 D modeled after the Calcia-Magnesia-Alumino-Silicates(CMAS), are injected at a constant mass flow rate of 1 gram per minute. The deposition of these particles on a solid substrate, placed 20 cm away from the inlet along the axial direction, is investi-gated. These simulations are modeled after the experiments per-formed using the Hot-Particle Ingestion Rig (HPIR) facility at the Army Research Laboratory. The particle rebound and deposition model given by Bons et al. ["A simple physics-based model for particle rebound and deposition in turbomachinery." Journal of Turbomachinery 139.8 (2017)] is implemented and used in this work. Euler-Lagrange simulations are carried out for three different synthetic sand particles (CMAS, AFRL 02 and AFRL 03). To isolate the effects of Stokes number mono-dispersed particles are injected with a Gaussian spatial distribution. The effect of material properties and particle size on particle properties such

as number of particle depositions, rebound velocity and coefficient of restitution are investigated.

- Particle property.  $(.)_{p}$
- Surface/coupon property.  $(.)_{s}$
- $V_{n1}$ Impact velocity in the normal direction.
- Rebound velocity in the normal direction.  $V_{n2}$

 $V_{n1crit}$  Critical velocity of impact in the normal direction.

- v Poisson's ratio.
- $E_c$ Composite Young's modulus.

## INTRODUCTION

Rotorcrafts operating in dusty environments have been observed to suffer structural damage due to the ingestion of solid particulates into the gas turbine engines (GTEs). The ingested particles can cause erosion due to repeated impact, accumulate in air pathways leading to blockages and cause material degradation due to molten particulate deposits on the hot sections of the GTE. An aircraft undergoing sand ingestion is shown in Fig. 1 along with molten particulate deposits on the engine vanes in the inset. Environmental barrier coatings (EBC) offer protection against kinetic impacts while the inertial particle separators filter out larger particles (>  $75\mu m$ ) without a significant

FIGURE 1. SAND INGESTION DURING TAKE-OFF AND MOLTEN PARTICULATE DEPOSIT (INSET).

pressure drop at the compressor inlet. Smaller particles, on the other hand, pass through the cold section, melt in the combustion chamber and the resulting molten material, comprised of calcia-magnesia-alumina-silicates (CMAS), adheres to and damages the thermal barrier coating on the hot-section components. The molten CMAS material has been observed to infiltrate, react chemically with the thermal barrier coating (TBC) and solidify into a glassy coating as it cools down [1] [2]. Apart from structural damage, the CMAS penetration has also been observed to alter the thermal properties of the TBCs such as volumetric heat capacity and thermal conductivity [1]. Some of the mitigation strategies involve tailoring the TBC microstructure [3] and accelerating the chemical reaction time between the molten CMAS deposit and the coating to induce solidification and thus prevent penetration. One popular choice for the TBC on hotsection components is a mixture of Yttria  $(Y_2O_3)$ -stabilized Zirconia  $(ZrO_2)$  (YSZ). This particular coating has several desirable features (for high-temperature application) such as high melting point (~ 2700 °C), low thermal conductivity at elevated temperatures (~ 2.3  $W \cdot m^{-1} \cdot K^{-1}$  at 1000 °C) and high thermal-expansion coefficient (~ 11 × 10<sup>-6</sup> °C<sup>-1</sup>) [4]. With the performance envelope of the GTEs ever expanding, the operating temperatures are bound to increase which will only exacerbate CMAS attack. At the US Army Research Laboratory (ARL), research is underway to develop novel 'sandphobic' TBCs for high-temperature applications.

Recent progress in sand modeling at ARL employed a multiscale approach to investigate particle transport, collisions, and surface impact. This involved investigation of the interactions of binary fluid droplets, resembling molten sand particles, using the volume-of-fluid approach [5, 6], smoothed particle hydrodynamics to investigate high-velocity impacts of molten sand particles [7] and two-way coupled Euler-Lagrange (EL) simulations to investigate the effect of Stokes number on particle impact and heat flux on a transonic guide vane [8, 9]. Building upon this past work at ARL, high-fidelity computational fluid dynamics analysis is carried out to investigate the underlying transport and deposition physics using two-way coupled EL simulations in a gas turbine engine relevant environment.

