National Association of Securities Dealers Automated Quotations(NASDAQ) is an American stock exchange based. It is one of the most valuable stock economic indices in the world and is located in New York City [21]. The volatility of the stock market and the influence of economic indicators such as crude oil, gold, and the dollar in the stock market, and NASDAQ shares are also affected and have a volatile and chaotic nature [39]. In this article, we have examined the effect of oil, dollar, gold, and the volatility of the stock market in the economic market, and then we have also examined the effect of these indicators on NASDAQ stocks. Then we started to analyze the impact of the feedback on the past prices of NASDAQ stocks and its impact on the current price. Using PCA and Linear Regression algorithm, we have designed an optimal dynamic learning experience for modeling these stocks. The results obtained from the quantitative analysis are consistent with the results of the qualitative analysis of economic studies, and the modeling done with the optimal dynamic experience of machine learning justifies the current price of NASDAQ shares.

I. INTRODUCTION

There is a dynamic and complex relationship between economic variables that has attracted the attention of many researchers, business people, and policy makers. All these variables have experienced significant changes over time, therefore, it is necessary to find a periodic relationship for them. Many economists and scientists seek to find a global perspective to examine the relationships between oil prices, gold, the US dollar, and stock prices. Crude oil is an important resource in the development and economic stability of all countries in the world. Estimating the price of crude oil is one of the topics of concern for many market participants and global policy-makers. Natural resources such as oil and minerals are precious wealth that can play an important and vital role in the economic development of a country [1]. However, the resource curse paradox states that countries with natural resources have slower economic growth than countries without resources. Many studies show that the abundance of natural resources has a negative correlation with economic growth [2, 3]. Countries like the United States and Australia are exceptions to this, but in general, it can be said that non-resource-rich countries have higher overall growth. For example, Asian economies and Western European countries experience higher economic growth rates. Crude oil accounts for about 40% of the world's energy consumption and

has the largest share in the commodity market. Uncertainty in the price of oil, especially in the economy of oil-dependent countries, is a destructive and destabilizing factor in the macro-economy, which can hinder sustainable economic growth in the long run. Oil crises such as oil embargo, war, recession and world economic crises and epidemics, etc., have caused an increase in oil price volatility, which in turn has played an effective role in the economic growth of countries.

On the other hand, gold also plays the role of a valuable financial asset or economic security against economic volatility. With the occurrence of the Covid-19 pandemic crisis, the price of gold faced fluctuations of 26% in 2020. Hence, it can be concluded that macroeconomic structures and business cycles are related to gold and oil price fluctuations [4]. A recent data set from 2000 to 2020 includes two crises and critical economic situations (the global economic crisis in 2008 and the ongoing Covid-19 pandemic in 2020), showing that in July 2008, oil prices reached their highest level of 145.18 dollars per barrel. However, with the outbreak of the pandemic, the price of oil reached an all-time low of \$37.63 per barrel. On the other hand, even though the price of crude oil was falling during the pandemic, the price of gold rose dramatically, reaching a peak of \$2,060 per ounce in August 2020. In the months that followed, the price of gold fell sharply, falling below \$1,800 per ounce in November 2020. These fluctuations for Gold were more than expected. Volatility and movement of prices in the crises of the last two decades have prompted many economists to examine the effects of volatility in oil and gold on the economic growth of resource-producing countries [4]. In Ref. [4], Lu Guan et al. show that regardless of the status of oil or gold exporting countries, volatility in the oil and gold markets undermines their real GDP growth. However, in the short term, gold price fluctuations may cause its growth in the world markets. They stated that the increase in growth may be due to the fact that 12 of the 18 countries they chose as a sample are gold producers. These countries may take advantage of market volatility when gold prices rise. Oil fluctuations in short-term periods have not had a significant impact on GDP growth. This is probably because oil contracts are mostly long-term contracts. In Ref. [5], Arfaoui has used a system of simultaneous equations to identify the direct and indirect links of these economic assets to each other, for a certain period of time. The author found a negative relationship between oil prices and stocks, a negative relationship between oil and the US dollar rate, and a negative relationship between the US dollar and gold prices. In addition, he states that there is a close relationship between the price of oil and the price of gold.

The relationship between oil prices and exchange rates and why changes in oil prices should affect exchange rates have been explored by Globe and Krugman [6, 7]. Globe argues that because oil is priced in dollars, an increase in the price of oil will increase the demand for dollars. However, Krugman focuses on the relationship between the portfolio investment preferences of oil exporters and exchange rate movements. He states that the increase in the price of oil will lead to more investment in the portfolio of oil exporters. Krugman believes that the exchange rate changes are basically determined by the movement of the current account, and as a result, if the increase in oil prices leads to a weakening of the

country's current account, then the exchange rate will decrease. Many other studies show that the impact of the dollar on the international price of oil is significant in the long run. Monetary policy and interest rate changes can also be factors in creating and intensifying the negative correlation between exchange rates and prices.

The price of oil, the dollar, and the stock market, along with the import of American oil and default insurance premiums of companies, can play a role in the price of gold and its changes. Following the increase in oil prices, business costs increase and the resulting profit decreases even for non-oil companies. The profit and commercial information of the listed companies are transferred to the stock markets, and as a result, the decrease in profit will lead to a decrease in the value of the stock market. When it comes to the financing process of oil and gold transactions and their international prices, many common features can be found. In fact, common factors such as the US dollar, economic foundations, and geopolitical events affect both commodity markets. Many studies show that factors such as stock markets, gold, and the dollar can have a positive effect on oil prices. Oil future prices and China's gross oil imports also affect oil price [5].

