Abstract. Parametric time Petri nets with inhibitor arcs (PITPNs) support flexibility for timed systems by allowing parameters in firing bounds. In this paper we present and prove correct a concrete and a symbolic rewriting logic semantics for PITPNs. We show how this allows us to use Maude combined with SMT solving to provide sound and complete formal analyses for PITPNs. We develop a new general folding approach for symbolic reachability that terminates whenever the parametric state-class graph of the PITPN is finite. We explain how almost all formal analysis and parameter synthesis supported by the state-of-the-art PITPN tool Roméo can be done in Maude with SMT. In addition, we also support analysis and parameter synthesis from *parametric* initial markings, as well as full LTL model checking and analysis with user-defined execution strategies. Experiments on three benchmarks show that our methods outperform Roméo in many cases.

Keywords: parametric timed Petri nets · semantics · rewriting logic · Maude · SMT · parameter synthesis · symbolic reachability analysis

1 Introduction

Time(d) Petri nets [\[27,](#page-25-0)[49](#page-26-0)[,19\]](#page-24-0) have been extensively used to model real-time systems. In time Petri nets, firing conditions are given as time intervals within which an enabled transition must fire. However, in system design we often do not know in advance the concrete values of key system parameters, and want to find those values that make the system behave as desired. Parametric time Petri nets with inhibitor arcs (PITPNs) [\[47,](#page-25-1)[18,](#page-24-1)[2,](#page-24-2)[25\]](#page-25-2) extend time Petri nets to the setting where bounds on when transitions can fire are unknown or only partially known.

The modeling and formal analysis of PITPNs—including synthesizing the values of the parameters which make the system satisfy desired properties—are supported by the state-of-the-art tool Roméo [\[26\]](#page-25-3), which has been applied to a number of applications, including oscillatory biological systems [\[3\]](#page-24-3), aerial video tracking systems [\[44\]](#page-25-4), and distributed software commissioning [\[17\]](#page-24-4). Roméo supports the analysis and parameter synthesis for reachability (is a certain marking reachable?), liveness (will a certain marking be reached in all behaviors?), time-bounded "until," and bounded response (will each P-marking be followed by a Q-marking within time Δ ?), all from *concrete* initial markings. Roméo does not support a number of desired features, including:

- Broader set of system properties, e.g., full (i.e., nested) temporal logic.
- Start with parametric initial markings and synthesize also the initial markings that make the system satisfy desired properties.
- Analysis with user-defined execution strategies. For example, what happens if I always choose to fire transition t instead of t' when they are both enabled at the same time? It is often possible to manually change the model to analyze the system under such scenarios, but this is arduous and error-prone.

[?] Supported by CNRS INS2I project ESPRiTS and PHC Aurora AESIR.

– Providing a "testbed" for PITPNs in which different analysis methods and algorithms can quickly be developed, tested, and evaluated. This is not well supported by Roméo, which is a high-performance tool with dedicated algorithms implemented in C^{++} .

PITPNs do not support many features needed for large distributed systems, such as user-defined data types and functions, as in, e.g., colored Petri nets [\[19\]](#page-24-0).

Rewriting logic [\[28](#page-25-5)[,29\]](#page-25-6)—supported by the Maude language and tool [\[16\]](#page-24-5), and by Real-Time Maude [\[40,](#page-25-7)[34\]](#page-25-8) for real-time systems—is an expressive logic for distributed and real-time systems. In rewriting logic, any computable data type can be specified as an (algebraic) equational specification, and the dynamic behaviors of a system are specified by rewriting rules over terms (representing states). Because of its expressiveness, Real-Time Maude has been successfully applied to a number of large and sophisticated real-time systems including 50-page active networks and IETF protocols [\[41,](#page-25-9)[24\]](#page-25-10), state-of-the-art wireless sensor network algorithms involving areas, angles, etc. [\[42\]](#page-25-11), scheduling algorithms with unbounded queues [\[36\]](#page-25-12), airplane turning algorithms [\[7\]](#page-24-6), and so on—beyond the scope of most popular formalisms for real-time systems. Its expressiveness has also made Real-Time Maude a useful semantic framework and formal analysis backend for (subsets of) industrial modeling languages [\[35,](#page-25-13)[1,](#page-24-7)[8](#page-24-8)[,33\]](#page-25-14).

This expressiveness comes at a price: most analysis problems are undecidable in general. Real-Time Maude uses explicit-state analysis where only some points in time are visited. All possible system behaviors are therefore not analyzed (for dense time domains), and hence the analysis is unsound in many cases [\[38\]](#page-25-15).

This paper exploits the recent integration of SMT solving into Maude to address the first problem above (more features for PITPNs) and to take the second step towards addressing the second problem (developing sound and complete analysis methods for rewriting-logic-based real-time systems).

Maude combined with SMT solving, e.g., as implemented in the Maude-SE tool [\[51\]](#page-26-1), allows us to perform symbolic rewriting of "states" $\phi \parallel t$, where the term t is a state pattern that contains variables, and ϕ is an SMT constraint restricting the possible values of those variables.

Section [3](#page-5-0) provides a "concrete" rewriting logic semantics for (instantiated) PITPNs in "Real-Time Maude style" [\[39\]](#page-25-16). In a dense-time setting, such as for PITPNs, this model is not executable. Section [4](#page-10-0) shows how we can do(in general unsound) time-sampling-based analysis where time increases in discrete steps, of concrete nets, to quickly experiment with different values for the parameter.

Section [5](#page-12-0) gives a Maude-with-SMT semantics for *parametric* PITPNs, and shows how to perform (sound) symbolic analysis of such nets using Maude with SMT. However, existing symbolic reachability analysis methods, including "folding" of symbolic states, may fail to terminate even when the state class graph of the PITPN is finite (and hence Roméo analysis terminates). We therefore develop and implement a new method for "folding" symbolic states for reachability analysis in Maude-with-SMT, and show that this new reachability analysis method terminates whenever the state class graph of the PITPN is finite.

In Sections [5](#page-12-0) and [6](#page-17-0) we show how a range of formal analyses and parameter synthesis can be performed with Maude-with-SMT, including unbounded and time-bounded reachability analysis. We show in Section [6](#page-17-0) how all analysis methods supported by Roméo—with one small exception: the time bounds in some temporal formulas cannot be parameters—also can be performed in Maude-with-SMT. In addition, we support state properties on both markings and "transition clocks," analysis and parameter synthesis for parametric initial markings, model checking full (i.e., nested) temporal logic formulas, and analysis w.r.t. user-defined execution strategies, as illustrated in Section [6.](#page-17-0) Our methods are formalized/implemented in Maude itself, using Maude's meta-programming features. This makes it very easy to develop new analysis methods for PITPNs.