The interaction between the particles and the (TBC) surfaces is crucial for particle deposition. The loss of energy of an impacting particle can be from a loss of kinetic energy and from energy required to overcome adhesive forces. There are multiple sources for the loss of energy from adhesion such as van der Walls force, capillary force, gravitational force and electrostatic force. A survey of the existing literature, points to various deposition models. In the critical velocity model of Brach & Dunn [10], the particle deposition is determined by the critical velocity of the impacting particle. The critical velocity is a function of material properties such as Young's modulus, yield stress and particle density. Below this critical velocity, the particle expends all its kinetic energy and deposits on the surface. This model was developed for low-velocity impacts. Another model proposed by Sreedharan & Tafti [11] is based on the sticking probability which is computed based on the critical viscosity approach. The critical viscosity is based on the softening temperature of a particle above which the viscosity decreases rapidly. The particle deposits if the actual sticking probability is greater than a probability drawn randomly from a uniform distribution. Additionally, the particle also deposits if the particle temperature is above the softening temperature. Drawing on these models, Singh & Tafti [12] proposed a hybrid model combining the critical velocity and critical viscosity approaches. In the current work, the deposition model developed by Bons et al. [13] is implemented and used. This model depends on the elastic-plastic deformation of a spherical particle idealized as a cylinder when treating the collision with the surface. The nature of the deformation, elastic or plastic, is determined based on the critical velocity of the particle. Based on this information, a contact area between the particle and the surface is computed which in turn is used to compute the work done by the adhesive forces. The kinetic energy at impact has to be greater the work of adhesion for the particle to rebound or else the particle deposits on the surface. Finally, the rebound normal and tangential velocities are computed using a soft-sphere analogy. In the current work, deposition characteristics of three different sand particles are investigated on a material coupon. The different sand particles used are CMAS, AFRL 02 and AFRL 03 particles which are treated as rigid spheres. The simulations are modeled after the experiments performed at the US Army Research Laboratory using the hot-particulate ingestion rig (HPIR) [1] [14].

## **GOVERNING EQUATIONS**

In this work, an Euler-Lagrange framework is used to handle the multiphase system. For the gas phase, compressible Navier-Stokes equations coupled with hydrodynamic drag and interphase heat-transfer are solved. These are given below.

$$\frac{\partial \boldsymbol{\rho}}{\partial t} + \nabla \cdot (\boldsymbol{\rho} \mathbf{u}) = 0 \tag{1}$$

$$\frac{\partial \rho \mathbf{u}}{\partial t} + \nabla \cdot (\rho \mathbf{u} \otimes \mathbf{u}) + \nabla p = \nabla \cdot \boldsymbol{\tau} - \mathbf{f}_{qs}$$
(2)

$$\frac{\partial \rho E}{\partial t} + \nabla \cdot \left( (\rho E + p) \mathbf{u} \right) - \nabla \cdot (\kappa \nabla T) = \nabla \cdot (\mathbf{u} \cdot \tau) - g_{qs} - q \quad (3)$$

where the shear stress  $\tau$  and the shear-rate tensor **S** are defined as,

$$\tau = 2\mu \mathbf{S} \tag{4}$$

$$\mathbf{S} = \frac{1}{2} \left( \nabla \mathbf{u} + \nabla \mathbf{u}^T \right) - \frac{1}{3} \nabla \cdot \mathbf{u}.$$
 (5)

