long as the proportion is not the same as  $\lambda$ . Longing or shorting the spot market is clearly not a random maturity arbitrage opportunity as the time to make a positive arbitrage profit is not bounded for the arbitrageur.  $\square$

To gain an intuition for this result, consider the three terms of Equation 2. The first term is the spread at unwinding discounted to the present. The second term is the initial spread. The last term is the present value of cumulated funding payments from initiation to unwinding. The last two terms account for gains to the arbitrageur in this scenario. The first term is the source of tension here. For fixed-maturity futures, this spread is guaranteed to be zero at expiration. However, an arbitrageur in perpetual futures faces

the risk that when they wish to unwind the trade, the spread may be arbitrarily large.

Our key insight is that a positive and even modestly large spread can still leave the arbitrageur with a positive payoff because funding payments also increase with the spread. As long as the spread does not diverge to infinity, there will be some future bounded unwinding time  $t$  when the accumulated funding rate payments overcome any finite potential losses at unwinding.

Note that if we relax the assumption that the short rate is constant for arbitrageurs, this may introduce some additional risk to the four parts of terms in Table 1: (1) mark-to-market changes in futures price; (2) funding-rate payment; (3) reinvestment in the spot market; (4) rollover of the short-term debt. This extension also relates to the literature examining the differences between futures and forwards in the context of stochastic interest rates, such as [Cox et al. \(1981\)](#) and [Grinblatt and Jegadeesh \(1996\)](#). They show that marking-to-market introduces an additional term in the futures price related to the covariance between the underlying asset and interest rate. Empirically, however, the volatility in the short rate is considerably smaller than the volatility in the deviation from futures to its fundamental price. Moreover, the changes in the short rate have opposite effects on payment from the cash market and the funding payment, as well as mark-to-market margin in the futures market and reinvestment in the spot market. Therefore, we abstract from short-rate randomness here but note it is an interesting avenue for future work.

Empirically, the arbitrageurs face trading costs when opening or terminating their positions. Suppose they face a round-trip trading cost of  $C$ . We can derive the no random maturity arbitrage bounds for perpetual futures.

**Proposition 2** (No-arbitrage bound). *Under Assumption 1 and 2, when there is a round-trip trading cost  $C$  of executing the trading strategy, the absence of random-maturity arbitrage opportunities implies that perpetual futures price will lie within the following bound relative to the*

spot:

$$|F_t - \frac{\kappa}{\kappa - (r - r')} S_t| \leq C. \quad (4)$$

*Proof.* Similar to the proof of proposition 1, consider the following two scenarios.

**Scenario 1:** If  $F_0 > \lambda S_0 + C$ , then we show the strategy of longing  $\lambda$  spot and shorting 1 futures is a random-maturity arbitrage strategy with trading cost. To prevent the arbitrageur from making a profit, now the payoff needs to satisfy:

$$-e^{-rt} u_t + u_0 - C + (\kappa - r) \int_0^t u_s e^{-rs} ds \leq 0.$$

Following the same argument as in the proof of proposition 1, we can find the lower bound process  $\underline{u}_t$  as:

$$\underline{u}_t = (u_0 - C)e^{\kappa t}.$$

When  $u_0 > C$ , this process will explode toward  $M$  at an exponential rate. Following the same argument as in proof proposition 1, the proposed trading strategy is a random-maturity arbitrage strategy.

**Scenario 2:** If  $F_0 < \lambda S_0 - C$ , then we show the strategy of longing 1 futures and shorting  $\lambda$  spot is a random-maturity arbitrage strategy despite the trading cost. Now, the payoff needs to satisfy the following condition to prevent the arbitrageur from making a profit:

$$e^{-rt} u_t - u_0 - C - (\kappa - r) \int_0^t u_s e^{-rs} ds \leq 0.$$

Similar to the argument in scenario 2 of proposition 1, we can find the upper bound process as:

$$\bar{u}_t = (u_0 + C)e^{\kappa t}.$$

When  $u_0 < -C$ , this process will explode toward  $M$  at an exponential rate. With the same argument, the proposed trading strategy is again a random-maturity arbitrage strategy.

In sum, with trading cost, the absence of random maturity arbitrage opportunity implies that the futures price lies within a bound relative to the spot:  $\lambda S_t - C \leq F_t \leq \lambda S_t + C$ .  $\square$

In the presence of trading costs, when the deviation of the perpetual futures price from  $\lambda S_t$ , is larger than the round-trip trading costs  $C$ , arbitrageurs would have a strong incentive to trade perpetual futures toward the price  $\lambda S_t$ . Proposition 2 also prescribes a trading strategy to exploit the futures-spot divergence in markets with different levels of trading costs. In the next section, we provide an empirical analysis of the futures-spot deviation and present arbitrage trading strategies motivated by our theory.

Before turning to the data, we pause to relate our results to two recent theoretical contributions. Angeris et al. (2022) consider an inverse problem to our setting. It assumes there is no arbitrage and that the perpetual futures price is a function of the spot, and derives the funding rate process that is consistent with the pricing formula. This takes a perspective of security design. However, empirically, funding rate mechanisms are predetermined and fixed for traders. Moreover, because of the limits of arbitrage, futures prices can deviate from the fixed function set by the designer. Our approach prescribes a strategy to exploit divergence from the fundamental price and offers a closer alignment with real-world trading conditions.

Compared to Akerer et al. (2023), our initial draft, disseminated December 2022 (see <https://arxiv.org/abs/2212.06888v1>), considers the case when the underlying pays no interest  $r' = 0$ . It shows that the absence of random-maturity arbitrage opportunities implies the price of perpetual futures lies within the following bound relative to the spot:

$$|F_t - \left(1 + \frac{r}{\kappa}\right) S_t| \leq C, \quad (5)$$

and that in the case without trading costs, the price would be

$$F_t = \left(1 + \frac{r}{\kappa}\right) S_t. \quad (6)$$

Ackerer et al. (2023, <https://arxiv.org/abs/2310.11771v1>), dated October 2023, uses a different set of assumptions and solution method to derive no-arbitrage prices for more general perpetual contracts including the one we study. In their paper, the price relevant for the case we analyzed is:

$$F_t = \frac{\kappa}{\kappa - r} S_t. \quad (7)$$

Their paper further pointed out an inconsistency in the cash flow specification in our original derivation. After correcting this issue, Equation (1) above is consistent with their derivation in this case, and they deserve credit for deriving the correct formula first.<sup>4</sup>

While different, to a first-order approximation, equations (6) and (7) are equivalent. Because our empirical analysis relies on first-order approximations for the deviations, the correction did not change any of our estimators. Moreover, the difference between the two benchmarks is negligible in practice because  $\kappa$  is much larger than  $r$ .

An advantage of our derivation is that it makes explicit the arbitrage trading strategy in case of deviations and provides bounds in the case of trading costs which we use in our empirical analysis. Another difference is that we assume that the *deviations* between the futures and spot are bounded, whereas Ackerer et al. (2023) assume that a transversality condition holds such that the futures price (and therefore the spot) grows at a slow enough rate relative to the funding payments intensity  $\kappa$ . But even under their assumptions, it can be shown that strategies aimed at arbitrage of deviations from their benchmark prices are necessarily random-maturity arbitrage strategies, as we emphasize here.

---

<sup>4</sup>We thank Damien Ackerer, Julien Hugonnier, and Urban Jermann for the comments that helped clarify the issue.

## 4 Data and Empirical Analysis

We conduct an empirical analysis of perpetual futures arbitrage strategies. We first describe the data. We then measure the deviations of the crypto futures-spot spread from the no-arbitrage benchmark. Finally, we implement a trading strategy that exploits deviations from random-maturity no-arbitrage bounds and quantify the gains from this strategy net of trading costs.

### 4.1 Data

We focus on the five largest cryptocurrencies excluding stablecoins: Bitcoin (BTC), Ether (ETH), BNB (BNB), Dogecoin (DOGE), and Cardano (ADA) with a total market cap of \$1.83 trillion, which account for 73.2% of the total market share of the Crypto market by March 2024.

For each token, we obtain perpetual futures and spot prices at a 1-hour frequency from Binance. Binance is by far the leading exchange in the crypto realm. Another major benefit of using the Binance data is: nearly every part of our trading strategies can be completed within the same platform without delay in transferring funds. As such, it approximates the real-world investment opportunities faced by traders.

We retrieve the perpetual funding rates from Binance. The funding rate is paid every 8 hours on Binance. So we have futures and spot prices every hour and realized funding rate payment at 8:00, 16:00, and 0:00 GMT each day. The perpetual and spot tradings occur 24 hours per day and 7 days a week so there are no after-market hours in this market.

We get the earliest possible data on perpetual futures trading from Binance. The table below lists the starting and ending dates of our data for each cryptocurrency. Our data ends on 2024-03-11, covering the fallout of the FTX.

Asset	Start date	End date	N
BTC	2020-01-08	2024-03-11	36,578
ETH	2020-01-08	2024-03-11	36,578
BNB	2020-02-10	2024-03-11	35,777
DOGE	2020-07-10	2024-03-11	32,152
ADA	2020-01-31	2024-03-11	36,017

**Table 2** Sample descriptions

This table presents the sample start and end dates for the five cryptocurrencies and their total number of observations.

We obtain trading costs from Binance’s website<sup>5</sup>. In general, trading costs for the spot market are significantly larger than those for the perpetual futures for similar trading volume because futures are typically traded with leverage. Fee tiers are attributed to the 30-day trading volume. We attribute high trading costs with a 30-day spot trading volume above \$1 million and futures trading volume above \$15 million (small individual trader). Medium trading costs are attributed to a 30-day spot trading volume above \$150 million and futures trading volume above \$1 billion (small funds). Low trading costs are attributed to a 30-day spot trading volume above \$2 billion and futures trading volume above 12.5 billion (large funds). Zero fees can be negotiated with customized contracts, for example, for market makers. We consider trading costs for makers instead of takers because institutions typically trade maker orders.<sup>6</sup>

Table 3 presents the specification of different trading costs. It also shows the random-maturity arbitrage bound for the deviation between the perpetual futures and the no-arbitrage price ( $\rho_l$  and  $\rho_u$ ). The bounds become wider as the trading costs increase. Detailed explanations of the trading costs specifications are also provided in appendix Figure 6 and Figure 7.