Many pieces of evidence prove that the increase in the consumption of oil as a financial asset in the past decades has intensified the relationship between oil and other assets. However, characteristics such as the chaotic and non-linear nature of crude oil time series have made accurate price estimation difficult. To overcome these problems, many economists and scientists have proposed different and new models to predict crude oil prices. Karasu and Altan have proposed a model for predicting the price of crude oil. The model includes short-term memory (LSTM), technical indicators such as trend, volatility, and movement, and the chaotic Henry gas solubility optimization (CHGSO) technique. In the proposed model, features based on technical indicators of trend, momentum, and fluctuations are also used. They separately obtained these indices for West Texas Intermediate (WTI) and Brent COTS [8]. Moreover in Ref. [9], the author investigated the chaotic structures in the time series of Brent and WTI crude oil price returns. In this work, Yun HE has obtained experimental evidence of chaos in the markets by using the phase space reconstruction technique (PSRT) and fractal integral method.

Gold is a high-liquidity asset that allows owners to use it as money for business at any time. Many investors see investing in the gold market as a hedge against inflation and currency depreciation. From the economic and financial perspective, gold price movements are highly regarded. Historically, despite the losses that occurred during periods of inflation, social unrest, and war, the price of gold changed little. As stock prices fall, financial advisors advise investors to maintain investments in gold during this period. On the contrary, some investors believed that during the boom period, the price of gold does not have a risk-averse portfolio value and it can be considered like other commodities whose price swings are based on supply and demand. As a result, in this case, gold investments often fall in value as stock prices rise. In the context of the stock market's inverse relationship with oil price volatility, oil investments also function as a risk deterrent [10]. In the foreign exchange market, exchange rate forecasts are often based on the health of a

country's economy. The exchange rate for the currency of a country with a growing economy actually reflects its higher value. A common commodity cannot be used to establish a straightforward relationship across currencies and the interconnection between the price of gold, the exchange rate, and the price of oil is intricate. The price of gold and crude oil may be influenced by a variety of factors, including governmental policies, the size of the budget, inflation, national economic and political conditions, etc [10].

Ref. [10] is focused on studying the dynamic relationship among gold price, exchange rate, stock return, and oil price. Using time series techniques, vector autoregression and cointegration techniques, the authors have obtained dynamic and stable relationships between these variables. The data obtained demonstrate that changes in other economic variables have a considerable impact on the exchange rate. The stock market, on the other hand, has less of an impact on the exchange rate. Two models were utilized in this study to illustrate the dynamic interaction. The first model uses the US dollar gold index, whereas the second model uses the euro gold index. To provide variability, they had employed WTI in the first model and Brent in the second. The Granger causality test is used to determine the order of the variables. Their findings demonstrate that the stock market index and the price of gold are directly impacted by the exchange rate. The variance decomposition reveals that changes in the gold index, WTI, and S&P stock market index account for the majority of the total variations in the exchange rate. Studies reveal that gold itself, as opposed to oil and other factors, is mostly responsible for changes in the price of gold. However, the WTI index is also impacted by the fluctuation in gold prices.

NASDAQ is a very important influencing factor in the stock market. Considering the effect of past prices on the current price of each index in the stock market, in this article we will examine and optimize the past prices on the current price. With the help of Lasso, we check the impact of the past price on its current price, and then with the help of PCA, we design an optimized learning experience for machine and check the results of modeling with linear regression. We calculate the impact of crude oil, gold and US dollar prices on NASDAQ with Lasso and compare it with effective correlation analysis. Finally, we compare the obtained results with the results of various economic researches.

II. OIL

Oil as a source of energy, and a substance which is caused industrial and production gears to move is the reason why oil is important for us. Ref. [11] has shown that fluctuations in oil prices impose some costs on all sectors. They claim that economy of many countries is based on oil production and oil trade and oil productions. In addition to the aforementioned details, Ref. [12] asserts the importance and urgency of oil price predictions. They also mention that the oil projection has an immediate impact on various economic sectors.

Oil-related items and goods will vary as the price of oil fluctuates, which has a significant impact on people's daily lives. According to Ref. [12], the oil price has an impact on political and economic processes that influence the value of oil firms, the inflation rate

in oil-importing nations, and the rate of economic growth. The pricing of stock market businesses, the rate of inflation, and the economic expansion of importing and exporting nations are all significantly influenced by the price of oil [11]. Thus, it can be inferred that the oil price has a significant impact on both oil-importing and oil-exporting nations.

The indirect impact of oil on airlines and ticket prices, the automobile industry, and those who use oil price estimates in simulations to make long-term purchases of items has been discussed in Ref. [12]. Due to the important role of oil price, we should more carefully examine the parameters that affect the oil price and how the oil price affects these parameters. Ref. [10] expresses that most oil contracts are traded in dollars almost everywhere. As a result, many oil-exporting countries usually peg their currency to the dollar. When the dollar falls, the oil revenues of the oil-exporting countries will decrease, and their costs will increase. Also, Ref. [10] points out that with the increase in oil prices, the value of the currency of oil-exporting countries will also increase but on the other hand, the value of the currency of oil-importing countries will decline. There is much evidence that the price of crude oil is one of the commodities that widely affects the global economy. Miao et al. estimate that the oil and gas drilling sectors account for approximately 3% of global GDP [13]. In addition, imports of petroleum products account for about 40% of US trade.