The dynamic viscosity  $(\mu)$  of the flow, computed using the Sutherland's law, is given by,

$$\mu(T) = \frac{1.485 \times 10^{-6} T^{1.5}}{T + 110.4} \tag{6}$$

and the coefficient of thermal conduction ( $\kappa$ ) is given by,

$$\kappa(T) = C_{p,gas} \kappa_0 T^n \tag{7}$$

where,  $\kappa_0 = 6.25 \times 10^{-7} kg \cdot (s \cdot m \cdot K^n)^{-1}$  and n = 0.7. The hydrodynamic force coupled back to the gas is represented by  $\mathbf{f}_{qs}$  and similarly the contributions from the interphase work done and heat transfer is represented by  $g_{qs}$  and q respectively. The system of equations for Lagrangian point-particles are:

$$\frac{\mathrm{d}\mathbf{X}}{\mathrm{d}t} = \mathbf{V} \tag{8}$$

$$\frac{\mathrm{d}\mathbf{V}}{\mathrm{d}t} = \mathbf{F}_{qs} \tag{9}$$

$$\frac{\mathrm{dT}_p}{\mathrm{dt}} = Q \tag{10}$$

where the quasi-steady force  $(\mathbf{F}_{qs})$  and the heat-transfer between the phases Q are given by,

$$\mathbf{F}_{qs} = \frac{\mathbf{u} - \mathbf{V}}{\tau_{v}} \tag{11}$$

$$Q = \frac{T - \mathcal{T}_p}{\tau_T}.$$
 (12)

The hydrodynamic and the thermal time scales are represented by  $\tau_v$  and  $\tau_T$  respectively.

$$\tau_{\nu} = \frac{4}{3} \frac{\rho_g}{\rho_p} \frac{d_p}{C_D} \frac{1}{|\mathbf{V} - \mathbf{u}|}$$
(13)

$$\tau_T = \frac{1}{6} d_p^2 C_{p,particle} \frac{\rho_p}{\kappa N u} \tag{14}$$

The drag coefficient  $C_D$  proposed by Loth [15] is used while the Nusselt number (*Nu*) is calculated using the correlation given by R. Ranz & Marshall [16].

The system of equations are solved using the massively parallel code Athena-RFX [17, 18]. The integration is carried out using an unsplit corner transport upwind (CTU) algorithm [19] based on the work of Collela [20]. An approximate HLLC Riemann solver is used along with a piecewise-parabolic method (PPM) for flux reconstruction resulting in a spatial accuracy of  $3^{rd}$ -order. The particle phase equations, Eqs. 8-10, are integrated in time using a semi-implicit predictor-corrector algorithm. This offers better numerical stability and the errors in particle trajectories remain bounded in time. This property of preserving particle trajectories typically used for Hamiltonian systems [21]. The Eulerian fluid properties are interpolated to the particle location using a 5-point stencil WENO scheme which is  $5^{th}$ -order accurate for smooth flows [22].

#### Model for Particle Deposition

The particle deposition model proposed by Bons *et al.* [13] is implemented and used in this work to explore the particle deposi-

tion mechanism. In this model, the spherical particle is idealised as a cylinder with an equal volume impacting the substrate along the axis of rotation of the cylinder. The particle-surface collision is treated as a spring-damper system and the effect of surface inhomogeneities are accounted for via an adhesion model. In this model, the quantity that determines if a particle is deposited is the normal coefficient of restitution  $\text{CoR}_n$  which is defined as the ratio of the rebound normal velocity ( $V_{n2}$ ) and the impact normal velocity ( $V_{n1}$ ). The particle deposits on the surface when  $\text{CoR}_n$ is equal to zero and for all the other values the particle rebounds off the surface. The procedure for computing  $V_{n2}$  is laid out in the next paragraph.

As mentioned in the preceding paragraph, the particles are represented as cylinders with the same volume as that of the sphere. The resulting length of the cylinder  $l = 2d_p/3$ . Based on the material properties of the particle such as yield stress ( $\sigma_y$ ), particle density ( $\rho_p$ ) and Young's modulus ( $E_c$ ), the critical normal velocity  $V_{n1crit} = \sigma_y/(\rho_p E_c)^{0.5}$  is computed at which plastic deformation of the particle begins. In this case, a composite modulus is defined based on the Poisson's ratio (v) and the Young's moduli of the particle and the surface.

$$\frac{1}{E_c} = \frac{1 - v_p^2}{E_p} + \frac{1 - v_s^2}{E_s}$$
(15)