<sup>5</sup><https://www.binance.com/en/fee/trading> provides data on trading fees in perpetual futures and the spot market

<sup>6</sup>Takers trade market orders while makers trade limit orders. Takers take liquidity from the market while makers make the market or provide liquidity to the market.

Fee tier	Spot	Futures	$\rho_l$	$\rho_u$
No	0%	0%	0.0%	0.0%
Low	0.0225%	0.0018%	-53.2%	53.2%
Medium	0.045%	0.0072%	-114.4%	114.3%
High	0.0675%	0.0144%	-179.5%	179.2%

**Table 3** Trading costs tiers

Fee tiers are assigned based on past 30-day trading volume. High fees correspond to a 30-day trading volume above \$1mn in spot and above \$15mn in perpetuals, typically an individual trader. Medium fees attribute to a 30-day trading volume above \$150mn in spot and above \$1bn in perpetuals (small funds). Low fees are attributed to a 30-day trading volume above \$2bn in spot and above \$12.5bn in perpetuals (large funds). The no-fee tier can be negotiated with customized contracts, for example for market makers. We also report the theory implied no arbitrage bound ( $\rho_l$  and  $\rho_u$ ) for  $\rho$  under different trading cost specifications. They are calculated using the following formulas:  $\rho_l = \kappa \log(1 - C)$ ,  $\rho_u = \kappa \log(1 + C)$ , where  $C$  is the round-trip percentage trading costs of the long-short strategy of perpetual and spot.

In addition to the direct trading fees, traders also face bid-ask spread and price impact costs in our arbitrage strategies. To assess the importance of such indirect trading costs, we attain from Kaiko a high-frequency sample with one month of order book snapshots taken every 30 seconds. With this data, we estimate that the average bid-ask spread for perpetual futures is less than 0.05 bps, and the price impact of a trade with a size equal to 0.5 million is less than 0.3 bps. Combined, these indirect costs are less than 0.35 bps, which is substantially smaller than our direct trading fees. Therefore, we focus our analysis on the direct trading fees, as they are the dominant form of trading costs for our arbitrage strategies.

To measure the deviation from the no-arbitrage price, we also obtain the interest rate data from Aave, a leading open-source DeFi liquidity protocol. Customers on Aave can either be suppliers or borrowers of cryptocurrencies. Because of the anonymity and decentralization of the DeFi system, all borrowings are over-collateralized and the collateral can serve as an additional supply to the system for borrowing. The customers can also supply spare currencies to the system to earn an interest rate. The supply

interest rate is typically different from the borrowing interest rate. Both interest rates and their wedge are determined algorithmically based on the market condition of supply and demand. We use interest rates from this platform because we believe it is a good proxy for the funding condition in the crypto market. Our results are robust if we use the interest rate from the traditional financial market.<sup>7</sup>

Our theory indicates using a risk-free rate available to the arbitrageurs. Therefore, we consider the interest rates on the stablecoins, which are not subject to volatile spot price movement and are the currency of denomination for perpetual futures margins. There are three major stablecoins traded on Aave: USDT, USDC, and DAI. To get a robust measure of the risk-free rate, we take an average of the three interest rates to arrive at our final risk-free supply and borrowing rate for the arbitrageurs.

We plot the time-series evolution of the interest rate in the appendix Figure 8. During the early years, we see higher interest rate volatility due to the funding liquidity of the DeFi platform. In later samples, interest rates are more stable and approach interest rates in traditional financial markets.

Our interest rate data starts from 2020-01-08. Therefore, for coins with perpetual data available before the time (BTC and ETH), we begin the analysis from 2020-01-08. For other coins (BNB, DOGE, ADA), we begin the analysis from the time when they have data available.

---

<sup>7</sup>We also run our analysis using daily T-bill rates obtained from Kenneth French's website at [https://mba.tuck.dartmouth.edu/pages/faculty/ken.french/Data\\_Library/f-f\\_factors.html](https://mba.tuck.dartmouth.edu/pages/faculty/ken.french/Data_Library/f-f_factors.html). The results are very close to ones using crypto market supply and borrowing rates.

## 4.2 Deviations of perpetual futures from no-arbitrage benchmarks

The focus of our empirical analysis is the annualized deviation  $\rho$ , defined as the interest rate spread that would rationalize an observed future-spot spread:

$$F = S \frac{\kappa}{\kappa - (r + \rho - r')}.$$

For example, an estimated  $\rho$  of one percentage point would mean that borrowing costs in the cash market faced by arbitrageurs would have to be one percentage point higher than the prevailing interest rate  $r$  in the cash market for the futures-spot gap to be arbitrage-free.

Using  $f$  and  $s$  to denote  $\log(F)$  and  $\log(S)$  respectively, we obtain the following approximate equation for  $\rho$ :

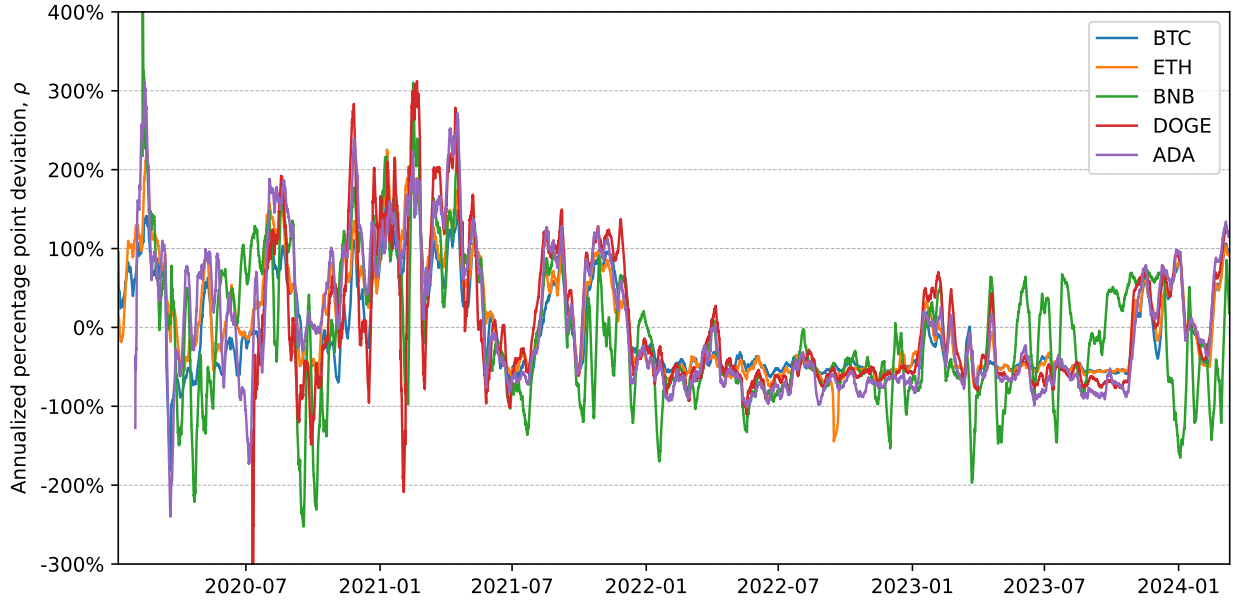

$$\rho = \kappa \left( 1 - e^{-(f-s)} \right) - (r - r') \approx \kappa(f - s) - (r - r'). \quad (8)$$

This definition is the same in spirit to [Du et al. \(2018\)](#), who measure covered interest parity (CIP) deviations with the wedge that would equate the dollar borrowing rate and the synthetic dollar borrowing rate. For the rest of our paper, we focus on the approximate measure and note that, in our setting, no interest is paid on spot crypto holdings ( $r' = 0$ ).<sup>8</sup>

Each hour, we calculate  $\rho$  defined in Equation (8) using data on the perpetual futures price, spot price, and the crypto risk-free interest rate. When the perpetual futures price is above the spot, an arbitrageur would short the futures and long the spot, and would finance her position by borrowing in the cash market (as is shown in Table 1). Therefore, we use the borrowing rate from Aave as the risk-free rate. On the other hand, when the perpetual futures price is below the spot, an arbitrageur would long the futures, short the spot, and invest the proceeds from shorting in the cash market (as is shown in Table 1). In such cases, we use the supply rate from Aave as the risk-free rate.

---

<sup>8</sup>The difference between the exact and the approximate measure is negligible.

**Figure 3** Deviations of perpetual futures from no-arbitrage benchmarks

This figure presents the 7-day moving averages of the annualized deviation of the perpetual futures-spot spread from the no-arbitrage benchmark for the five cryptocurrencies.

Asset	$\rho$				$ \rho $			
	Mean	Median	Std	p-value	Mean	Median	Std	p-value
BTC	-0.06	-0.32	0.74	0.80	0.57	0.51	0.48	0.00
ETH	0.04	-0.24	0.85	0.31	0.63	0.53	0.57	0.00
BNB	-0.10	-0.17	1.22	0.85	0.88	0.70	0.85	0.00
DOGE	0.01	-0.28	1.38	0.45	0.86	0.64	1.07	0.00
ADA	0.03	-0.21	1.14	0.39	0.83	0.70	0.79	0.00

**Table 4** Summary Statistics for Deviations from No-arbitrage Prices

The table below summarizes statistics for  $\rho$  and  $|\rho|$  across various crypto tokens.  $p_{NW}$  corresponds to the Newey-West adjusted p-value, testing the null hypothesis that the mean  $\rho$  (or  $|\rho|$ ) is zero. The sample periods are shown in Table 2.

Table 4 reports summary statistics for  $\rho$  and  $|\rho|$  in our sample. As can be seen, the mean future-spot spread is modest, lying between  $-2$  and  $12$  percentage points. The p-values show we cannot reject the hypothesis that the deviations are zero on average. Thus, on average, our theoretical prices provide a useful benchmark. Around this

benchmark, however, perpetual futures prices vary significantly from spot prices. The mean absolute deviation is about 60% to 90% per year across different cryptocurrency tokens. Figure 3 depicts the 7-day moving average of  $\rho$  for each of the five examined cryptocurrencies. It reveals considerable comovement in futures-spot spreads across these cryptocurrencies, suggesting a common factor at play that drives the observed divergence. This observation is corroborated by Table 5, which demonstrates high correlations among futures-spot deviations across the different cryptocurrencies. This trend underscores the interconnectedness of cryptocurrency markets and is consistent with the comovement of traditional currencies documented by [Lustig, Roussanov, and Verdelhan \(2011\)](#).