Ref. [10] reports that oil price risk affects stock prices in emerging markets. In Ref. [11], An et al. state based on the analysis that the price of oil is mostly influenced by the indices of the US dollar and the US federal reserve rate. He also points out that the popularity of investing in precious metals has not affected companies' investments in oil and the stock market. In Ref. [14], the author believes that there is a significant relationship between the oil price and the dollar rate since 1990. They found an inverse relationship between the dollar rate and the price of oil and further concluded that a 1% weakening of the dollar caused a 2.1% increase in the price of oil. He also cited the increase in industrial production as the reason for the increase in the dollar and the increase in interest rates as the reason for the decrease in oil prices. Novotný also makes an important point about economies that are not correlated with the dollar: The inverse relation between the dollar exchange rate and Brent crude oil price dampens the impact of sharp fluctuations of dollar-Brent crude oil in "non-dollar" economies.

One of the things that have always influenced the price of oil is the amount of production capacity and the amount of oil entering the market, in this regard Ref. [15] states that the existence of a non-linear relationship between the price of oil and the amount of oil that has been supplied to the market is possible to affect the determination of oil prices. He further states that the non-linearity is likely due to delays associated with the creation of additional extraction and refining capacity, and as production capacity approaches, oil prices will become more sensitive to supply. The studies of Ref. [15] show the effect of the utilization rate of the refinery on the price of crude oil, which demonstrates that a decrease in the refining rate leads to an increase in the price of oil. However, its results indicate that there is little evidence that increasing the capacity of refineries can reduce oil prices.

According to his research, only the stock price of crude oil can effectively reduce the price. These two articles show that there is no causal relationship between crude oil prices and crude oil refineries.

Regarding the impact of the war on the price of oil, Ref. [12] has concluded by examining the Iraq war in 2004 that the importance of military operations in oil-producing countries has a negligible effect on the price of oil. However, this can be challenged in light of the recent Ukraine-Russia war, which saw oil prices fluctuate wildly. Although this phenomenon can be temporary, it shows the importance of military operations on oil prices [20].

III. GOLD

Gold price is also one of the influential factors in the market. Ref. [16] states that gold has long been appreciated and has been a key financial tool. Gold can be viewed as a resource that is independent of all nations and industries. According to the author, many who possess gold think that investing in the gold market can provide protection against inflation. Ref. [5] further underlines that there is ample proof that gold prices rise and stock prices fall during a period of economic turbulence. All eyes are on gold in this situation as a haven of safety.

According to Ref. [16], changes in the dollar index have a detrimental impact on the price of gold globally. For instance, it is true that the price of gold lowers as the dollar index rises and vice versa. The author acknowledges that the dollar index often declines in relation to inflation and stock market recession, which is in agreement with [5].

Ref. [17] has concluded that the relationship between gold reserves and the price of energy products and the spot price of gold is positive. Also, his studies show that the effect of financial market indicators and the gold spot price is negative. (This result can also be taken from Refs. [5, 16] that in times of crisis and recession, shareholders prefer gold as a safe haven. During economic growth, they leave the gold market and re-enter the capital market in the hope of making more profit. Therefore, this negative relationship is not far from the mind and applies in normal conditions). The author further claims that there is a negative correlation between global macroeconomic data and gold spot prices. The price of gold and the rate of inflation are related because both of these variables affect people's daily lives.

Ref. [18] indicates that the effect of the gold price shock remains for a long time on the inflation rate of developing countries and for a short period on the inflation rate of developed countries. The findings of Ref. [19] about gold prices and inflation rates indicate that gold contains significant information for future inflation for several countries, especially for countries that have adopted official inflation targets.

IV. NASDAQ

The NASDAQ stock market is an American stock exchange that ranks second in the list of stock exchanges in terms of traded stock market value. According to Ref. [21], a number of top NASDAQ market participants were well aware of the issue of inefficient pricing in opening and closing before it was implemented in the NASDAQ call auction. Following this issue, the corporation was under criticism for a number of quarters to explain the pricing. In a letter to Frank Zarb, then president and chief executive officer of the National Association of Securities Dealers, on May 16, 2000, Arthur Levitt, then-chairman of the U.S. Securities and Exchange Commission, stated, “I urge the NASD to pursue a unified opening procedure, and in the interim, to press forward with measures to make the opening process more reliable and fair to investors.”

Regarding the prices obtained during the night, the night feedback’s initial prices are influenced by the market’s activity at the start of a trading day. A few contract modifications are decided based on the initial costs. Closing prices are used for market marking and a number of legal valuation purposes. Academic research also makes advantage of closing prices [22]. According to Ref. [22], continuous trading on the NASDAQ links orders to calls in the order that they entered the market. The majority of trades are two-way, and they frequently span a wide range of values in a short amount of time.

In contrast, orders are combined for simultaneous execution in a single transaction—typically multilateral—and all cross-orders are executed at a single price when an auction is called. In addition, Pagano et al. note that order grouping in a call auction is anticipated to lessen transient inefficiencies by grouping a number of the purchase and sell orders within particular time intervals. The findings of Ref. [23] demonstrate that calls for smaller-cap stocks may experience a significant failure rate in opening and closing the market. Calls might not always be the best approach to initiate and complete a trade, according to the author.

The findings of Ref. [22] can be summarized as follows:

1. The continuous market bid-ask spread after the open and before the close across all market cap sizes decreased noticeably after the NASDAQ call started.
2. The closing volatility among all market share sizes significantly decreased after the final call (closing) was announced. For the open, a comparable (though marginally weaker) overall pattern of decreased volatility is seen.
3. The mutual impact of volatility spreads and opening calls has had a significant impact on the spread for medium- and small-cap companies as well as on large market equities.
4. Opening calls for large-cap NASDAQ stocks draw a significant amount of pre-market trading because of the routing of orders. While none of the NASDAQ calls have drawn a sizable number of large-cap companies, medium-cap stocks, or both in the close.