Furthermore, the impacting particle expends additional energy to overcome the adhesive forces. The resulting kinetic energy of the particle is computed by subtracting the work of adhesion (*Wa*) from the critical elastic energy ( $E_{crit}$ ). The work of adhesion depends on two quantities 1) contact surface area ( $A_{cont}$ ) and 2) deformation of the particle (*w*) upon impact. The work of adhesion is computed using the expression  $W_a = A_{cont} \gamma_s$  where  $\gamma_s$ is the surface free energy taken to be 0.8. The contact area is computed using the following expression

$$A_{cont} = A_{crit} \left[ a + b \left( \frac{w_{max}}{w_{crit}} \right)^c \right]$$
(16)

where a = 0.1, b = 1/7, c = 0.5 are empirical constants and  $w_{max}$ ,  $w_{crit}$  denote the maximum plastic deformation and maximum elastic deformation respectively. The surface area at maximum elastic deformation is given by

$$A_{crit} = \frac{\pi d_p^2 l}{4(l - w_{crit})}.$$
(17)

For the definitions of  $w_{max}$ ,  $w_{crit}$  and  $E_{crit}$  see [13].

Upon collision, some particles lose all the elastic energy to the work of adhesion and deposit on the surface. While particles with enough elastic energy undergo an elastic rebound. The normal and tangential components of the rebound velocity are given below.

$$V_{n2} = -CoR_n V_{n1} \tag{18}$$

$$V_{t2} = V_{t1} - \beta V_{n1} \cos^2(\alpha) (1 + \text{CoR}_{\text{in}}) \left( 1 + \frac{2W_a}{\text{CoR}_{\text{in}}} m_p V_{n1}^2 \right)$$
(19)

The ideal normal coefficient of restitution (CoR<sub>in</sub>) is the ratio of  $V_{n1crit}$  and  $V_{n1}$ . The angle of impact is calculated using  $\alpha = \arctan(V_{n1}/V_{t1})$  where  $V_{t1}$  is the impact tangential velocity. Finally, the impulse ratio  $\beta$  is given by

$$\beta = \frac{V_{t1}}{V_{t2}} \left[ 1 + \text{CoR}_{\text{in}}^2 + \frac{2W_a}{m_p V_{n1}^2} \right]^{-0.5}.$$
 (20)

#### SIMULATION SETUP

The simulations are performed in a three dimensional (3D) Cartesian box with the jet aligned along the z-axis. A schematic of the setup is shown in Fig. 2. Along the streamwise direction, the jet is issued from a circular inflow region at one end and at the other end is the coupon. Apart from the inflow boundary condition, rest of the boundaries are set to no-slip walls for the gas flow. For the particles on the other hand, the deposition boundary condition is specified on the coupon. The grid spacing in the streamwise direction is 781.25  $\mu m$  and about 1.17 mm in the other two directions which amounts to around 16.7 million cells in total. The initial conditions of the gas and the particles are given in Table 1 and are based on experimental measurements. The initial temperature and the velocity of all the particles in the radial and axial directions is the same as the hot jet and the mass flow rate of the particles is set to 1 gram/min. To maintain a steady mass flow rate, the particles are injected into the domain in pulses. Particles are currently assumed to be in thermal equilibrium. Thus, phase-change or surface chemistry is not modeled but will be addressed in future works. A photograph of the HPIR experimental facility is shown in Fig. 2(b). The ambient pressure and temperature are set to 1 atm and 298 K. The gas in this simulation is treated as air with  $\gamma = 1.4$  and  $R = 287J \cdot (kg \cdot K)^{-1}$ .