One hypothesis for this significant comovement in  $\rho$  across various cryptocurrencies pertains to time-varying funding constraints encountered by arbitrageurs in the market ([Brunnermeier and Pedersen, 2009](#); [Garleanu and Pedersen, 2011](#)). Because arbitrageurs often serve as marginal traders in all markets, their funding constraints are potentially reflected in the  $\rho$  across all major cryptocurrency markets. Our theoretical and empirical analyses underscore the importance of measuring  $\rho$ . Doing so not only sheds light on potential market stress but also provides a gauge for the shadow costs associated with the trading and funding constraints arbitrageurs face.

Conversely, from the demand side, shared sentiment across various cryptocurrencies could also contribute to explaining the concurrent movement of  $\rho$  across different markets. Our theoretical analysis suggests that arbitrageurs will only meet the market demand if the price deviation surpasses the combined trading and funding costs. As a result, the overall market sentiment in the futures market relative to the spot market becomes evident in the price difference between futures and spot prices. If the sentiment across different markets is influenced by a common factor, we would anticipate a significant comovement in the futures-spot spread.

Moreover, arbitrageurs are willing to absorb the idiosyncratic demand first because

		Arbitrage Deviation				Funding Rate					Spot Return				
		$\rho_{ETH}$	$\rho_{BNB}$	$\rho_{DOGE}$	$\rho_{ADA}$	$fr_{BTC}$	$fr_{ETH}$	$fr_{BNB}$	$fr_{DOGE}$	$fr_{ADA}$	$R_{BTC}$	$R_{ETH}$	$R_{BNB}$	$R_{DOGE}$	$R_{ADA}$

	$R_{ETH}$												0.73	0.43	0.74
	$R_{BNB}$													0.34	0.65
	$R_{DOGE}$														0.42

**Table 5** Correlation of arbitrage deviation ( $\rho$ ), funding rate ( $fr$ ), and spot returns ( $R$ )

This table presents the correlation among different cryptocurrencies' futures-spot deviation  $\rho$  (rows 3 to 7), funding rate (rows 8 to 12), and spot returns (rows 13 to 16).

combining the arbitrage trades across different idiosyncratic deviations would generate a high Sharpe ratio strategy as in [Kozak et al. \(2018\)](#). Therefore, in equilibrium, after arbitrageurs have absorbed the idiosyncratic demand, we anticipate the emergence of a common factor in deviations across different cryptocurrencies, driven by limits to arbitrage.

In Section 5, we delve deeper into explaining the futures-spot spread. Our results demonstrate that the past returns of each cryptocurrency serve as significant explanatory variables for the time-series variation in the spread.

Interestingly, the correlation between deviations and spot market returns is quite modest. Although spot market returns are highly correlated among themselves, in line with the strong market factor results from [Liu et al. \(2022\)](#), and no-arbitrage price deviations are highly correlated among themselves, it appears that different forces drive these distinct phenomena.

Furthermore, we find that after the year 2022, futures-spot spreads become smaller in magnitude and less volatile compared to earlier years. The 7-day moving average stays around -50% most of the time for the five cryptocurrencies while larger sways in earlier years are quite common. This suggests the market is becoming increasingly efficient. In terms of the sign of the deviation, which appears to stabilize at the negative region, two forces are potentially at play: (1) on the futures customer end, the relative demand in the futures market is weaker compared to the spot; (2) for arbitrageurs, because of the lack of infrastructure to short the cryptos in the spot market (high shorting costs), their funding constraints would be larger in the negative region. All these forces contribute to the stabilization of the futures spot deviation around -50 percentage points.

Last but not least, by design,  $\rho$  is also highly correlated with the funding rate. The funding rate does not correlate perfectly with  $\rho$  because in real-world implementations: (1) there is a clamp region, within which the funding rate is fixed at 0.01%; (2) the funding

rate is calculated as a weighted average of futures-spot price deviations, with larger weight given to more recent observations; (3) in calculating the funding rate, Binance does not just consider the quote price, they also use an impact margin notional to consider price impact of the trade.<sup>9</sup>

### 4.3 Random-maturity Arbitrage Strategy

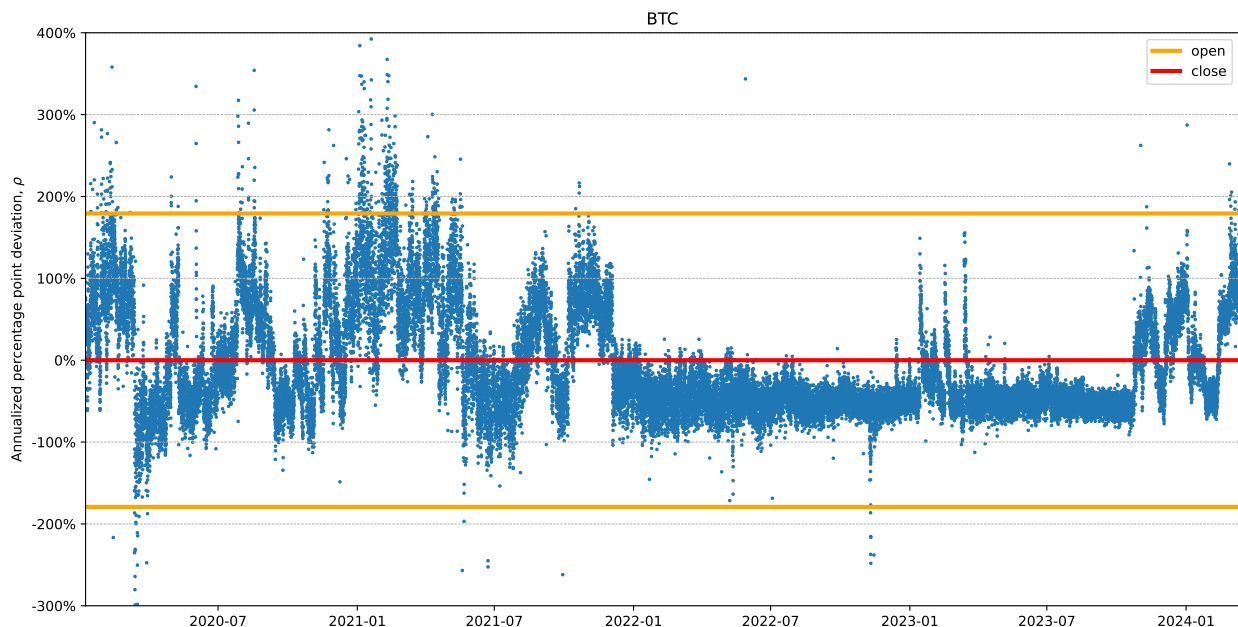

We next provide a trading strategy motivated by our random-maturity arbitrage theory. Table 3 reports for different trading cost tiers, the bounds ( $\rho_l$  and  $\rho_u$ ) beyond which there exist random-maturity arbitrage opportunities. We consider a simple trading strategy: whenever  $\rho$  enters the region outside the annualized round-trip trading costs in Table 3, we open the position. We close the position when  $\rho$  first goes back to 0.

Figure 4 provides an illustration of the trading strategy. When the deviation is beyond the orange lines, the strategy opens a trading position. The position is closed when the futures/spot deviation first hits the red line. We present trading thresholds across different trading costs for different currencies in Figure 9 in the appendix. Different trading strategies have the same close-position line, which is equal to 0, while the open-position line adjusts to the level of trading costs. In Appendix C, we also present the performance of a data-driven strategy that determines the open and close threshold optimally using the past 6-month data. The data-driven strategy can potentially improve upon this simpler strategy.

Since our trading strategy is a threshold trading rule, to annualize Sharpe ratios we follow Lucca and Moench (2015), which considers a trading strategy that is only active on FOMC announcement dates. We first calculate the mean ( $\mu$ ) and standard deviation ( $\sigma$ ) of our trading strategy during the time it is active. Next, we scale  $\mu/\sigma$  by the number of

---

<sup>9</sup>See <https://www.binance.com/en/support/faq/360033525031> for details of the funding rate calculation.

**Figure 4** Random-maturity Arbitrage Strategy: Bitcoin, high trading costs

Futures-spot deviations and trading thresholds of the random-maturity arbitrage strategy we implement for BTC under high trading costs. Each blue dot in the figure represents the hourly deviation of futures from the spot  $\rho = \kappa(f - s) - r$ . The number is annualized for ease of interpretation. The orange line is the open-position threshold, and the red line is the close-position threshold.

periods the strategy is active in a year:

$$SR = \frac{\mu}{\sigma} \sqrt{N_a},$$

where  $\mu$  and  $\sigma$  are average hourly returns and  $N_a$  is the average number of hours the strategy is active in a year. We follow the same approach to annualize the returns and standard deviations:  $\mu_{ann} = \mu N_a$ ,  $\sigma_{ann} = \sigma \sqrt{N_a}$ .

Table 6 presents the strategy's performance under different fee tiers. As trading costs decrease, the random-maturity arbitrage strategy engages in more active trading, leading to an increase in the SRs and a decrease in the average duration of open-to-close positions. The strategy also delivers highly significant alphas relative to the 3-factor model by Liu et al. (2022) and the 5-factor model by Cong et al. (2022a). Evidently, the strategy's

		Fee tiers

**Table 6** Performance of Random-maturity Arbitrage Strategy

Performance under different trading cost tiers. The fees for spot (futures) are 2.25 (0.18) bps, 4.5 (0.72) bps, and 6.75 (1.44) bps for the low, medium, and high trading cost levels. Statistics reported are the annualized Sharpe ratio, return (%), volatility (%), max drawdown (%), alpha (%), t-stat of the alpha, proportion of time the strategy is active (%), and average open-to-close (OtC) position duration in hours. The returns reported are excess returns from the random maturity arbitrage strategies. The 3-factor data from [Liu et al. \(2022\)](#) used to calculate alpha ends on April 9th, 2023.

performance cannot be explained by previously suggested risk factors.