The flow of orders and auction calls, according to Ellul et al., is undirected [23]. According to Ref. [22], which supports their conclusions, the distribution of order flow among various trading venues is endogenously determined in equilibrium with transactions. The calls had a beneficial spillover impact, they discovered. In fact, the trading environment in the continuous market around calls had greatly improved after the launch of NASDAQ calls.

Even while the system of offering calls and orders is beneficial, especially when a sufficient number of individuals engage, some environmental and personal variables will influence the decisions. This is what [23] refers to as the motivation for business collaboration. The coordination motives for trading are modeled by Diamond (1982) and Pagano (1989) [24]. Pagano et al. believe that this indicates that traders will halt their own orders if they think that others are doing the same. Similar findings emerge from the analyses of Chakraborty, Pagano, and Schwartz [25].

V. LASSO

The LASSO regression analysis method in statistics and machine learning combines variable selection and regularization to improve the predictability and understandability of the produced statistical model. Since its initial introduction by Tibshirani [26], it has gradually found use in the energy sector, including in the consumption of electricity, the cost of electricity, and the cost of natural gas. The LASSO approach alters the cost function by adding a penalty term that minimizes the estimated value of the regression coefficients and prevents the inflation of standard errors that is frequently observed in the presence of multicollinearity. LASSO minimizes the residual sum of squares when choosing variables, provided that the total of the absolute values of the coefficients is less than a constant. More particularly:

$$\hat{\beta}^L = \operatorname{argmin} \left\{ \sum_{i=1}^n \left(y_i - \alpha - \sum_{i=1}^n \beta_j x_{ij} \right)^2 \right\}, \quad (1)$$

provided that $\sum_{j=1}^p |\hat{\beta}_j^L| \leq c(\text{Constant})$.

This issue can be expressed as follows:

$$\hat{\beta}^L = \operatorname{argmin} \left\{ \sum_{i=1}^n \left(y_i - \alpha - \sum_{i=1}^n \beta_j x_{ij} \right)^2 + \lambda \sum_j |\beta_j| \right\}, \quad (2)$$

where $\lambda > 0$ is selected such that $\sum_{j=1}^p |\hat{\beta}_j^L| = c(\text{Constant})$, and each λ is equivalent to a different LASSO parameter c [13]. Some of the regression coefficients decrease to zero when the LASSO value is sufficiently small. As a result, for each LASSO parameter, the LASSO algorithm only chooses a subset of the regression coefficients. The amount of shrinkage that is applied to the estimations is controlled by the LASSO parameter $c > 0$. Tibshirani

[26] solves each relevant LASSO parameter using quadratic programming methods. For all values of c , Osborne also created a "homotopy" method for parameter estimation [27].

In Ref. [13], the authors considered six categories of factors influencing crude oil price forecasting (supply, demand, financial market, commodity market, speculation, and geopolitics) and examined their impact on crude oil price through different forecasting models. In this study, the Absolute Shrinkage and Selection Operator (LASSO) regression method has provided significant improvements in price prediction accuracy compared to other methods. LASSO forecasts at the 8-step ahead horizon yield significant reductions in Mean Squared Prediction Error (MSPE), with MSPE ratios of 0.873 and 0.898, respectively. LASSO forecasts at the 8-step ahead horizon yield significant reductions in Mean Squared Prediction Error (MSPE), with MSPE ratios of 0.873 and 0.898, respectively.

In Ref. [28], the authors have investigated the efficacy of a broad range of indicators in predicting crude oil price volatility, including uncertainty and market sentiment, macroeconomic indicators, and technical indicators. To forecast the most significant variables influencing changes in oil prices, they employed OLS, LASSO regression, and a variety of combined forecasts. The forecasts made by LASSO and the combined techniques are both statistically and economically significant. In their studies, the combined and LASSO techniques outperform inflation by a large margin.

To forecast oil price returns with a high number of variables, Zhang et al. used two shrinkage methods: the lasso and elastic net. The results indicate that the lasso and elastic net models outperform many widely-applied rival models in terms of out-of-sample R-square and success ratio. Based on the return forecasts of the lasso and elastic net methods in comparison to both the benchmark forecasts and competitor forecasts, a mean-variance investor achieves positive and sizable economic advantages in an asset allocation exercise. They have discovered that the lasso and elastic net approaches are effective at choosing strong predictors and those that can offer further data [29].

VI. PRINCIPAL COMPONENT ANALYSIS(PCA)

An unsupervised learning approach called principal component analysis is used in machine learning to reduce dimensionality. With the use of orthogonal transformation, it is a statistical process that transforms the observations of correlated features into a set of linearly uncorrelated data. The objective of PCA, one of the most established and widely used techniques in data analysis, is to extract low-dimensional subspaces from high-dimensional data while retaining as much diversity and unpredictability as feasible [30]. Three key issues are frequently addressed by PCA: 1) Dimensionality reduction for big, high-dimensional data sets, also known as low-rank subspace approximation [31]. 2) Subspace learning for applications in machine learning [32] 3) Protect the low-rank matrix from invalid data, such as missing samples [33, 34].

When there are lots of data and some of them are irrelevant, this strategy can help minimize the quantity of data storage needed while also speeding up and improving the

functionality of machine learning algorithms. The concept of PCA has traditionally been introduced algebraically through covariance matrices. In fact, this approach seeks a set of factors that are invariably linked to one another. PCA will significantly reduce complexity with little information loss by combining them into a new parameter. It will be possible to find a simpler explanation for the original data set if the majority of the variance in the original data can be explained by just a few new variables. By displaying which important variables are correlated, PCA may produce new physical insights beyond describing the statistical domain [35].