This work also constitutes the second step in our quest to develop sound and complete formal analysis methods for dense-time real-time systems in Real-Time Maude. One reason for presenting both a "standard" Real-Time Maude-style concrete semantics in Section [3](#page-5-0) and the symbolic semantics in Section [5](#page-12-0) is to explore how we can transform Real-Time Maude models into Maude-with-SMT models for symbolic analysis. In our first step in this quest, we studied symbolic rewrite methods for the much simpler parametric timed automata (PTA) [\[4\]](#page-24-9). In [\[4\]](#page-24-9) we specify a new rewrite theory for each automaton, whereas in this paper we specify a single rewrite theory ("interpreter") for all PITPNs. Furthermore, no equations or user-defined functions are needed for PTAs, in contrast to the models in this paper. Finally, known folding methods are sufficient for PTAs, whereas we had to develop stronger folding methods for PITPNs.

In Section [7](#page-20-0) we benchmark both Roméo and our Maude-with-SMT methods on three PITPNs. Somewhat surprisingly, in many cases our high-level prototype outperforms Roméo. We also discovered that Roméo answered "maybe" in some cases where Maude found solutions, and that Roméo sometimes failed to synthesize parameters even when solutions existed.

All executable Maude files with analysis commands, tools for translating Roméo files into Maude, and data from the benchmarking are available at [\[5\]](#page-24-10).

2 Preliminaries

This section introduces transition systems, bisimulation [\[14\]](#page-24-11), parametric time Petri nets with inhibitor arcs [\[47\]](#page-25-1), rewriting logic [\[28\]](#page-25-5), rewriting modulo SMT [\[45\]](#page-25-17) and Maude/Maude-SE [\[15,](#page-24-12)[51\]](#page-26-1).

A transition system A is a triple (A, a_0, \rightarrow_A) , where A is a set of states, $a_0 \in A$ is the *initial state*, and $\rightarrow_{\mathcal{A}} \subseteq A \times A$ is a transition relation. We say that A is finite if the set of states reachable by $\rightarrow_{\mathcal{A}}$ from a_0 is finite. A relation $\sim \subseteq A \times B$ is a bisimulation [\[14\]](#page-24-11) from A to $\mathcal{B} = (B, b_0, \rightarrow_B)$ iff: (i) $a_0 \sim b_0$; and (ii) for all a, b s.t. $a \sim b$: if $a \to a$ a' then there is a b' s.t. $b \to_B b'$ and $a' \sim b'$, and, vice versa, if $b \to_B b''$, then there is a a'' s.t. $a \rightarrow_A a''$ and $a'' \sim b''$.

2.1 Parametric Time Petri Nets with Inhibitor Arcs (PITPN).

We recall the definitions from [\[47\]](#page-25-1). N, \mathbb{Q}_+ , and \mathbb{R}_+ denote, resp., the natural numbers, the non-negative rational numbers, and the non-negative real numbers. Throughout this paper, we assume a finite set $\Lambda =$ $\{\lambda_1,\ldots,\lambda_l\}$ of time parameters. A parameter valuation π is a function $\pi: \Lambda \to \mathbb{R}_+$. A (linear) inequality over A is an expression $\sum_{1 \leq i \leq l} a_i \lambda_i \prec b$, where $\prec \in \{ \leq, \leq, =, \geq, \geq \}$ and $a_i, b \in \mathbb{R}$. A constraint is a conjunction of such inequalities. $\mathcal{L}(\Lambda)$ denotes the set of all constraints over Λ . A parameter valuation π satisfies a constraint $K \in \mathcal{L}(\Lambda)$, written $\pi \models K$, if the expression obtained by replacing each parameter λ in K with $\pi(\lambda)$ evaluates to true. An interval I of \mathbb{R}_+ is a \mathbb{Q}_+ -interval if its left endpoint $\uparrow I$ belongs to \mathbb{Q}_+ and its right endpoint I^{\uparrow} belongs to $\mathbb{Q}_+ \cup \{\infty\}$. We denote by $\mathcal{I}(\mathbb{Q}_+)$ the set of \mathbb{Q}_+ -intervals. A parametric time interval is a function $I: \mathbb{Q}_+^{\Lambda} \to \mathcal{I}(\mathbb{Q}_+)$ that associates with each parameter valuation a \mathbb{Q}_+ -interval. The set of parametric time intervals over Λ is denoted $\mathcal{I}(\Lambda)$.

Definition 1 (PITPN). A parametric time Petri net with inhibitor arcs is a tuple

- $\mathcal{N} = \langle P, T, \Lambda, \bullet(.), (.) \bullet, \circ(.), M_0, J, K_0 \rangle$ where
- $-P = \{p_1, \ldots, p_m\}$ is a non-empty finite set (of places),
- $-T = \{t_1, \ldots, t_n\}$ is a non-empty finite set (of transitions), with $P \cap T = \emptyset$,
- $A = {\lambda_1, \ldots, \lambda_l}$ is a finite set of parameters,
- $-$ (.) \in $[T \to \mathbb{N}^P]$ is the backward incidence function,
- $-$ (.) $\bullet \in [T \to \mathbb{N}^P]$ is the forward incidence function,
- $-\circ(.) \in [T \to \mathbb{N}^P]$ is the inhibition function,
- $M_0 \in \mathbb{N}^P$ is the initial marking,
- $-I \in [T \to I(\Lambda)]$ assigns a parametric time interval to each transition, and
- $K_0 \in \mathcal{L}(\Lambda)$ is the initial constraint over Λ .

If $\Lambda = \emptyset$ then N is a (non-parametric) time Petri net with inhibitor arcs (ITPN).