Table 7 and Table 8 zoom in and present the trading performance of the strategy under high trading costs. We consider two cases: (1) unrestricted and (2) long-spot only. We consider the second case because, in earlier years of crypto derivatives, the infrastructure for shorting cryptocurrencies was not well-developed. We find that, as is implied by our theory, whenever the deviation between futures and spot is larger than the trading costs, performing a random-maturity arbitrage strategy would generate returns with high SR. After trading costs, the strategy generates an SR of 1.80 for BTC and much higher SRs for other cryptocurrencies.

Table 7 also shows that over time, the perpetual futures market seems to become more efficient. As we can see in 2022, the deviation of crypto price from the arbitrage-free bound is less frequent compared to earlier years. But when the deviation happens, the resulting SR from the trade remains high.

Comparing the results with [Du, Tepper, and Verdelhan \(2018\)](#), we find that deviations in crypto perpetual futures are considerably larger in magnitude. As a result, gains from the arbitrage strategies we study are also larger. Even though the volatility of the trading strategy also scales up, the Sharpe ratios in the crypto space are still larger than those in the traditional foreign exchange market, as reported in [Du, Tepper, and Verdelhan \(2018\)](#).

When a futures-spot gap opens up, gains from the trading strategy could potentially arise from two main sources: price convergence and funding rate payments. While industry publications usually emphasize the funding rate channel, we note that price convergence can generate quicker gains from arbitrage if dislocations are short-lived. To examine these two sources empirically, in Table 9, we provide a decomposition of the trading strategy's performance into price convergence versus funding rate payment. We find that price convergence plays a dominant role in total trading returns, while funding rate payments have a more minor role, which seems to diminish over time.

**Table 8** Performance of Long-spot-only Trading Strategy Over Time: High Trading Costs Tier

This table presents the Sharpe ratios, annualized returns (%), standard deviations (%), maximum drawdowns (%), active percentages (%), and the average open-to-close time (hours) of the long-spot only random-maturity arbitrage trading strategies for five different cryptocurrencies with high trading costs. For the long-spot-only strategy, shorting the spot is not allowed. The returns reported are excess returns from the random maturity arbitrage strategies. In 2022, for ADA, there is no positive deviation of  $\rho$  from the high-trading cost threshold. Therefore, the trading strategy is not active during the year for ADA.

**Table 9** Return Decomposition: Price Convergence vs Funding Rate Payment for Random-maturity Arbitrage Strategies

This table decomposes the portfolio return into the part due to price convergence and the part due to funding rate payment. The returns reported are excess returns from the random-maturity arbitrage strategies. There are a few negative funding rate payments due to the difference in the empirical specification of funding rate payment (see Appendix B for details) with our theoretical framework when the deviation is small.

convergence tends to generate a positive payoff at some uncertain future time. Therefore, the convergence arbitrage trade generates high Sharpe ratios.

## 5 Explaining Futures-spot Deviations

From Figure 3, we observe a strong common comovement of the futures-spot deviation across all crypto assets. Our goal is to understand the fundamental forces driving this common factor. We consider two potential hypotheses: (1) the time-varying funding constraints of arbitrageurs and (2) the time-varying relative demand from end-users for perpetual futures compared to the spot.

Both forces could potentially explain these patterns. Arbitrageurs will accommodate the relative demand from end-users only until the price deviation lies within the random-maturity no-arbitrage bound, which depends on arbitrageurs' funding conditions. As arbitrageurs are likely the marginal investors in all cryptocurrency markets, their time-varying funding constraints may create common time-series variation in  $\rho$  across different cryptocurrencies.

On the other hand, when the deviation lies within the no-arbitrage bound, variations in demand from the perpetual futures market compared to the spot market will influence the price deviation. It is plausible that relative demand has common factors across different cryptocurrencies. For instance, sentiment could drive their common variation, as perpetual futures allow for high leverage, which attracts overconfident, extrapolative, and sentiment-driven investors.

Determining which of the two factors better explains the observed price deviation is an empirical question. To shed light on this, we use past returns as a proxy for relative extrapolative demand in the perpetual futures market compared to the spot market. Past returns correlate with the demand from investors with extrapolative beliefs, who are more likely to trade in the perpetual futures market, given the high leverage it provides. Therefore, past returns would correlate with the relative demand in the perpetual futures market compared to the spot.

For the time-varying funding constraint, we consider using crypto return volatility as a proxy because, as in [Adrian and Shin \(2010\)](#), arbitrageurs likely face Value-at-Risk (VaR) type constraints, which are more likely to bind when market volatility is high.

Moreover, from [Figure 3](#), we see a downward trend for the magnitude of the deviation. [Kondor \(2009\)](#)'s model of convergence trading predicts that greater competition among arbitrageurs reduces the profitability of arbitrage opportunities and deviations approach a martingale. Therefore, we add a time trend variable to the regression to test if the market

becomes more efficient as more arbitrageurs and capital compete in this market.

In sum, the regression models can be represented as:

$$\rho_{i,t} = \beta_{0,i} + \beta_1(t/365) + \beta_2 R_{i,t-120:t-1} + \beta_3 \sigma_{i,t-120:t-1} + \varepsilon_{i,t}, \quad (9)$$

$$|\rho_{i,t}| = \beta_{0,i} + \beta_1(t/365) + \beta_2 R_{i,t-120:t-1} + \beta_3 \sigma_{i,t-120:t-1} + \varepsilon_{i,t}, \quad (10)$$

where  $\rho_{i,t}$  represents the futures-spot deviation,  $\beta_{0,i}$  is the currency fixed effect,  $t$  is the number of days since the beginning of the sample,  $R_{i,t-120:t-1}$  is the annualized spot return to currency  $i$  over the past 120 days, and  $\sigma_{i,t-120:t-1}$  is the annualized standard deviation of spot return of currency  $i$  over the past 120 days. Since we scale the time trend by the number of trading days in a year, the regression coefficient  $\beta_1$  has an interpretation of the average annual change in the futures-spot deviation.

Table 10 presents the regression results. The regression coefficients on the time trend are negative and highly significant for both  $\rho$  and  $|\rho|$ , indicating that the futures-spot gap has been decreasing both in level and in magnitude over time on average. Throughout our sample, on average,  $|\rho|$  shrinks about 11% per year, which accumulates to over 44% over the whole sample. This indicates that the perpetual futures market is becoming more efficient over time.

The coefficients on past returns are positive and highly significant for both  $\rho$  and  $|\rho|$ . This suggests that when past returns are high, perpetual futures exhibit a more positive deviation against the spot. Mapping this back to our second hypothesis, when past returns are high, the demand for futures relative to the spot is also likely to be high. Consequently, even after arbitrageurs accommodate the demand outside of trading costs, the residual demand still manifests itself through the perpetual-spot deviation.

This observation on limits to arbitrage is related to [Makarov and Schoar \(2020\)](#) which finds that crypto price deviations across international exchanges tend to comove with one

Dependent Variable:	$\rho$			$ \rho $		
	Time	-0.23*** (-4.52)	-0.14*** (-3.53)	-0.25*** (-6.47)	-0.11*** (-5.22)	-0.08*** (-4.88)

$N$	7235	7235	7235	7235	7235	7235

**Table 10** Regression of the futures-spot gap against explanatory variables

We present regression results of  $\rho$  and  $|\rho|$  on a time trend (Time) measured in units of years, past 120 days' annualized returns (Ret), and volatility (Vol) in the spot market. We add a currency fixed effect to the regression and consider three specifications: (1) regressing  $\rho/|\rho|$  on the time trend, (2) regressing  $\rho/|\rho|$  on past returns, and (3) regressing  $\rho/|\rho|$  on past returns and volatility. The observations are at a daily frequency. The sample period spans from January 8, 2020 to March 11, 2024, totaling 1,495 days. The table also reports the  $R^2$  values for each regression model. We report Newey-West t-statistics in parentheses with a lag of 120 days. \*  $p < .1$ , \*\*  $p < .05$ , \*\*\*  $p < .01$ .

another. The driving force behind this comovement is investors' buying pressure across various countries, with cross-country capital controls serving as the primary impediment to arbitrage capital. In the context of perpetual futures, end-user demand contributes to the comovement of different cryptocurrencies. The limits to arbitrage predominantly manifest in the form of trading frictions.

[Liu and Tsyvinski \(2021\)](#) document a significant time-series momentum pattern in the crypto market. Given that positive past returns lead to a positive gap between futures and spot prices, it is worth examining further whether the time-series momentum phenomenon is driven by margin trading and price pressure from the perpetual futures market. We leave this as an open question for future research.

We find that volatility does not significantly covary with  $|\rho|$ . This suggests that time-varying funding constraints of arbitrageurs do not drive the comovement in futures-spot deviations across different cryptocurrencies.

In summary, a prerequisite for the gap between futures and spot prices to occur is the existence of trading costs for arbitrageurs. Arbitrage trading will accommodate all the demand in the futures until the price deviation is within a trading cost bound. Within the bound, the relative demand of futures compared to the spot will still manifest itself in the deviation of futures prices from the spot. Due to the comovement of the time-varying relative demand, we observe a significant common factor in crypto future-spot deviations.

## 6 Conclusion

Perpetual futures play an important role in today's crypto markets and could potentially be adopted in non-crypto markets in the future. Understanding the fundamental mechanism of this financial derivative is a crucial first step for understanding speculation and hedging dynamics in this fast-evolving area. We provide a comprehensive analysis of the arbitrage and funding rate payment mechanisms that underpin perpetual futures.

In an ideal, frictionless world, we show that arbitrageurs would trade perpetual futures in such a way that a constant proportional relationship would hold between the futures price and the spot price. In the presence of trading costs, the deviation of the futures price from the spot would lie within a bound.

Motivated by our theory, we empirically examine the comovement of the futures-spot spread across different cryptocurrencies and implement a theory-motivated arbitrage strategy. We find that this simple strategy yields substantial Sharpe ratios across various trading cost scenarios. The evidence supports our theoretical argument that perpetual futures-spot spreads exceeding trading costs represent a random-maturity arbitrage opportunity.

Finally, we provide an explanation for the common comovement in futures-spot spreads across different crypto-currencies: arbitrageurs can only accommodate market

demand if the price deviation exceeds trading costs. As a result, the overall sentiment in the futures market relative to the spot market is reflected in the spread. Our empirical findings suggest that past return momentum can account for a significant portion of the time-series variation in the futures-spot spread.