VII. CHAOTIC SYSTEMS

Ref. [36] states that Stock market price forecasting is considered one of the most challenging financial time series tasks. The difficulty of these forecasts comes from the time series' inherent non-constancy and the market's non-linearity. Ref. [37] also explains that financial transaction data are highly volatile and complex as a type of non-stationary time series data. Juárezza expresses that, according to the high volatility of economic sectors in some countries, methods for more reliable predictions of fluctuations are needed [17]. He also adds that complexity and chaotic models provide the possibility of studying non-linear phenomena in a precise manner, in addition to finding unknown relationships between several types of variables and providing a mathematical model for changing behavior. Juárezza believes that many financial indexes have a chaotic nature.

As we mentioned earlier, the price of crude oil is very important for the economic development of countries, as well as the development and stability of the global economy, and it can also play a political role. Regarding the chaotic and non-linear nature of crude oil prices, Karasu and Altan state that the chaotic and non-linear characteristics of crude oil time series make it difficult to predict crude oil prices with high accuracy [8].

According to the above-mentioned points, it can be said that complex and chaotic models are suitable and useful for estimating and forecasting the price of crude oil. Ref. [10] about the price of gold, oil, and the relationship between currencies concluded that there is no simple relationship between currencies through a common commodity, and as a result, the mutual relationship between gold price, exchange rate, and oil price is complex in nature. He also states that many factors can affect the price of gold and crude oil.

In Ref. [38], the authors express that, the stock price is affected by many factors such as oil price, exchange rate, money interest rate, stock price indices in other countries, and economic conditions. He also continued, although these factors affect the stock price independently, they affect the stock price through a complex interrelationship.

VIII. CONCLUSION

To investigate the impact of crude oil, gold and dollar on NASDAQ, we have used daily time step data from 12/12/2014 to 11/21/2022. According to Fig. (2), the results of

correlation interpretation are as follows:

- The NASDAQ index has a strong direct relationship with gold, the dollar and crude oil.
- Gold has a strong direct relationship with the dollar and NASDAQ stocks and has a weak direct relationship with crude oil.
- The dollar has a strong direct relationship with NASDAQ stocks, gold and crude oil.

Then, we have used lasso to investigate the influence of each economic index (dollar, crude oil and gold) in NASDAQ modeling and the results of lasso analysis are shown in Fig. (1).

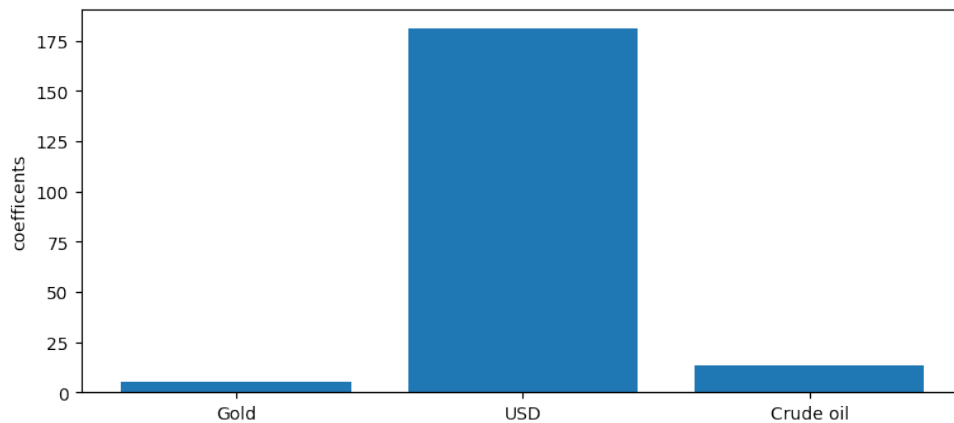

FIG. 1: Lasso analysis results for the impact of oil, US dollar and gold on NASDAQ

According to Fig. (1), the price of the dollar has a great impact, because the weight of the dollar is equal to 181.4. The weight of crude oil is equal to 13.52 and the weight of gold is equal to 5.41, which have less weight against the dollar.

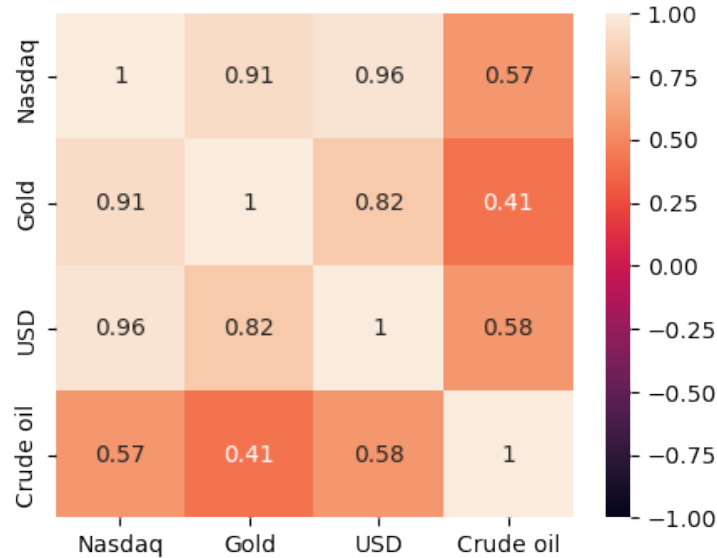

FIG. 2: Effective correlation heat map for oil, US dollar, gold and NASDAQ.