A marking of N is an element $M \in \mathbb{N}^P$, where $M(p)$ is the number of tokens in place p. $\pi(\mathcal{N})$ denotes the ITPN where each occurrence of λ_i in the PITPN $\mathcal N$ has been replaced by $\pi(\lambda_i)$ for a parameter valuation π . For example, the ITPN in Fig. [1b](#page-3-0) corresponds to the PITPN in Fig. [1a](#page-3-0) where the parameters are instantiated with $\pi = {\lambda_1^- \to 5, \lambda_1^+ \to 6, \lambda_2^- \to 3, \lambda_2^+ \to 4, \lambda_3^- \to 1, \lambda_3^+ \to 2}.$

The concrete semantics of a PITPN N is defined in terms of concrete ITPNs $\pi(\mathcal{N})$ where $\pi \models K_0$. We say that a transition t is enabled in M if $M \geq \cdot t$ (the number of tokens in M in each input place of t is greater than or equal to the value on the arc between this place and t). A transition t is *inhibited* if the place

Fig. 1: A PITPN and its valuation.

connected to one of its inhibitor arcs is marked with at least as many tokens as the weight of the inhibitor arc. A transition t is active if it is enabled and not inhibited. The sets of enabled and inhibited transitions in marking M are denoted $Enabled(M)$ and $Inhibited(M)$, respectively. Transition t is firable if it has been (continuously) enabled for at least time $\tau J(t)$, without counting the time it has been inhibited. Transition t is newly enabled by the firing of transition t_f in M if it is enabled in the resulting marking $M' = M - \cdot t_f + t_f^*$ but was not enabled in $M - t_f$:

$$
NewlyEnabeled(t, M, t_f) = (\mathbf{e}^t \leq M - \mathbf{e}^t) + t_f^{\bullet}) \wedge ((t = t_f) \vee \neg (\mathbf{e}^t \leq M - \mathbf{e}^t))
$$

NewlyEnabled(M, t_f) denotes the transitions newly enabled by firing t_f in M.

The semantics of an ITPN is defined as a transition system with states (M, I) , where M is a marking and I is a function mapping each transition enabled in M to a time interval, and two kinds of transitions: time transitions where time elapses, and discrete transitions when a transition in the net is fired.

Definition 2 (Semantics of an ITPN [\[47\]](#page-25-1)). The dynamic behaviors of an ITPN $\pi(\mathcal{N})$ are defined by the transition system $\mathcal{S}_{\pi(\mathcal{N})} = (\mathcal{A}, a_0, \to)$, where: $\mathcal{A} = \mathbb{N}^P \times [T \to \mathcal{I}(\mathbb{Q})]$, $a_0 = (M_0, J)$ and $(M, I) \to (M', I')$ if there exist $\delta \in \mathbb{R}_+$, $t \in T$, and state (M'', I'') such that $(M, I) \stackrel{\delta}{\to} (M'', I'')$ and $(M'', I'') \stackrel{t}{\to} (M', I')$, for the following relations:

– the time transition relation, defined $\forall \delta \in \mathbb{R}_+$ by: $(M, I) \stackrel{\delta}{\rightarrow} (M, I')$ $\sqrt{ }$) *iff* $∀t ∈ T$: \int $\overline{\mathcal{L}}$ $I'(t) =$ $\sqrt{ }$ J \mathcal{L} $I(t)$ if $t \in$ Enabled(M) and $t \in$ Inhibited(M) $\mathcal{T}I'(t) = \max(0, \mathcal{T}I(t) - \delta), \text{ and } I'(t)\mathcal{T} = I'(t)\mathcal{T} - \delta \text{ otherwise}$ $M \geq \bullet(t) \implies I'(t)^{\uparrow} \geq 0$

– the discrete transition relation, defined $\forall t_f \in T$ by: $(M, I) \stackrel{t_f}{\rightarrow} (M', I')$ iff $\sqrt{ }$ \int $\overline{\mathcal{L}}$ $t_f \in Enabel(M) \wedge t_f \notin Inhibited(M) \wedge M' = M - \cdot t_f + t_f^{\bullet} \wedge \overline{t}I(t_f) = 0$ $\forall t \in T, I'(t) =$ $\sqrt{ }$ J \mathcal{L} $J(t)$ if NewlyEnabled (t, M, t_f) $I(t)$ otherwise

The symbolic semantics of PITPNs is given in [\[2\]](#page-24-2) as a transition system $(N^P \times \mathcal{L}(\Lambda), (M_0, K_0), \Rightarrow)$ on state classes, i.e., pairs $c = (M, D)$ consisting of a marking M and a constraint D over Λ. The firing of a transition leads to a new marking as in the concrete semantics, and also captures the new constraints induced by the time that has passed for the transition to fire. For example, for the PITPN in Fig. [1a,](#page-3-0) the initial class is $(\{A, B\}, \lambda_1^- \leq \lambda_1^+ \wedge \lambda_2^- \leq \lambda_2^+ \wedge \lambda_3^- \leq \lambda_3^+).$ When firing transition t_1 , the time spent for t_1 to be firable is such that the other transitions $(t_3$ in this case) do not miss their deadlines. So we obtain an additional inequality $\lambda_1^- \leq \lambda_3^+$ and the new state class, obtained after firing t_1 is $(\{C, B\}, \lambda_1^- \leq \lambda_1^+ \wedge \lambda_2^- \leq \lambda_2^+ \wedge \lambda_3^- \leq \lambda_3^+ \wedge \lambda_1^- \leq \lambda_3^+)$. See [\[2\]](#page-24-2) for details.

2.2 Rewriting with SMT and Maude

Rewrite Theories. A rewrite theory [\[28\]](#page-25-5) is a tuple $\mathcal{R} = (\Sigma, E, L, R)$ such that

- Σ is a signature that declares sorts, subsorts, and function symbols;
- E is a set of equations of the form $t = t'$ if ψ , where t and t' are terms of the same sort, and ψ is a conjunction of equations;
- L is a set of *labels*; and
- R is a set of rewrite rules of the form $l : q \longrightarrow r$ if ψ , where $l \in L$ is a label, q and r are terms of the same sort, and ψ is a conjunction of equations.

 $T_{\Sigma,s}$ denotes the set of ground (*i.e.*, not containing variables) terms of sort s, and $T_{\Sigma}(X)$ _s the set of terms of sort s over a set of variables X. $T_{\Sigma}(X)$ and T_{Σ} denote all terms and ground terms, respectively. A substitution $\sigma: X \to T_{\Sigma}(X)$ maps each variable to a term of the same sort, and to denotes the term obtained by simultaneously replacing each variable x in a term t with $\sigma(x)$. The domain of a substitution σ is $dom(\sigma) = \{x \in X \mid \sigma(x) \neq x\}$, assumed to be finite.