## A. Additional Figures

**Figure 5** Trading view of BTC perpetual futures on Binance

This figure presents the perpetual futures trading view on Binance. The key information includes the futures price (Mark), spot price (Index), real-time funding rate based on the rolling average of the past 8 hours' observations, and countdown toward funding rate payment (Funding / Countdown) (illustrated with a red rectangle). In this example, futures are trading at a lower price than the spot. The funding rate is negative and is to be paid in 1 hour and 12 minutes.

**Figure 6** Trading costs tiers for the spot market

This figure presents the trading cost tiers for the crypto spot market from Binance: <https://www.binance.com/en/fee/trading>. Our high, medium, and low trading cost specification corresponds to VIP 1, VIP 5, and VIP 8 tiers, as illustrated with red rectangles in the picture. The 30-day trading volume requirements for VIP 1, 5, and 8 are 1 million, 150 million, and 2 billion, respectively, in the spot market. We consider the trading costs for makers as institutions typically trade maker orders. Binance offers a temporary discount for VIP 4-8 to have the same trading cost as VIP 9. We consider the non-discounted trading costs to make the comparison more reliable and fair.

**Figure 7** Trading costs tiers for the perp market

This figure presents the trading cost tiers for the crypto perpetual market from Binance: <https://www.binance.com/en/fee/trading>. Our high, medium, and low trading cost specification corresponds to VIP 1, VIP 5, and VIP 8 tiers, as illustrated with red rectangles in the picture. The 30-day trading volume requirements for VIP 1, 5, and 8 are 15 million, 1 billion, and 12.5 billion, respectively, in the perpetual market. We consider the trading costs for makers as institutions typically trade maker orders.

**Figure 8** Annualized interest rate from Aave

This figure presents the daily supply and borrowing rate from Aave. We consider three stablecoins: USDT, USDC, and DAI. Each day, we take the average interest rate of the three crypto stablecoins to get the proxy for the risk-free funding rate of the arbitrageurs. The averaging removes the idiosyncratic noise in borrowing and supply in individual stablecoins. The sample period is from 2020-01-08 to 2024-03-11.

**Figure 9** Trading Strategy Visualization: Random-maturity Arbitrage

This figure presents the random-maturity arbitrage strategy motivated by the theory. The orange, green, and purple lines correspond to the open-position threshold under high, medium, and low trading costs. The red line represents the close-position threshold.

## B. Funding Rate Calculation on Binance

In this section, we discuss in more detail the funding rate mechanism on the Binance platform based on the methodology given on the Binance website.<sup>10</sup>

There are five general steps in obtaining the funding rate. The first step is to find the Impact Bid/Ask Price Series in a given funding period by analyzing the order book and determining the average fill price to execute a certain notional value (Impact Margin Notional) on the bid and ask sides.

The impact margin notional is defined as the notional available to trade with a margin of 200 USD. So it can be calculated using the following equation:

$$\text{IMN} = 200 / \text{Initial margin rate at maximum leverage level.}$$

Given the definition of impact margin notional, the impact bid/ask price is defined as the average trade price after a market sell/buy order with the total quoted notional quantity given by the IMN.

Given impact bid and ask prices (denoted as IBP and IAP, respectively), the second step is to calculate the premium index (denoted as P) series every 5 seconds using the following equation:

$$P = [\text{Max}(0, \text{IBP} - \text{Price Index}) - \text{Max}(0, \text{Price Index} - \text{IAP})] / \text{Price Index},$$

where 'Price Index' is the weighted average spot price of the underlying asset listed on major spot exchanges.

The rationale behind this formula is to capture the relative difference between the perpetual contract's price and the underlying asset's price, taking into account the actual market liquidity and depth represented by the IBP and IAP.

The third step is to calculate the time-weighted average premium index over the funding period (8 hours for Binance) using the premium index series:

$$\bar{P} = \frac{\sum_{t=1}^T w_t P_t}{\sum_{t=1}^T w_t},$$

where  $P_t$  denotes the  $t$ -th 5-second in the 8-hour funding period,  $w_t = t$  is the weight for

---

<sup>10</sup><https://www.binance.com/en/support/faq/360033525031>

each observation, and  $T$  is the total number of 5-second intervals within the 8-hour period. For Binance,  $T = 12 \times 6 \times 8 = 5760$ . With this weighting scheme, the observations closer to the funding rate payment receive larger weights. The weights decrease linearly in time over the 8-hour interval.

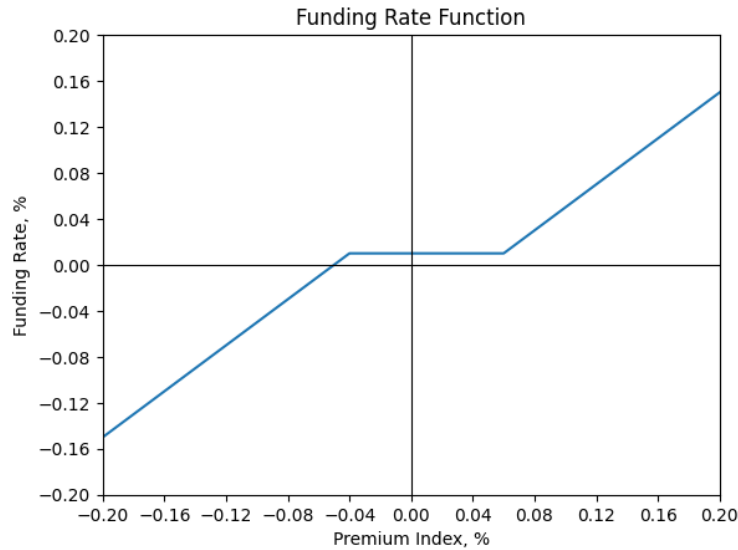

Given the average premium index, the fourth step is to calculate the funding rate using the equation below:

$$fr = \bar{P} + \text{clamp}(\gamma - \bar{P}, -0.05\%, 0.05\%),$$

where  $fr$  is the funding rate,  $\gamma$  is the interest component set by Binance, and

$$\text{clamp}(x, \min, \max) = \begin{cases} \min, & \text{if } x < \min \\ x, & \text{if } \min \leq x \leq \max \\ \max, & \text{if } x > \max \end{cases}$$

Empirically, for Binance futures, the interest rate  $r$  is fixed at 0.01% per 8 hours for most perpetual futures. Figure 10 plots the funding rate as a function of the premium index. As can be seen when the premium index is close to the interest rate 0.01%, the funding is fixed at the interest rate.

**Figure 10** Funding Rate Function

This figure plots funding rate as a function of the average premium index.

This design allows the funding rate to be fixed to a constant positive rate under normal market conditions. When markets are relatively stable and the perpetual contract price is

trading close to the index price, the premium index will be small. The clamp ensures that under these normal conditions, the funding rate matches the pre-defined interest rate set by the exchange. This makes funding rate payments more predictable.

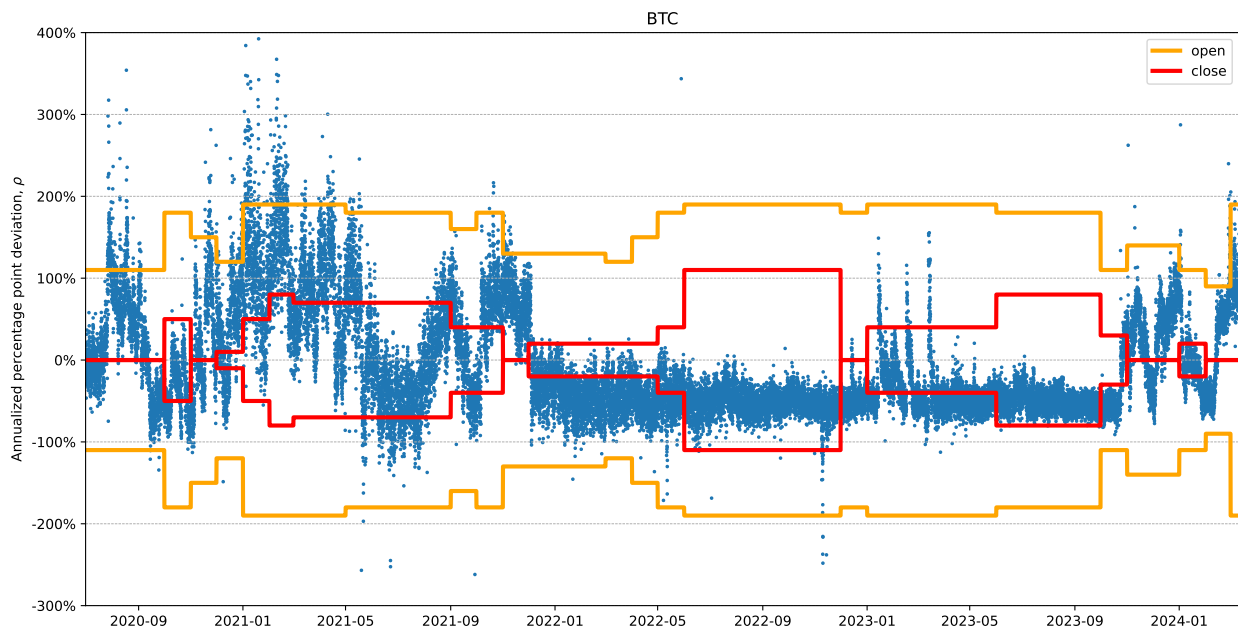

Note that this still allows larger funding rates when there are significant deviations. If the premium index differs from the interest rate by more than 0.05% in either direction, the clamp will not cap the funding rate. Larger premiums or discounts in the contract price will flow through to correspondingly larger funding payments to incentivize price convergence.

Last but not least, the fifth step is to apply a Capped Funding Rate based on the maximum leverage of the contract. For contracts with a maximum leverage of 30x or above, the cap and floor are determined by the Maintenance Margin Ratio. For contracts with a maximum leverage of 25x or below, the cap and floor are fixed at  $\pm 3\%$ . For contracts with higher leverage, the cap and floor can expand based on maximum leverage.