Regarding Fig. (2), the NASDAQ stock has a correlation of 0.96 with the dollar, and the weight of the dollar in the modeling of the NASDAQ stock is equal to 181.1, the NASDAQ index with gold has a correlation of 0.91. And the effective weight of gold in the modeling is equal to 5.41, and the NASDAQ stock has a correlation of 0.57 with crude oil, and its effective weight is equal to 13.52. Although gold has a higher correlation than crude oil, the effect of crude oil is about 2.5 times higher than that of gold in NASDAQ stocks. The characteristic of a volatile system Ref. [39] consists of a series of positive and negative feedback Ref. [40–42], and this is the reason for the existence of dynamic supersizing Ref. [43] in stock markets. The effects of the global financial crisis of 2008 on the market for crude oil and the positive feedback of oil prices have been researched by Joo et al. [40]. The Hurst exponent, scaling exponent, and Shannon entropy have all been used to characterize how the financial crisis has altered the oil market’s features. Their research demonstrates that although oil market volatility remained steady throughout the crisis, the crisis disrupted the market’s scale-invariant characteristics and adversely impacted its efficiency and long-run equilibrium.

Many people think that feedback loop tendencies can be seen in financial markets. The idea of feedback loops was initially devised as a theory to explain economic concepts, but it is now widely used in behavioral finance and capital markets theory, among other fields of finance. During difficult times, the value of feedback in the financial markets increases considerably. Markets frequently become erratic during times of uncertainty because humans have a tendency to overreact to feelings of greed and fear. The fear that occurs during abrupt market corrections is a good example of this. Positive feedback occurs when the outcome strengthens the initial act. Positive feedback loops can drive the price of security well above its fundamentals during asset bubbles. Positive feedback

frequently alludes to investors' propensity for herd mentality, which when used to buy or sell assets can turn into irrational enthusiasm. Investor elation can turn into unreasonable exuberance when a cycle of favorable feedback lasts too long; this can cause asset bubbles and eventually cause a market disaster. Although these additional acts can also have positive effects, if they are not reined in, they frequently have negative effects. An investor who makes money right away after buying a stock could overestimate their own trading skills and undervalue luck or other market circumstances. This could eventually result in overconfidence while choosing investments.

In Refs. [44–46], the authors claim that during the global financial crisis, higher oil prices were anticipated as a result of a stronger economy. As a result, traders often took long positions in the futures market and sold and then bought back at higher prices. These investors have produced dynamics that continue on their own [42]. Their investment strategies resulted in positive oil price feedback, which in turn caused a return distribution to gradually deteriorate. The interactions between these cooperative investors in particular reinforced the positive feedback on oil prices and caused a narrower scale-invariant return distribution to emerge [47]. Crude oil is a key input for economic activity and is traded by different participants in the market. Therefore, it is crucial for a variety of stakeholders, such as policymakers and regulators, to comprehend the crude oil market. However, speculators' excessive financialization of the oil market has simplified the pricing channel, resulting in a larger positive feedback loop with a smaller scaling exponent [40].

Moreover, a system with negative feedback is one in which the outputs dampen or moderate the initial inputs. Negative feedback loops in markets can thereby lessen volatility, for instance through contrarian or value investment. Using a negative feedback technique, a contrarian investor would, in contrast to the majority of investors, buy stocks when prices are falling and sell them when prices are rising. According to this definition, negative feedback encourages systems to reach equilibrium, which reduces market volatility [42].

To check the past influence of NASDAQ shares for its current price, we set the value of history point to 100. This means that in addition to characteristics such as open, high, low, close and volume, the dataset has the prices of the previous day, the current price, and the price of 400 days ago. Then, in order to optimize this history point number, we perform dimension reduction with the help of PCA and then perform modeling by linear regression. We repeat this work from the number of 5 components to 105 components and the results are illustrated in Fig. (3).