A one-step rewrite $t \rightarrow_{\mathcal{R}} t'$ holds if there are a rule $l : q \rightarrow r$ if ψ , a subterm u of t, and a substitution σ such that $u = q\sigma$ (modulo equations), t' is the term obtained from t by replacing u with $r\sigma$, and $v\sigma = v'\sigma$ holds for each $v = v'$ in ψ . We denote by $\longrightarrow_{\mathcal{R}}^*$ the reflexive-transitive closure of $\longrightarrow_{\mathcal{R}}$.

A rewrite theory $\mathcal R$ is called *topmost* iff there is a sort *State* at the top of one of the connected components of the subsort partial order such that for each rule $l : q \longrightarrow r$ if ψ , both q and r have the top sort *State*, and no operator has sort State or any of its subsorts as an argument sort.

Rewriting with SMT [\[45\]](#page-25-17). For a signature Σ and a set of equations E, a built-in theory \mathcal{E}_0 is a first-order theory with a signature $\Sigma_0 \subseteq \Sigma$, where (1) each sort s in Σ_0 is minimal in Σ ; (2) s $\notin \Sigma_0$ for each operator $f: s_1 \times \cdots \times s_n \to s$ in $\Sigma \setminus \Sigma_0$; and (3) f has no other subsort-overloaded typing in Σ_0 . The satisfiability of a constraint in \mathcal{E}_0 is assumed to be decidable using the SMT theory $\mathcal{T}_{\mathcal{E}_0}$ which is consistent with (\mathcal{Z}, E) , i.e., for Σ_0 -terms t_1 and t_2 , if $t_1 = t_2$ modulo E, then $\mathcal{T}_{\mathcal{E}_0} \models t_1 = t_2$.

A constrained term is a pair $\phi \parallel t$ of a constraint ϕ in \mathcal{E}_0 and a term t in $T_\Sigma(X_0)$ over variables $X_0 \subseteq X$ of the built-in sorts in \mathcal{E}_0 [\[45,](#page-25-17)[10\]](#page-24-13). A constrained term $\phi \parallel t$ symbolically represents all instances of the pattern t such that ϕ holds: $[\![\phi \parallel t]\!] = \{t' \mid t' = t\sigma \pmod{E} \text{ and } \mathcal{T}_{\mathcal{E}_0} \models \phi \sigma \text{ for ground } \sigma : X_0 \to T_{\Sigma_0}\}.$
An enterpretion of huilt ing for a Σ torm $t \in T_{\Sigma}(X)$ is a pair $(t^{\circ} \sigma^{\circ})$ of a torm $t^{\circ} \in T$.

An abstraction of built-ins for a Σ -term $t \in T_{\Sigma}(X)$ is a pair $(t^{\circ}, \sigma^{\circ})$ of a term $t^{\circ} \in T_{\Sigma \setminus \Sigma_0}(X)$ and a substitution $\sigma^{\circ}: X_0 \to T_{\Sigma_0}(X_0)$ such that $t = t^{\circ} \sigma^{\circ}$ and t° contains no duplicate variables in X_0 . Any nonvariable built-in subterms of t are replaced by distinct built-in variables in t° . $\Psi_{\sigma^{\circ}} = \bigwedge_{x \in dom(\sigma^{\circ})} x = x\sigma^{\circ}$. Let $\phi \parallel t$ be a constrained term and $(t^{\circ}, \sigma^{\circ})$ an abstraction of built-ins for t. If $dom(\sigma^{\circ}) \cap vars(\phi \parallel t) = \emptyset$, then $[\![\phi \parallel t]\!] = [\![\phi \land \Psi_{\sigma^{\circ}} \parallel t^{\circ}]\!]$ [\[45\]](#page-25-17)

Let R be a topmost theory such that for each rule $l : q \longrightarrow r$ if ψ , extra variables not occurring in the left-hand side q are in X_0 , and ψ is a constraint in a built-in theory \mathcal{E}_0 . A one-step symbolic rewrite $\phi \parallel t \leadsto_{\mathcal{R}} \phi' \parallel t'$ holds iff there exist a rule $l : q \longrightarrow r$ if ψ and a substitution $\sigma : X \longrightarrow T_{\Sigma}(X_0)$ such that (1) $t = q\sigma$ and $t' = r\sigma$ (modulo equations), (2) $\mathcal{T}_{\mathcal{E}_0} \models (\phi \land \psi \sigma) \Leftrightarrow \phi'$, and (3) ϕ' is $\mathcal{T}_{\mathcal{E}_0}$ -satisfiable. We denote by $\rightsquigarrow_{\mathcal{R}}^*$ the reflexive-transitive closure of $\rightsquigarrow_{\mathcal{R}}$.

A symbolic rewrite on constrained terms symbolically represents a (possibly infinite) set of system transitions. If $\phi_t \parallel t \rightarrow^* \phi_u \parallel u$ is a symbolic rewrite, then there exists a "concrete" rewrite $t' \rightarrow^* u'$ with $t' \in [\![\phi_t \parallel t]\!]$ and $u' \in [\![\phi_u \parallel u]\!]$. Conversely, for any concrete rewrite $t' \longrightarrow^* u'$ with $t' \in [\![\phi_t \parallel t]\!]$, there exists a symbolic rewrite ϕ_t \parallel t $\leadsto^* \phi_u \parallel u$ with $u' \in [\![\phi_u \!Vert u]\!]$.

Maude. Maude [\[16\]](#page-24-5) is a language and tool supporting the specification and analysis of rewrite theories. We summarize its syntax below:

Maude provides a number of analysis methods, including computing the normal form of a term t (command red t), simulation by rewriting (rew t) and rewriting following a given strategy (srew t using str). Basic strategies include r[σ] (apply rule r once with the optional ground substitution σ), all (apply any of the rules once), and match P s.t. C that checks whether the current term matches the pattern P subject to the constraint C. Compound strategies can be defined using concatenation $(\alpha ; \beta)$, disjunction $(\alpha | \beta)$, iteration (α *), α or-else β (execute β if α fails), normalization α ! (execute α until it cannot be further applied), etc.