For this design, extremely high funding rates can lead to significant losses for traders holding positions, especially those with high leverage. By capping the funding rate, Binance limits the potential downside from holding a position during volatile periods. This can help prevent accounts from being liquidated due to surging funding costs.

## C. Data-driven Arbitrage Strategy

In the main text of our paper, we demonstrate the profitability of a simple theory-motivated trading strategy. The trading threshold can also be potentially further improved using a data-driven approach. In this part, we implement a data-driven two-threshold arbitrage trading strategy in the perpetual futures market. The strategy can be characterized with a tuple of two thresholds:  $(u, l)$ , where  $u$  denotes the upper bar and  $l$  denotes the lower bar,  $u > l$ . When  $\rho > u$ , we long the spot and short the futures. When  $-l < \rho < l$ , we close the position. When  $\rho < -u$ , we long the futures and short the spot. Figure 11 presents an illustration of the strategy for Bitcoin with the trading thresholds estimated using real-time data.

**Figure 11** Data-driven strategy: Bitcoin, high trading costs

This figure presents real-time trading thresholds of the arbitrage strategy we implement for BTC under high trading costs. Each blue dot in the figure represents the hourly deviation of futures from the spot  $\rho = \kappa(f - s) - r$ . The number is annualized for ease of interpretation. The orange line is the open-position threshold, and the red line is the close-position threshold.

To determine the optimal  $(u, l)$ , at the beginning of each month, we calculate the returns of the two-threshold trading strategy based on the past six months' data on a grid of parameters. From Table 3, we find the theory implied bounds for price deviation across all trading costs specifications lie within  $-200\%$  to  $+200\%$ . So we choose the grid as increasing from  $0\%$  to  $200\%$  with an incremental step of  $10\%$  for  $u$  and  $l$  ( $u \geq l$ ). In total,

there are 210 model specifications. We choose the model that delivers the highest Sharpe Ratio in the validation sample of the past six months.

Figure 11 presents the real-time trading thresholds of our arbitrage strategy for BTC under high trading costs. To mitigate the trading cost, the strategy automatically chooses a much lower close-position threshold compared to the open-position threshold. We also present the visualization of all trading strategies under zero to high trading costs in appendix Figure 12 to Figure 15. Under no-trading costs, the strategy chooses a low open-position threshold, and the open- and close-position thresholds coincide with each other. Since there is no trading cost, the strategy no longer needs to wait for price convergence to avoid high turnover. On the contrary, with high trading costs, the strategy chooses a larger open-position threshold and a smaller close-position threshold. This reflects the automatic adjustment from the algorithm for trading costs and turnovers.

Table 12 and Table 13 present the return statistics for this strategy under high trading costs over time. In the baseline ‘unrestricted’ strategy, we allow for both (1) longing the futures and shorting the spot and (2) shorting the futures and longing the spot, while in the ‘long-spot only’ strategy, we only allow for shorting the futures and longing the spot. The reason we consider the ‘long-spot only’ strategy is the infrastructure for shorting the spot is not well-developed. So we want to examine the performance of the trading strategy in the presence of such limits to arbitrage.

We find the arbitrage trading strategy has a high Sharpe ratio under high trading costs. The annualized Sharpe ratio for Bitcoin is 2.00 in our sample. They are even higher for other cryptos. The high Sharpe ratio of the trading strategy corroborates our theoretical results that when the price deviation is large enough, the trading would be a random-maturity arbitrage opportunity.

Since the year 2022, the deviation between the futures and the spot has become smaller and less volatile. There seems to be a structural break. We indeed find the trading strategy takes less active positions and significantly lower annualized returns. However, when there is a large enough deviation, the strategy can still generate sizeable Sharpe ratios in trading.

**Table 12** Performance of Unrestricted Trading Strategy Over Time: Data-driven Strategy, High Trading Costs Tier

This table presents the Sharpe ratios, annualized returns (%), standard deviations (%), and active percentages (%) of the random-maturity arbitrage trading strategies for five different cryptocurrencies with high trading costs. We break down returns for each year and provide summary statistics across all time. The left panel shows the performance of the unrestricted trading strategy, where both long and short spot positions are allowed. The right panel shows the performance of the long-spot-only trading strategy, where shorting the spot is not allowed. The returns reported are excess returns from the random maturity arbitrage strategies.

**Table 13** Performance of Long-spot-only Trading Strategy Over Time: Data-driven Strategy, High Trading Costs Tier

This table presents the Sharpe ratios, annualized returns (%), standard deviations (%), and active percentages (%) of the random-maturity arbitrage trading strategies for five different cryptocurrencies with high trading costs. We break down returns for each year and provide summary statistics across all time. The left panel shows the performance of the unrestricted trading strategy, where both long and short spot positions are allowed. The right panel shows the performance of the long-spot-only trading strategy, where shorting the spot is not allowed. The returns reported are excess returns from the random maturity arbitrage strategies.

The conclusion and results remain similar if we consider ‘long-spot only’ trading strategies where only shorting the futures and longing the spot is allowed. Considering this one-sided trade slightly lowers the Sharpe ratio, but the algorithm automatically adjusts by increasing the proportion of times being active. The resulting annualized returns increase. In the year 2022, since most of the time, the futures price is below the spot and we don’t allow longing the futures and shorting the spot trade, the proportion of time the strategy is active is very low.

Table 11 further reports the performance of the trading strategy under different trading costs specifications laid out in Table 2. The results from Table 12 correspond to the last column in Table 11. As trading costs increase, our trading strategy dynamically adjusts by lowering the proportion of time being active. The annualized return decreases and annualized standard deviation are of similar magnitude across different trading costs. As a result, SR decreases as trading costs increase. Under no trading cost, we see a Sharpe ratio of 6.72 for BTC and Sharpe ratios above 10 for all other cryptos. This also confirms our theoretical results that when there is no trading cost, any deviation of perpetual price from the no-arbitrage benchmark would be a random-maturity arbitrage opportunity.

Comparing Table 11 with Table 6, we find under low and no trading costs, the potential incremental benefits from using a data-driven two-threshold trading rule are much larger compared to higher trading costs. The intuition can be easily illustrated by comparing the empirical real-time trading thresholds in the theory-motivated strategy and the data-driven strategy under low trading costs (Figure 9 and Figure 12). With persistent  $\rho$  the data-driven approach can find the optimal close-position threshold corresponding to the level of  $\rho$  while the theory-motivated one is too conservative in setting a close-position threshold equal to 0.