In this work, three different particles are used which are primarily composed of calcia-magnesia-alumino-silicates (CMAS). These are referred to as CMAS, AFRL 02 and AFRL 03. The AFRL particles are assumed to have identical chemical composition in this work and hence have the same mechanical properties. The only difference between the two different AFRL particles is in the size of the particles. The AFRL 02 particles are smaller in size and are used for test-bed analysis while the (comparatively) larger sized AFRL 03 particles are synthesized for engine-level testing [23]. The mechanical properties of the AFRL particles

**FIGURE 2**. (a) SIMULATION SETUP AND (b) HPIR FACILITY [1].

are taken from the works of Bojdo, N. and Filippone, A. [24] and Whitaker, S. M. [25] while that of the CMAS particles are taken from a NASA report by Bansal, N. P., and Choi, S. R. [26] on desert sand and CMAS glass. The coupon is representative of bulk Yttria stabilized Zirconia (YSZ). The material properties related to the coupon are accounted for in the deposition model via the Young's modulus  $(E_s)$  and the Poisson's ratio  $(v_s)$ . Following the work of Nieto *et al.* [27], these values are set to  $E_s = 220$ GPa and  $v_s = 0.3$ . The material properties of the CMAS and the AFRL particles are listed in Table 2. These bulk properties are computed using volume fraction weighted summation of individual constituents. The solid particle characterization measurements were conducted at ARL to statistically quantify the particle distributions. Following this, the particle diameters chosen were 20.15  $\mu m$  for the CMAS particles and 17.86  $\mu m$  and 22.89 µm for the AFRL 02 and AFRL 03 particles respectively. Finally, the yield stress of the particles is computed as a function of temperature given by the

$$\sigma_{\rm v}(T) = 200 - 0.255(T - 1000)MPa. \tag{21}$$

## TABLE 1. INITIAL CONDITIONS

| Parameter             | Value   | Definition                               |
|-----------------------|---------|--|
| <i>u</i> <sub>z</sub> | 250 m/s | Axial velocity of the jet                |

#### RESULTS

The general feature of the flow can be seen in the instantaneous snapshot of the flow field in Fig. 3. The vortex roll-up of the gas reminiscent of Kelvin-Helmholtz instability is seen as the hot gas enters into cooler and less viscous ambient gas. Based on the injection parameters of the gas, the Mach number is 0.29 and the Reynolds number based on the injector diameter is 44668. The location of the particles hitting the coupon can be seen in the close-up image in Fig. 3

In Fig. 4(a), the cumulative number of particles being deposited as a fraction of the total number of particles hitting the coupon is represented as a percentage. In the bottom figure, average impact and rebound velocity of all the particles hitting the coupon is shown. Among the three different particles, AFRL 03 particles show the least amount of deposition. CMAS and AFRL 02 on the other hand, have a peak deposition percentages of about 4% and 3.5% respectively. A direct correlation can be seen between the average impact velocities of the particles and the deposition percentage. The impact velocities of the AFRL

**FIGURE 3.** (TOP) INSTANTANEOUS SNAPSHOT OF THE FLOW FIELD AND (BOTTOM) CLOSE-UP VIEW OF THE COUPON.

02 and the CMAS particles begin to dip at around the same time particles begin depositing on the coupon. This is clearly an effect of the deposition model which relies on the loss of kinetic energy during impact, in the normal direction, due to surface interaction to determine the deposition rate. As the incoming particles lose their kinetic energy, the particles begin depositing on the coupon. The average rebound velocity of all the particles is around 15 m/s. This suggests that the rebound velocity of the AFRL 03 particles is low but not quite low enough for the particles to deposit which explains the low deposition rate. The

**FIGURE 4**. PLOT OF THE CUMULATIVE PERCENTAGE OF PARTICLES BEING DEPOSITED ON THE COUPON (TOP) AND THE AVERAGE IMPACT AND REBOUND VELOCITIES OF THE PARTICLES (BOTTOM).

time averaged distribution (in %) of normal and tangential components of the particle rebound velocity from the experiment are shown in Fig. 5. The deposition percentage (where the velocity is 0) corresponding to the normal velocity is about 4% and that of the tangential component is a little over 7%. While comparing with the experiments it is important to note that the sand particles in the experiments were polydisperse in nature whereas the particle sizes in the simulations are the volume averaged mean values of the polydisperse mix.