Maude also offers explicit-state reachability analysis from a ground term t (search $[n,m]$ $t \Rightarrow * t'$ such that Φ) and model checking an LTL formula F (red modelCheck(t, F)). Atomic propositions in F are user-defined terms of sort Prop, and the function op _|=_ : State Prop -> Bool specifies which states satisfy a given proposition. LTL formulas are then built from state formulas, boolean connectives and the temporal logic operators \Box ("always"), \leftrightarrow ("eventually") and U ("until"). For symbolic reachability analysis, the command

smt-search $[n, m]$: $t \Rightarrow$ t' such that Φ --- n and m are optional

symbolically searches for n states, reachable from $t \in T_{\Sigma}(X_0)$ within m steps, that match the pattern $t' \in T_\Sigma(X)$ and satisfy the constraint Φ in \mathcal{E}_0 . More precisely, it searches for a constrained term $\phi_u \parallel u$ such that true $|| t \leadsto^* \phi_u || u$ and for some $\sigma : X \to T_\Sigma(X)$, $u = t' \sigma$ (modulo equations) and $\mathcal{T}_{\mathcal{E}_0} \models \phi_u \Rightarrow \Phi \sigma$.

Maude provides built-in sorts Boolean, Integer, and Real for the SMT theories of Booleans, integers, and reals. Rational constants of sort Real are written n/m (e.g., $0/1$). Maude-SE [\[51\]](#page-26-1) extends Maude with additional functionality for rewriting modulo SMT, including witness generation for smt-search. It uses two theory transformations to implement symbolic rewriting [\[45\]](#page-25-17). In essence, a rewrite rule $l : q \longrightarrow r$ if ψ is transformed into a constrained-term rule

 $l : \texttt{PHI} \parallel q^{\circ} \longrightarrow (\texttt{PHI} \text{ and } \psi \text{ and } \Psi_{\sigma^{\circ}}) \parallel r \text{ if } \texttt{smtCheck}(\texttt{PHI} \text{ and } \psi \text{ and } \Psi_{\sigma^{\circ}})$

where PHI is a Boolean variable, $(q^{\circ}, \sigma^{\circ})$ is an abstraction of built-ins for q, and smtCheck invokes the underlying SMT solver to check the satisfiability of an SMT condition. This rule is executable if the extra SMT variables in $(vars(r) \cup vars(\psi) \cup vars(\Psi_{\sigma} \circ)) \setminus vars(q^{\circ})$ are considered constants.

3 A Rewriting Logic Semantics for ITPNs

This section presents a rewriting logic semantics for (non-parametric) ITPNs, using a (non-executable) rewrite theory \mathcal{R}_0 . We provide a bisimulation relating the concrete semantics of a net N and a rewrite relation in \mathcal{R}_{0} , and discuss variants of \mathcal{R}_{0} to avoid consecutive tick steps and to enable time-bounded analysis.

3.1 Formalizing ITPNs in Maude: The Theory \mathcal{R}_0

We fix N to be the ITPN $\langle P, T, \emptyset, \bullet(.)$, $\circ(.)$, \circ , \circ , $M_0, J, true$, and show how ITPNs and markings of such nets can be represented as Maude terms.

We first define sorts for representing transition labels, places, and time values in Maude. The usual approach is to represent each transition t_i and each place p_j as a constant of sort Label and Place, respectively (e.g., ops p_1 p_2 ... p_m : -> Place [ctor]). To avoid even this simple parameterization and just use a single rewrite theory \mathcal{R}_0 to define the semantics of all ITPNs, we assume that places and transition (labels) can be represented as strings. Formally, we assume that there is an injective naming function $\eta : P \cup T \to$ String; to avoid cluttering the paper with subscripts, we usually do not mention η explicitly.

```
protecting STRING . protecting RAT .<br>sorts Label Place . --- identifiers
                        --- identifiers for transitions and places
subsorts String < Label Place . --- we use strings for simplicity
sorts Time TimeInf . --- time values
subsort Zero PosRat < Time < TimeInf
op inf : -> TimeInf [ctor] .
vars T T1 T2 : Time
eq T \leq int = true.
```
The sort TimeInf adds an "infinity" value inf to the sort Time of time values, which are the non-negative rational numbers (PosRat).

The "standard" way of formalizing Petri nets in rewriting logic (see, e.g., [\[28,](#page-25-5)[46\]](#page-25-18)) represents, e.g., a marking with two tokens in place p and three tokens in place q as the Maude term p p q q q. This is crucial to support *concurrent* firings of transitions in a net. However, since the semantics of PITPNs is an *interleaving* semantics, and to support rewriting-with-SMT-based analysis from parametric initial markings (Example [8\)](#page-18-0), we instead represent markings as maps from places to the number of tokens in that place, so that the above marking is represented by the Maude term $\eta(p)$ |->2; $\eta(q)$ |->3.

The following declarations define the sort Marking to consist of ;-separated sets of pairs $\eta(p)$ |-> n. Time intervals are represented as terms [lower : upper] where the upper bound upper, of sort TimeInf, also can be the infinity value inf. The Maude term $\eta(t)$: pre -> post inhibit *inhibit* in *interval* represents a transition $t \in T$, where pre, post, and inhibit are markings representing, respectively, \bullet (t), (t), \bullet , \circ (t); and interval represents the interval $J(t)$. A Net is represented as a ;-separated set of such transitions (lines $11-12$:

```
sort Marking . --- Markings
op empty : -> Marking [ctor] .
op _|->_ : Place Nat -> Marking [ctor] .
op _;_ : Marking Marking -> Marking [ctor assoc comm id: empty] .
sort Interval . --- Time intervals (the upper bound can be infinite)
op '[\ ]: [ : Time TimeInf -> Interval [ctor] .<br>sorts Net Transition . --- Transitions and
                            --- Transitions and nets
subsort Transition < Net .
op _':_-->_inhibit_in_ :
 Label Marking Marking Marking Interval -> Transition [ctor] .
op emptyNet : -> Net [ctor] .
op _;_ : Net Net -> Net [ctor assoc comm id: emptyNet] .
```
Example [1](#page-3-0). Assuming the obvious naming function η mapping A to "A", and so on, the net in Fig. 1 is represented as the following term of sort Net:

"t1" : $("A" |-> 1) ---> ("C" |-> 1)$ in $[5 : 6]$; "t2" : ("B" |-> 1) –-> ("D" |-> 1) inhibit ("A" |-> 1) in [3 : 4] ; "t3" : ("B" |-> 1) --> ("E" |-> 1) in [1 : 2].