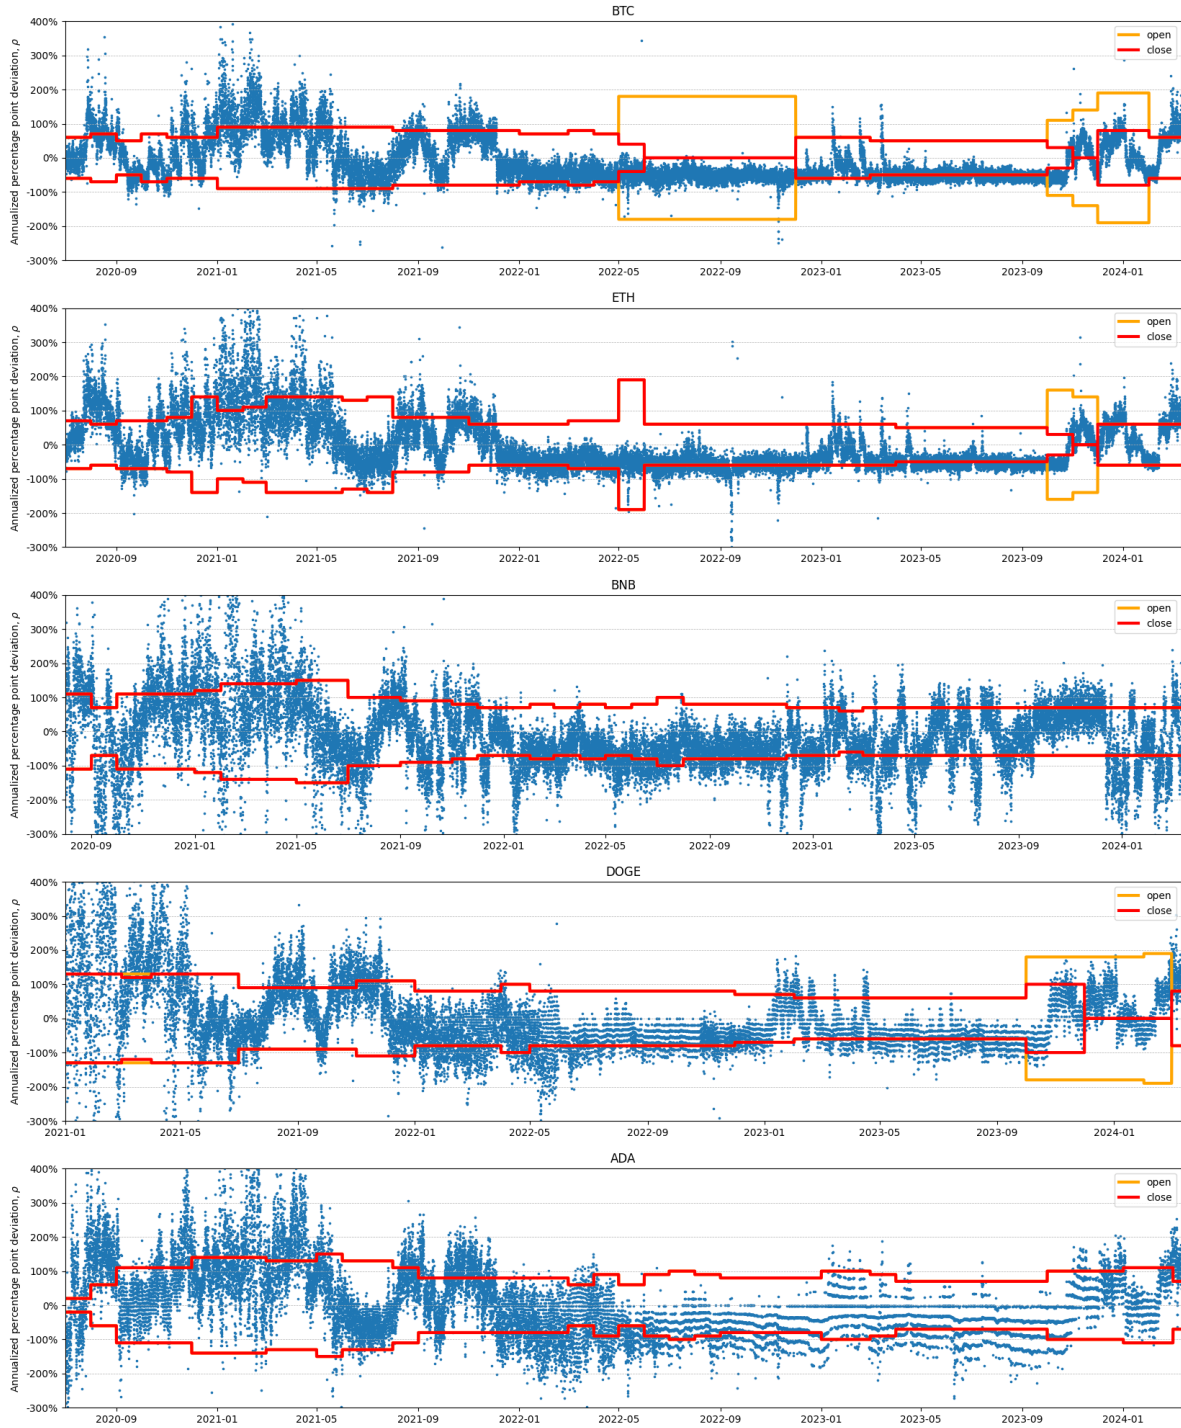

There are two sources of trading profit for our trading strategy: (1) the price convergence; (2) the funding rate payment. In Table 14, we decompose the return to our trading strategy without trading cost into the two sources. We find across different cryptos, the return from price convergence accounts for a larger proportion of the total profit. For BTC, the price convergence accounts for more than 2/3 of the profits, and for ETH, it accounts for about 3/4. Additionally, the decomposition for the year 2022 generates different patterns, the return due to funding rate plays a much smaller role across different cryptos. This is because the deviation from perpetual to spot is much smaller during the year. The results suggest when more sophisticated arbitrageurs enter the market, the large deviation of perpetual from the spot would be more of an off-equilibrium outcome. As a result, the funding rate payment will also be small.

		2020	2021	2022	2023	2024	All

	Funding	11.27	10.52	1.30	0.32	5.69	5.74

**Table 14** Data-driven strategy: Price Convergence vs Funding Rate Payment

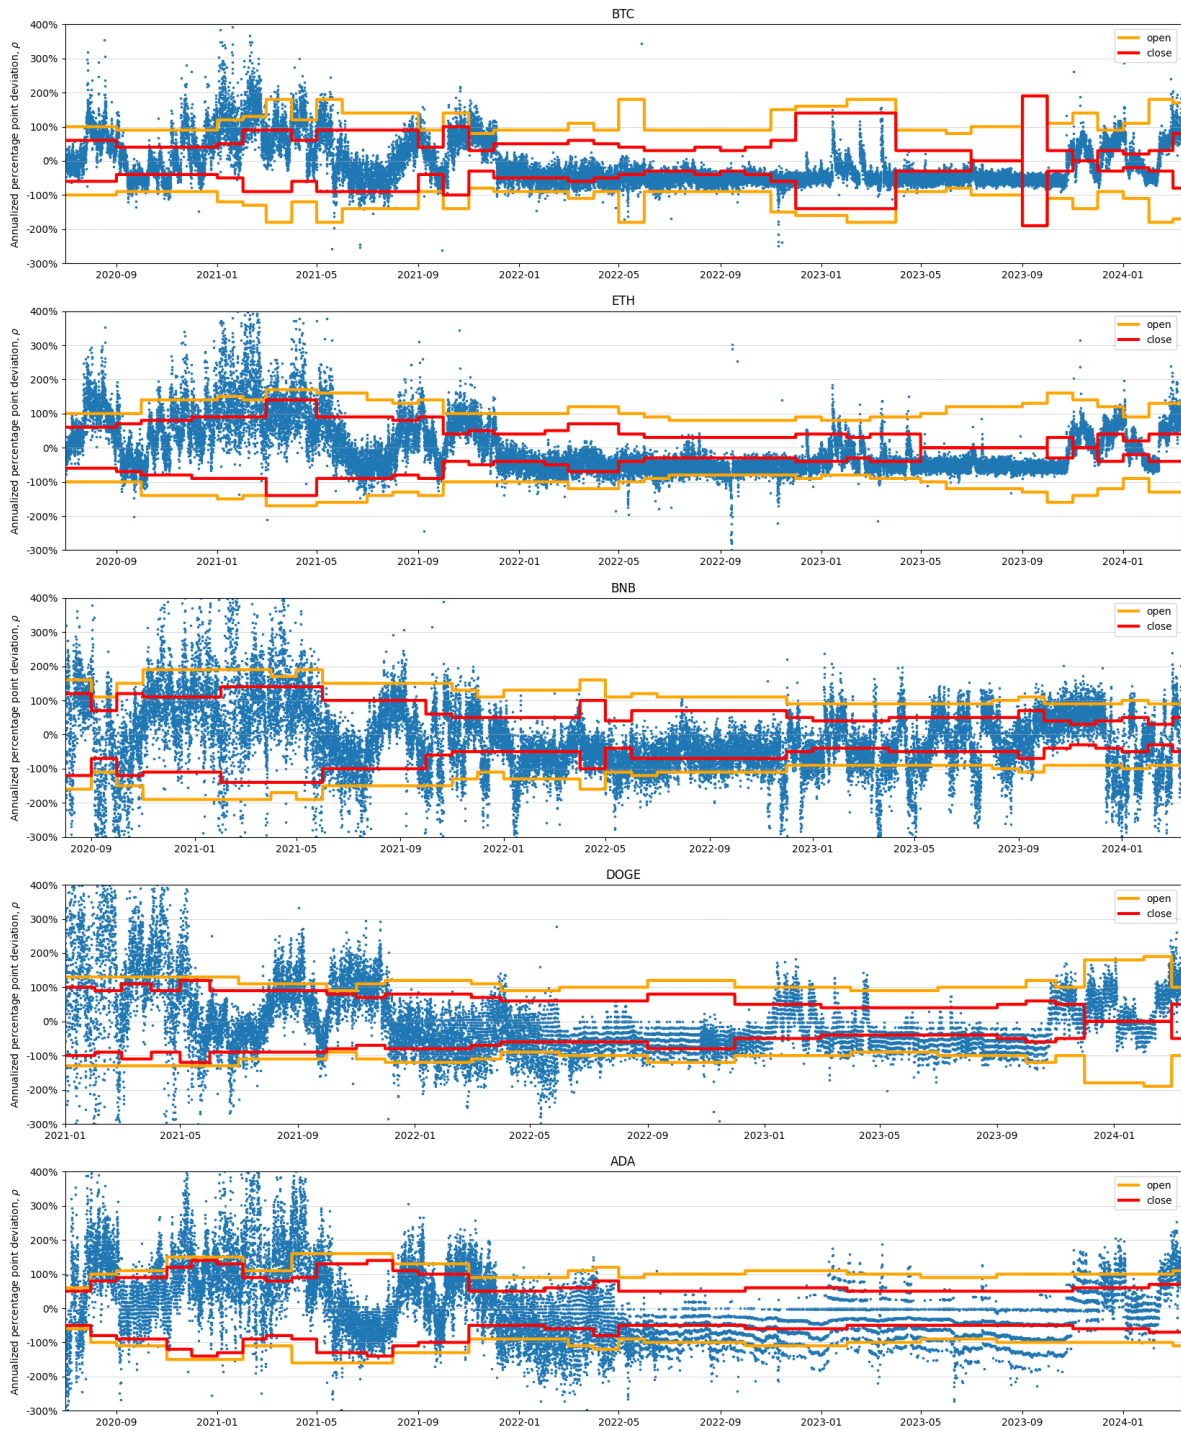

This table decomposes the portfolio return into the part due to price convergence and the part due to funding rate payment.

In all, our analysis of the trading strategy demonstrates the profitability of perpetual-spot arbitrage trade. The deviation of the futures to spot can also serve as an important measure for the frictions, trading costs, and limits to arbitrage in the market.