#### Effect of Stokes Number

The AFRL 03 particles are about 30% larger than the AFRL 02 particles and to investigate the effect of particle size it is useful to compute the Stokes number of the particles. The Stokes number is computed using the formula

$$Stk = \frac{\rho_p d_p^2}{18\mu_f C_D} \cdot \frac{U_{inj}}{d_{inj}}$$
(22)

where  $U_{inj}$  is the velocity magnitude of the gas injected into the domain. Based on this, the Stokes numbers come out to 1.33, 2.56 and 1.93 for AFRL 02, AFRL 03 and CMAS particles re-

**FIGURE 5**. REBOUND VELOCITIES OF SAND PARTICLES FROM THE HPIR EXPERIMENT. THE DEPOSITION PERCENT-AGES ARE DENOTED BY THE ARROWS.

spectively. Although all the particles are of the same order of magnitude we see a difference in the deposition of the AFRL particles. It is likely that the larger AFRL 03 particles are more ballistic than the AFRL 02 particles and are hence less affected by the gas flow especially in the vicinity of the coupon. This can be seen in the impact velocities of these particles in Fig. 4 and in the instantaneous snapshots of the flow fields, taken at about 7.4 ms, in Fig. 7. In the case of the larger AFRL 03 particles, the trailing particles are about to reach the end of the domain whereas the AFRL 02 and the CMAS particles can be seen already reaching the end of the domain and hitting the coupon. These trailing particles are a consequence of maintaining a uniform mass flow rate of particles wherein the particles are injected in pulses. The batch of AFRL 02 and CMAS particles accompanying the AFRL 03 particles has already reached the end of the domain. Further evidence of this argument can be seen in the total number of particle impacts on the coupon shown in Fig. 6. The smaller AFRL 02 particles register the highest number of hits on the coupon, more than twice, than the AFRL 03 and CMAS particles. То isolate the effects of particle material and composition on deposition percentage, simulation was carried out with equi-sized CMAS and AFRL 02 particles with the particle diameter set to 20.15  $\mu m$ . The cumulative deposition percentage along with the cumulative average impact and rebound velocity is shown in Fig. 8. Compared to the CMAS particles, the AFRL 02 particles begin depositing on the coupon at a later time and have a lower percentage of deposition at about 2.5%. The average impact and rebound velocities in the normal direction are are quite comparable.

# SUMMARY

In this work, two-way coupled Euler-Lagrange simulations are carried out to investigate sand particle deposition on a YSZ

**FIGURE 6**. CUMULATIVE SUM OF ALL THE PARTICLE IM-PACTS ON THE COUPON.

coupon using the deposition model proposed by Bons et al. [13]. These simulations were modeled after the experiments performed at the HPIR facility at the US Army Research Laboratory. Monodisperse particles representing two different materials, CMAS and AFRL sand were used in this work. The CMAS were shown to have the highest amount of deposition of about 4% on the coupon followed by the smaller AFRL 02 sand particles with  $\sim 3.5\%$ . Notwithstanding the differences between the experiments and the simulations in terms of the particle size distributions, the deposition rates were observed to be quite comparable to the experiments. The larger AFRL 03 particles shown negligible amount of deposition amongst all the different particles. The Stokes number of the AFRL 03 particles, although being the same order of magnitude as the rest, could explain the ballistic behavior of these particles. Another interesting observation can be seen between the AFRL 03 particles and the CMAS particles in regards to the total number of impacts and the deposition percentages. Although both these particles register a comparable number of impacts on the coupon, the amount deposited is starkly different. This could possibly arise due to differences 1) in material properties or/and 2) in particle size. The results from equi-sized CMAS and AFRL particles, with comparable Stk 1.93 and 1.83 respectively, suggest that the differences could be due to the material properties rather than the particle size. In addition to this, there are also uncertainties associated with experimental data of the rebounding particles. Future work is reserved for investigations pertaining to polydisperse particle mixtures and different TBC materials. An experimental campaign is underway at ARL which is aimed at quantifying parameter uncertainty related to particle measurements used in the modeling.