We define some useful operations on markings, such as $-$ - and $-$ - \cdot :

```
vars N1 N2 : Nat . vars M M1 M2 : Marking . var P : Place .
op _+_ : Marking Marking -> Marking .
eq ((P |-> N1) ; M1) + ((P |-> N2) ; M2) = (P |-> N1 + N2) ; (M1 + M2) .
eq M1 + empty = M1.
```

```
(This definition assumes that each place in M2 appears once in M1 and M1 + M2.) The function --- on
markings is defined similarly. The following functions compare markings and check whether a transition is
active in a marking:
```

```
op _<=_ : Marking Marking -> Bool . --- Comparing markings
eq ((P |-> N1) ; M1) <= ((P |-> N2) ; M2) = N1 <= N2 and (M1 <= M2) .
eq empty \leq M2 = true.
ceq M1 \leq empty = false if M1 =/= empty.
op active : Marking Transition -> Bool . --- Active transition
eq active(M, L : PRE --> POST inhibit INHIBIT in INTERVAL) =
      (PRE <= M) and not inhibited(M, INHIBIT) .
```

```
op inhibited : Marking Marking -> Bool . --- Inhibited transition
eq inhibited(M, empty) = false
eq inhibited((P \mid -> N2); M, (P \mid -> N); INHIBIT) =
      ((N > 0) and (N2 \ge N)) or inhibited(M, INHIBIT).
```
Dynamics. We define the dynamics of ITPNs as a Maude "interpreter" for such nets. The concrete ITPN semantics in [\[47\]](#page-25-1) dynamically adjusts the "time intervals" of non-inhibited transitions when time elapses. Unfortunately, the definitions in [\[47\]](#page-25-1) seem slightly contradictory: On the one hand, time interval end-points should be non-negative, and only enabled transitions have intervals in the states; on the other hand, the definition of time and discrete transitions in [\[47\]](#page-25-1) mentions $\forall t \in T, I'(t) = ...$ and $M \geq (t) \implies I'(t)^{\uparrow} \geq 0$, which seems superfluous if all end-points are non-negative. Taking the definition of time and transition steps in [\[47\]](#page-25-1) (our Definition [2\)](#page-3-1) leads us to time intervals where the right end-points of disabled transitions could have negative values. This has some disadvantages: (i) "time values" can be negative numbers; (ii) we have counterintuitive "intervals" $[0, -r]$ where the right end-point is smaller than the left end-point; (iii) the reachable "state spaces" (in suitable discretizations) could be infinite when these negative values could be unbounded.

To avoid these "inconsistencies", and to have a simple and well-defined semantics, we use "clocks" instead of "decreasing intervals"; a clock denotes how long the corresponding transition has been enabled (but not inhibited). Furthermore, to reduce the state space, the clocks of disabled transitions are always zero. The resulting semantics is equivalent to the (most natural interpretation of the) one in [\[47\]](#page-25-1) in a way made precise in Theorem [1.](#page-9-0)

The sort ClockValues denotes sets of ;-separated terms $\eta(t) \rightarrow \tau$, where t is the (label of the) transition and τ represents the current value of t's "clock."

```
sort ClockValues . --- Values for clocks
op empty : -> ClockValues [ctor] .
op _->_ : Label Time -> ClockValues [ctor] .
op _;_ : ClockValues ClockValues -> ClockValues [ctor assoc comm id: empty] .
```
The states in \mathcal{R}_0 are terms m : clocks : net of sort State, where m represents the current marking, clocks the current values of the transition clocks, and net the representation of the Petri net:

sort State op _:_:_ : Marking ClockValues Net -> State [ctor] .

The following rewrite rule models the application of a transition L in the net (L : PRE –-> POST inhibit INHIBIT in INTERVAL) ; NET'. Since $\frac{1}{1}$ is declared to be associative and commutative, any transition L in the net can be applied using this rewrite rule:

```
crl [applyTransition] :
     M : (L -> T) ; CLOCKS :
     (L : PRE –-> POST inhibit INHIBIT in INTERVAL) ; NET
\Rightarrow (M - PRE) + POST:
     L -> 0 ; updateClocks(CLOCKS, M - PRE, NET) :
     (L : PRE –-> POST inhibit INHIBIT in INTERVAL) ; NET'
if active(M, L : PRE –-> POST inhibit INHIBIT in INTERVAL)
    and (T in INTERVAL) .
op _in_ : Time Interval -> Bool .
eq T in [T1 : T2] = (T1 \le T) and (T \le T2).
eq T in [T1 : inf] = T1 \le T.
```
The transition L is active (enabled and not inhibited) in the marking M and its clock value T is in the INTERVAL. After performing the transition, the marking is $(M - PRE) + POST$, the clock of L is reset^{[5](#page-7-0)} and the other clocks are updated using the following function:

eq updateClocks($(L' \rightarrow T')$; CLOCKS, INTERM-M, (L' : PRE –-> POST inhibit INHIBIT in INTERVAL) ; NET)

⁵ Since in our semantics clocks of disabled transitions should be zero, we can safely set L to 0 in this rule.

```
= if PRE <= INTERM-M then (L' \rightarrow T') else (L' \rightarrow 0) fi ;
   updateClocks(CLOCKS, INTERM-M, NET) .
eq updateClocks(empty, INTERM-M, NET) = empty .
```
The second rewrite rule in \mathcal{R}_{0} specifies how time advances. Time can advance by any value T, as long as time does not advance beyond the time when an active transition must be taken. The clocks are updated according to the elapsed time T, except for those transitions that are disabled or inhibited:

crl [tick] : M : CLOCKS : NET => M : increaseClocks(M, CLOCKS, NET, T) : NET if T <= mte(M, CLOCKS, NET) [nonexec] .