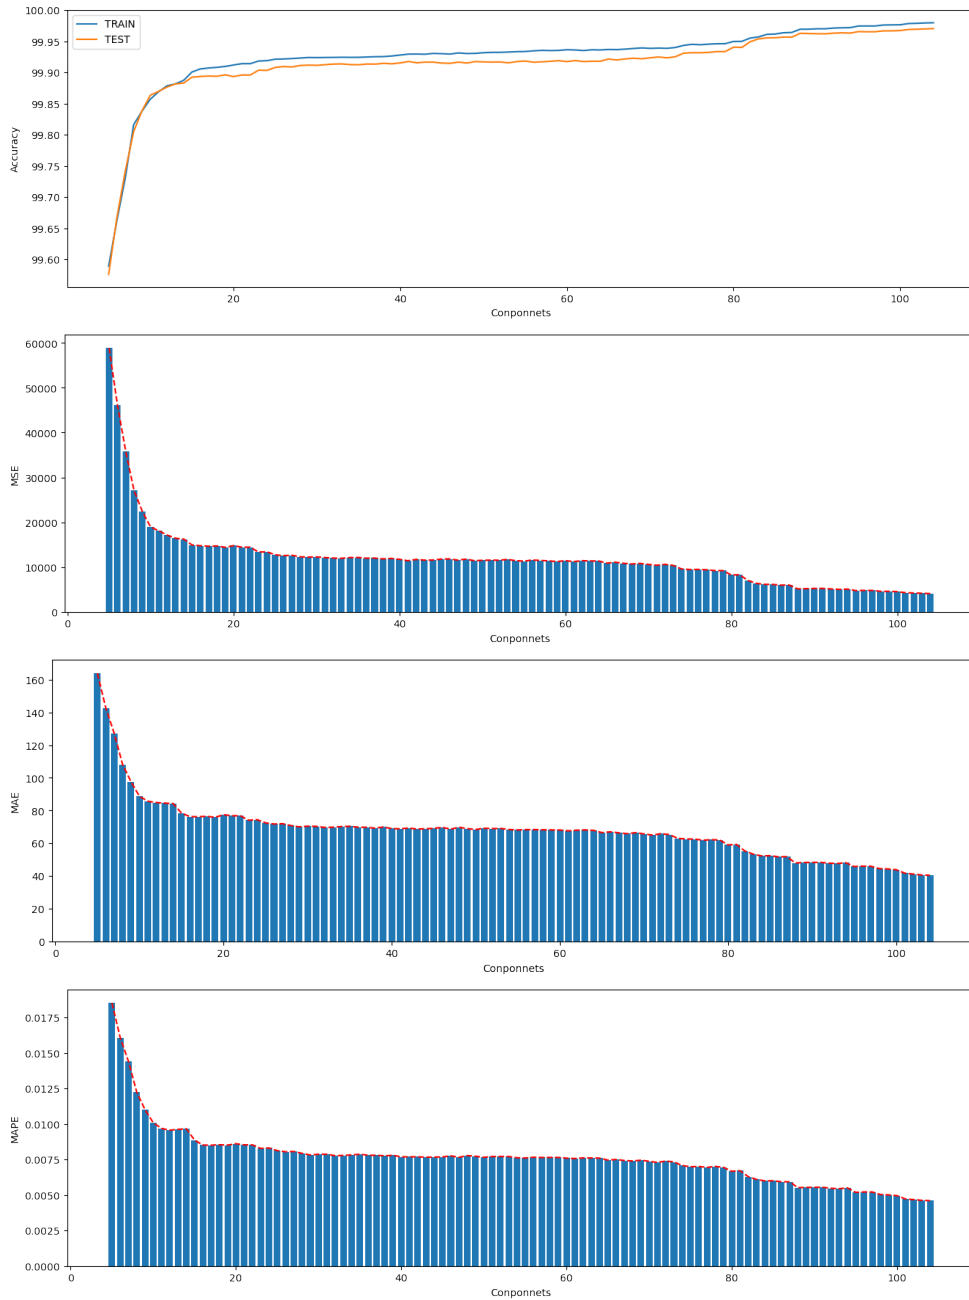

FIG. 3: Modeling results with the number of different components obtained from PCA with linear regression (examining the past impact on the current price of NASDAQ and optimizing the amount of components).

In Fig. (4), with the help of lasso, we checked the influence of each day from the past, which has a daily time step and is considered as a dynamic node. Through the Lasso method, we have been able to observe the positive and negative feedback of the past as chaotic dynamics. In fact, this chaotic dynamic shows the complexity of the NASDAQ market.

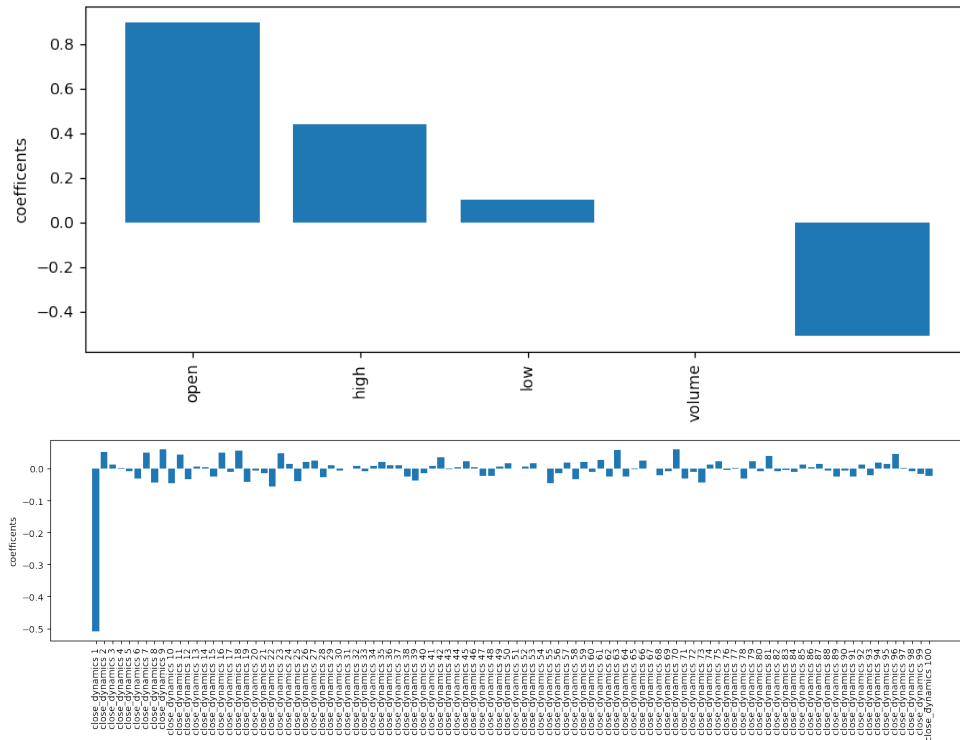

FIG. 4: The results of Lasso analysis and the impact of the past price along with the open, high, and low prices on the closing price.

In Fig. (5), we have increased the number of dynamics to 405 nodes in order to reduce dimension and feature selection. Then, with the help of linear regression, we have checked the done modeling.