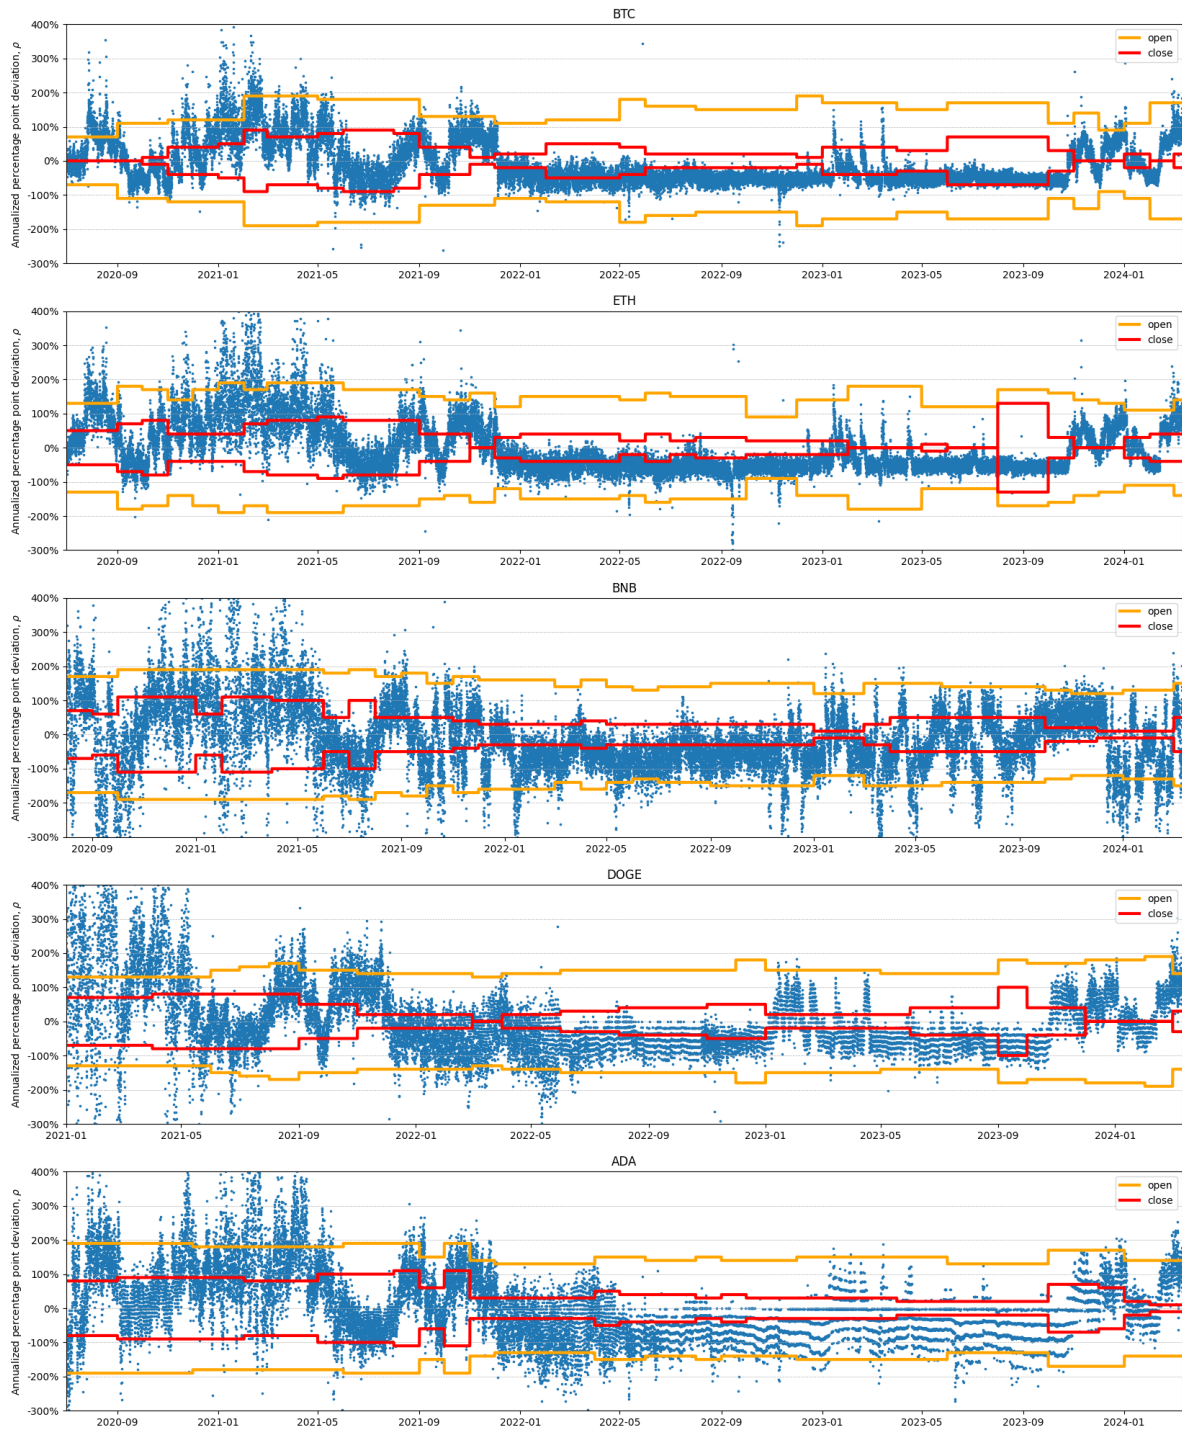

**Figure 12** Trading Strategy Visualization: No Trading Costs

This figure presents the real-time trading thresholds under no trading costs. The orange line is the open-position threshold, and the red line is the close-position threshold. The trading thresholds are determined based on the adjusted SR from the past six months.

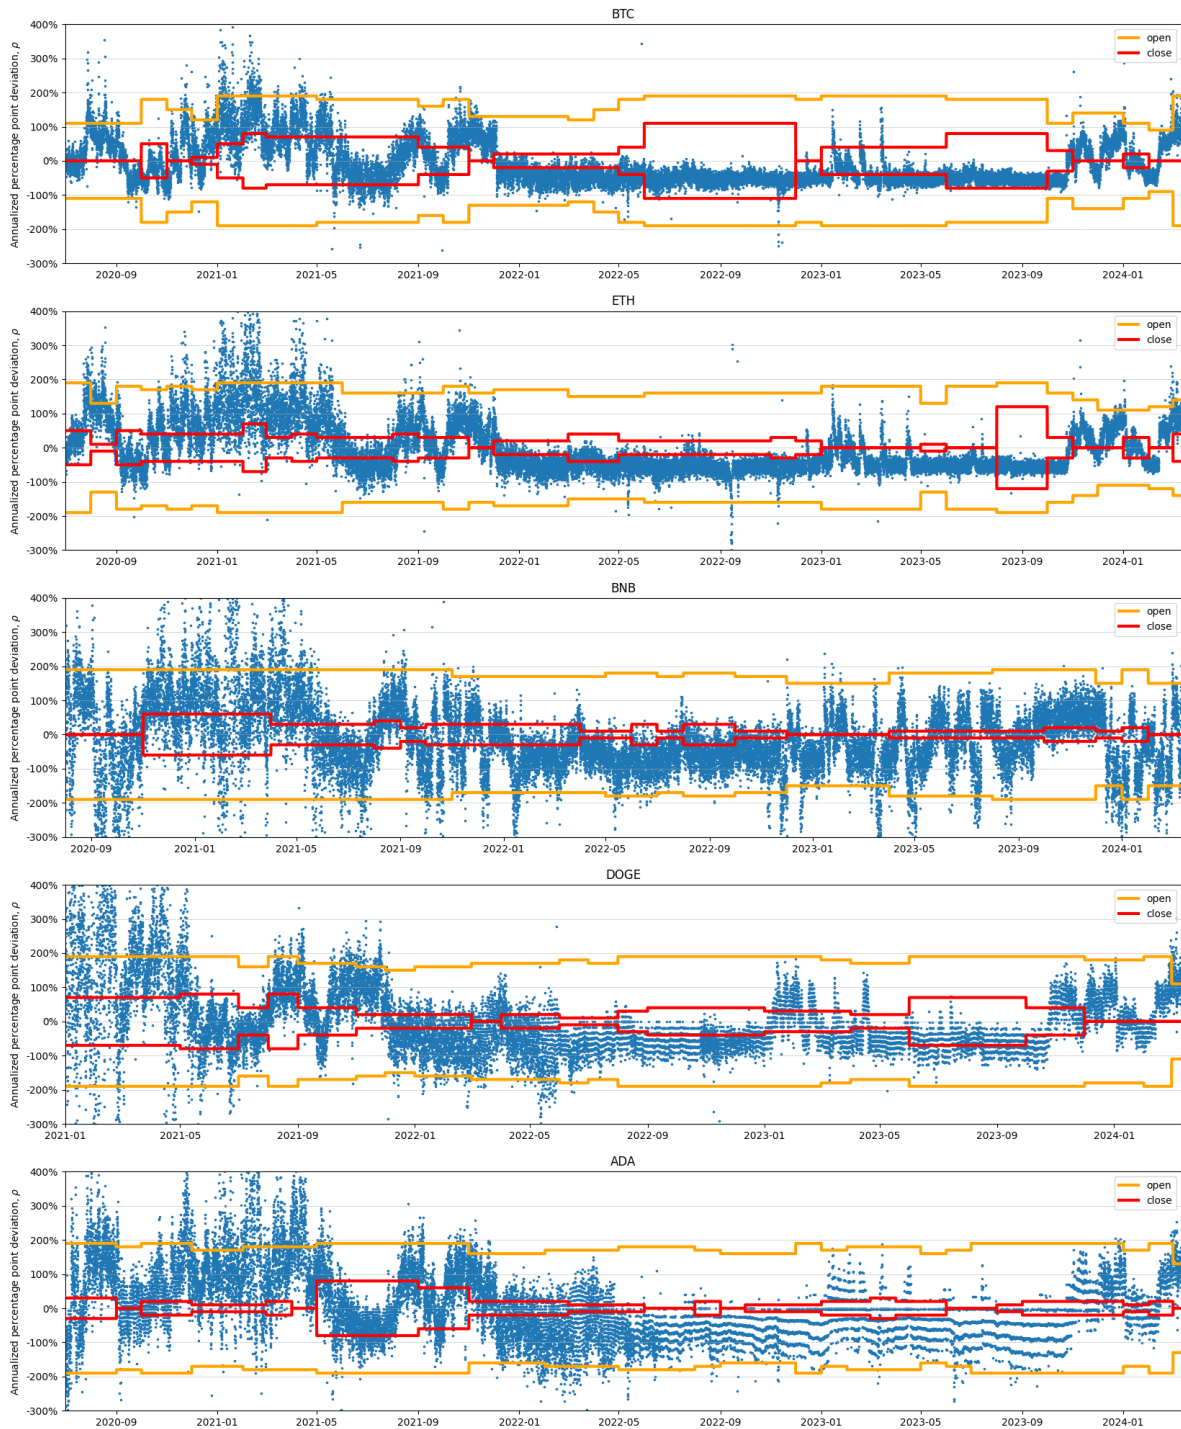

**Figure 13** Trading Strategy Visualization: Low Trading Costs

This figure presents the real-time trading thresholds under low trading costs (2.25 bps for spot trading and 0.18 bp for futures trading). The orange line is the open-position threshold, and the red line is the close-position threshold. The trading thresholds are determined based on the adjusted SR from the past six months.

**Figure 14** Trading Strategy Visualization: Medium Trading Costs

This figure presents the real-time trading thresholds under medium trading costs (4.5 bps for spot trading and 0.72 bp for futures trading). The orange line is the open-position threshold, and the red line is the close-position threshold. The trading thresholds are determined based on the adjusted SR from the past six months.

**Figure 15** Trading Strategy Visualization: High Trading Costs

This figure presents the real-time trading thresholds under high trading costs (6.75 bps for spot trading and 1.44 bps for futures trading). The orange line is the open-position threshold, and the red line is the close-position threshold. The trading thresholds are determined based on the adjusted SR from the past six months.