This rule is not executable ([nonexec]), since the variable T, which denotes how much time advances, only occurs in the right-hand side of the rule. T is therefore not assigned any value by the substitution matching the rule with the state being rewritten. This time advance T must be less or equal to the minimum of the upper bounds of the enabled transitions in the marking M:

```
op mte : Marking ClockValues Net -> TimeInf .
eq mte(M, (L \rightarrow T); CLOCKS, (L : PRE \rightarrow POST \dots in [T1 : inf]); NET)
= mte(M, CLOCKS, NET).
eq mte(M, (L \rightarrow T); CLOCKS, (L : PRE \rightarrow ... \text{ in } [T1 : T2]); NET)
 = if active(M, L : ...) then min(T2 - T, mte(M, CLOCKS, NET))
   else mte(M, CLOCKS, NET) fi .
eq mte(M, empty, NET) = inf.
```
The function increaseClocks increases the transitions clocks according to the elapsed time, except for those transitions that are disabled or inhibited:

```
op increaseClocks : Marking ClockValues Net Time -> ClockValues .
eq increaseClocks(M, (L \rightarrow T1); CLOCKS, (L : PRE -- > ...); NET, T)
 = if active(M, L : PRE --> ...)
   then (L \rightarrow T1 + T) else (L \rightarrow T1) fi ; increaseClocks(M, CLOCKS, NET, T).
eq increaseClocks(M, empty, NET, T) = empty .
```
The following function $[\![\]\!]_{\mathcal{R}_0}$ formalizes how markings and nets are represented as terms, of respective sorts Marking and Net, in rewriting logic.^{[6](#page-8-0)}

Definition 3. Let $\mathcal{N} = \langle P, T, \emptyset, \bullet(.), (.) \bullet, \circ(.), M_0, J, true \rangle$ be an ITPN. Then $[\![\;]\!]_{\mathcal{R}_0} : \mathbb{N}^P \to \mathcal{T}_{\mathcal{R}_0, \text{Marking}}$ is defined by $\llbracket \{p_1 \mapsto n_1, \ldots, p_m \mapsto n_m\} \rrbracket_{\mathcal{R}_0} = \eta(p_1)$ |-> n_1 ; ...; $\eta(p_m)$ |-> n_m , where we can omit entries $\eta(p_j)$ |->0. The Maude representation $[\![\mathcal{N}]\!]_{\mathcal{R}_0}$ of the net $\mathcal N$ is the term $[\![t_1]\!]_{\mathcal{R}_0}$; \cdots ; $[\![t_n]\!]_{\mathcal{R}_0}$ of sort Net, where, for each $t_i \in T$, $\llbracket t_i \rrbracket_{\mathcal{R}_0}$ is $\eta(t_i) : [\! [\mathbf{``}(t_i)]\!]_{\mathcal{R}_0} \ \dashrightarrow \ [\! [(t_i) \mathbf{``}]\!]_{\mathcal{R}_0} \ \ \textit{inhibit} \ \ [\! [\! \degree(t_i)]\!]_{\mathcal{R}_0} \ \ \textit{in} \ \ \Gamma \cdot \textit{J}(t_i) \ : \ \textit{J}(t_i) \, \urcorner \, \textit{J}$

3.2 Correctness of the Semantics

In this section we show that our rewriting logic semantics \mathcal{R}_0 correctly simulates any ITPN N. More concretely, we provide a bisimulation result relating behaviors from $a_0 = (M_0, J)$ in N with behaviors in \mathcal{R}_0 starting from the initial state $[\![M_0]\!]_{\mathcal{R}_0}$: $\mathrm{initClocks}([\![\mathcal{N}]\!]_{\mathcal{R}_0},$ $\mathrm{where}\ \mathrm{initClocks}(\mathit{net})$ is the clock valuation that assigns the value 0 to each transition (clock) $\eta(t)$ for each transition (label) $\eta(t)$ in net.

Since a transition in $\mathcal N$ consists of a delay followed by a discrete transition, we define a corresponding rewrite relation \mapsto combining the tick and applyTransition rules, and prove the bisimulation for this relation.

Definition 4. Let t_1, t_2, t_3 be terms of sort **State** in \mathcal{R}_0 . We write $t_1 \mapsto t_3$ if there exists a t_2 such that $t_1 \longrightarrow t_2$ is a one-step rewrite applying the **tick** rule in \mathcal{R}_0 and $t_2 \longrightarrow t_3$ is a one-step rewrite applying the applyTransition rule in \mathcal{R}_0 . Furthermore, we write $t_1 \mapsto * t_2$ to indicate that there exists a sequence of \mapsto rewrites from t_1 to t_2 .

 $\int_{0}^{6} \llbracket \cdot \rrbracket_{\mathcal{R}_{0}}$ is parametrized by the naming function η ; however, we do not show this parameter explicitly.

The following relation relates our clock-based states with the changing-interval-based states; the correspondence is a straightforward function, except for the case when the upper bound of a transition is ∞ :

Definition 5. Let $\mathcal{N} = \langle P, T, \emptyset, \bullet(.), (.) \bullet, \circ(.), M_0, J, true \rangle$ be an ITPN and $\mathcal{S}_{\mathcal{N}} = (\mathcal{A}, a_0, \to)$ be its concrete semantics. Let $T_{\Sigma, State}$ denote the set of E-equivalence classes of ground terms of sort State in \mathcal{R}_0 . We define a relation $\approx \subseteq A \times T_{\Sigma, state}$, relating states in the concrete semantics of N to states (of sort State) in \mathcal{R}_0 , where for all states $(M, I) \in \mathcal{A}$, $(M, I) \approx m$: clocks : net if and only if $m = M\|_{\mathcal{R}_0}$ and net $= M\|_{\mathcal{R}_0}$ and for each transition $t \in T$,

– the value of $\eta(t)$ in clocks is 0 if t in not enabled in M;

```
– otherwise:
```
- if $J(t)^{\uparrow} \neq \infty$ then the value of clock $\eta(t)$ in clocks is $J(t)^{\uparrow} I(t)^{\uparrow}$;
- otherwise, if $\hat{I}(t) > 0$ then $\eta(t)$ has the value $\hat{I}(t) \hat{I}(t)$ in clocks; otherwise, the value of $\eta(t)$ in clocks could be any value $\tau \geq \hat{f}(t)$.

Theorem 1. Let $\mathcal{N} = \langle P, T, \emptyset, \bullet(.), (.) \bullet, \circ(.), M_0, J, true \rangle$ be an ITPN, and $\mathcal{R}_0 = (\Sigma, E, L, R)$. Then, \approx is a bisimulation between the transition systems $\mathcal{S}_{\mathcal{N}}=(\mathcal{A},a_0,\to)$ and $(T_{\Sigma,State},(\llbracket M_0 \rrbracket_{\mathcal{R}_0}:\, \text{initClocks}(\llbracket \mathcal{N} \rrbracket_{\mathcal{R}_0}), \mapsto)$.