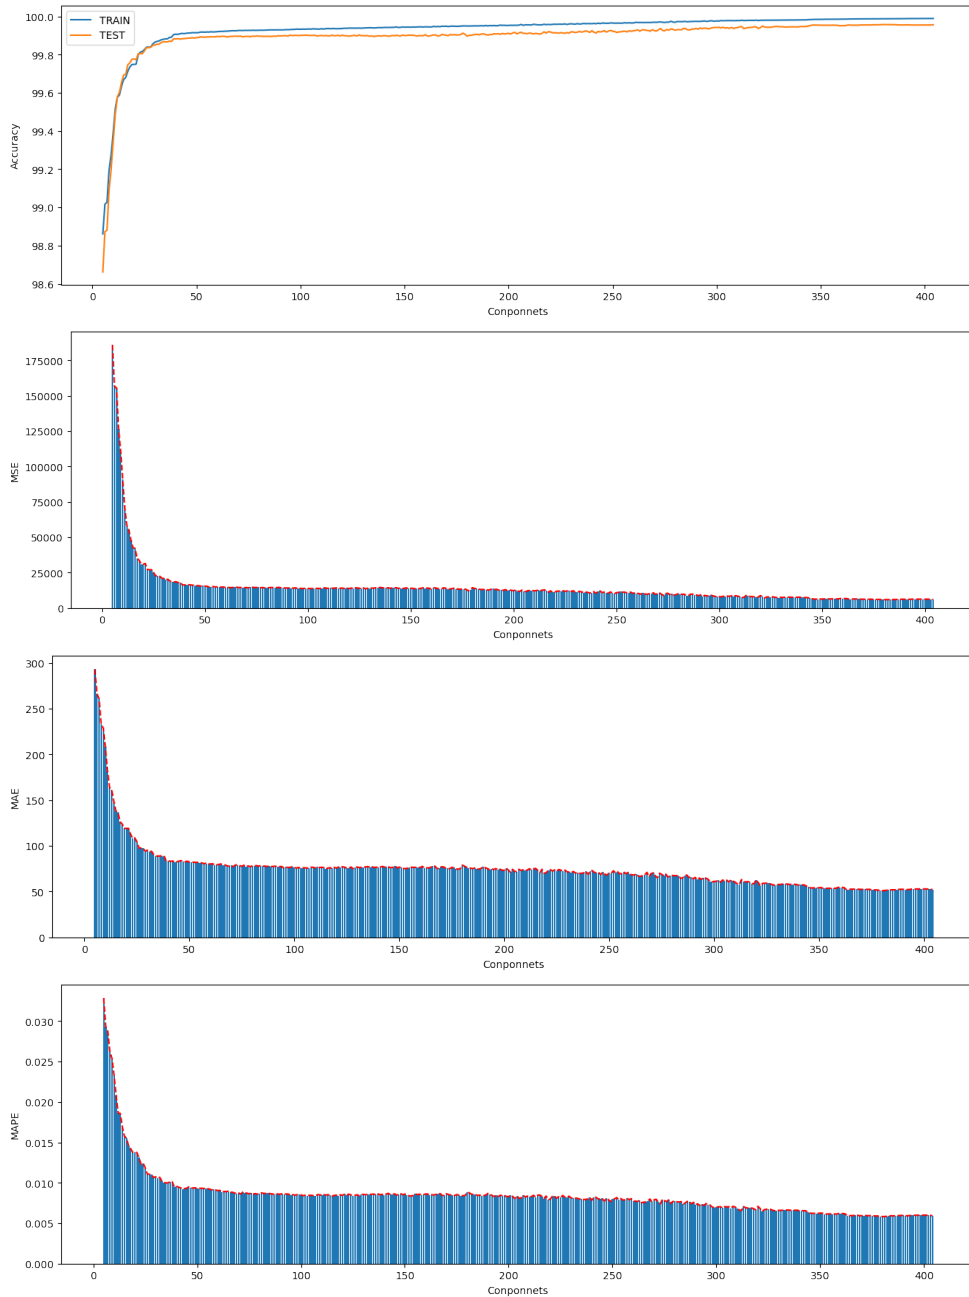

FIG. 5: Modeling results with the number of different components obtained from PCA with linear regression (examining the past impact on the current price of NASDAQ and optimizing the amount of components).

According to what has been said about gold and oil, our results also show similar points, and that is that there is a relationship between gold and oil, but the effect of gold on oil is small [11]. This case can be expressed in the following way: when the value of currencies decreases or the value of stocks decreases and the market is turbulent, gold and oil are safe havens where people invest against the decrease in exchange rates. This also shows the high relationship between oil, gold, the dollar, and the stock market and

the negative relationship between NASDAQ and the dollar with gold and oil. According to Conclusion Section, the dollar and the NASDAQ market have a direct and significant positive relationship. It can also be seen in the market that when the value of currencies increases, people are more willing to convert capital goods such as gold and oil into currency and stocks so that they can earn more profit during positive dynamics and market growth. This shows the effective connection of gold with the dollar and NASDAQ. The effective and negative relationship of oil with the market and the dollar is of great interest because it is a capital commodity against the dollar and a supplier of energy and raw material for factories and the impact on their production. From another point of view, this has an important impact on the political relationship between oil-exporting countries and importing countries. A suitable and lower price of oil causes the market to grow and strengthen the dollar, while the increase in the price of the dollar causes the price of oil to decrease, and this causes loss to the exporting countries. Therefore, by reducing the supply, they try to increase the price. This depreciates the dollar. Sometimes, some events in the world cause this balance to shift (war, political developments, etc.), and gold becomes a capital commodity against these very important changes. In this situation, some capitalists prefer to convert their capital into gold with less risk.

According to figure (4), the influence of past prices on the current price is in the form of fluctuating feedback, and except for the price of one day before, the rest of the prices in the past have positive and negative feedback of the same size. According to figures (3) and (5) and the previous paragraph, the more the past is examined by the algorithm, the more feedback from the past increases the accuracy in training and prediction. Based on the dynamic memory, it should be proportional to the number of training data.