3.3 Some Variations of \mathcal{R}_0

This section introduces the theories \mathcal{R}_1 and \mathcal{R}_2 , two variations of \mathcal{R}_0 to reduce the reachable state space (in symbolic analyses) and to enable time-bounded analysis. \mathcal{R}_1 avoids consecutive application of the tick rule. This is useful for *symbolic* analysis since in concrete executions of \mathcal{R}_1 , a tick rule application may not advance time far enough for a transition to become enabled, leading to a deadlock. \mathcal{R}_2 adds a "global clock", denoting how much time has elapsed in the system. (In \mathcal{R}_{0} such a global clock can also be encoded by the clock of a "new" transition which is never enabled). This allows for analyzing time-bounded properties (can a certain state be reached in a certain time interval?).

The Theory \mathcal{R}_1 . To avoid consecutive tick rule applications, we can add a new component—whose value is either tickOk or tickNotOk—to the global state. The tick rule can only be applied when this new component of the global state has the value tickOk. We therefore add a new constructor _:_:_:_ for these extended global states, a new sort TickState with values tickOk and tickNotOk, and modify (or add) the two rewrite rules below:

```
sort TickState .
ops tickOk tickNotOk : -> TickState [ctor] .
op _:_:_:_ : TickState Marking ClockValues Net -> State [ctor] .
var TS : TickState .
crl [applyTransition] :
TS : M : ((L -> T) ; CLOCKS) : (L : PRE --> ...) ; NET) =>
tickOk : ((M - PRE) + POST) : ... if active(...) and (T \text{ in INTERVAL}).
crl [tick] : tickOk : M : ... => tickNotOk : M : increaseClocks(...) ...
if T <= mte(M, CLOCKS, NET) [nonexec] .
```

```
Theorem 2. Let t = m : clocks : net be a term of sort State in \mathcal{R}_0. Then,
     t\longrightarrow_{\mathcal{R}_{\mathbf{0}}}^* m' : clocks' : net iff
tickOk : m: clocks: net \longrightarrow_{\mathcal{R}_1}^*tickNotOk : m': clocks': net.
```
Although reachability is preserved, an "arbitrary" application of the tick rule in \mathcal{R}_1 , where time does not advance far enough for a transition to be taken, could lead to a deadlock in \mathcal{R}_1 but not in \mathcal{R}_0 .

The Theory \mathcal{R}_2 . To answer questions such as whether a certain state can be reached in a certain time interval, and to enable time-bounded analysis where behaviors beyond the time bound are not explored, we add a new component, denoting the "global time," to the global state:

op _:_:_:_@_ : TickState Marking ClockValues Net Time -> State [ctor] .

The tick and applyTransition rules are modified as expected. For instance, the rule tick becomes:

crl [tick] : tickOk : M : CLOCKS : NET @ GT => tickNotOk : M : increaseClocks(..., T) : NET @ GT + T if $T \leq m \times (M, CLOCKS, NET)$ [nonexec].

where GT is a variable of sort Time. For a time bound Δ , we can add a conjunct GT+T $\leq \Delta$ in the condition of this rule to stop executing beyond the time bound.

Let t and t' be terms of sort State in \mathcal{R}_0 . We say that t' is reached in time d from t, written $t \stackrel{d}{\longrightarrow}_{\mathcal{R}}^*$ $\mathcal{R}_{\mathbf{0}}$ t', if $t \rightarrow_{\mathcal{R}_0}^* t'$ and d is the sum of the values taken by the variable T in the different applications of the rule tick in such a trace.

Theorem 3. Let $t = m$: clocks : net be a term of sort State in \mathcal{R}_0 . Then, $t \stackrel{d}{\longrightarrow}_{\mathcal{R}_0} m'$: clocks' : net iff tickOk : $m: clocks: net \ \text{\O} \longrightarrow_{\mathcal{R}_2}^*$ tickNotOk : $m': clocks': net \ \text{\O} \ d.$

4 Explicit-state Analysis of ITPNs in Maude

The theories $\mathcal{R}_0-\mathcal{R}_2$ cannot be directly executed in Maude, since the tick rule introduces a new variable T in its right-hand side. Following the Real-Time Maude [\[40,](#page-25-7)[39\]](#page-25-16) methodology for analyzing dense-time systems, although we cannot cover all time points, we can choose to "sample" system execution at some time points. For example, in this section we change the **tick** rule to increase time by one time unit in each application:

crl [tickOne] : M : CLOCKS : NET => M : increaseClocks(M, CLOCKS, NET, 1) : NET if $1 \leq m \neq (M, CLOCKS, NET)$.

Analysis with such time sampling is in general not sound and complete, since it does not cover all possible system behaviors: for example, if some transition's firing interval is [0.5, 0.6], we could not execute that transition with this time sampling. Nevertheless, if all interval bounds are natural numbers, then "all behaviors" should be covered.

We can therefore quickly prototype our specification and experiment with different parameter values, before applying the sound and complete symbolic analysis and parameter synthesis methods developed in the following sections.

The term $\texttt{net3}(a, b)$ represents (a more general version of) the net in Fig. [2,](#page-14-0) where a and b are the lower and upper bounds of the interval for transition t_3 :

```
op net3 : Time TimeInf -> Net .
var LOWER : Time . var UPPER : TimeInf .
eq net3(LOWER, UPPER)
= "t1" : "p5" |-> 1 --> "p1" |-> 1 in [2 : 6] ;
   "t2" : "p1" |-> 1 --> "p2" |-> 1 ; "p5" |-> 1 in [2 : 4] ;
   "t3" : "p2" |-> 1 ; "p4" |-> 1 --> "p3" |-> 1 in [LOWER : UPPER] ;
   "t4" : "p3" |-> 1 --> "p4" |-> 1 in [0 : 0] .
```
The initial marking in Fig. [2](#page-14-0) is represented by the term init3:

op init3 : -> Marking . eq init3 = "p1" $\vert ->0$; "p2" $\vert ->0$; "p3" $\vert ->0$; "p4" $\vert ->1$; "p5" $\vert ->1$.

We can simulate 2000 steps of the net with different parameter values:^{[7](#page-10-1)}

Maude> rew [2000] $init3$: $initClocks(net3(3,5))$: $net3(3,5)$.

⁷ Parts of Maude code and output from Maude executions will be replaced by '...' throughout the paper.

result State: "p1" |-> 0; "p2" |-> 1; "p3" |-> 0; "p4" |-> 1; "p5" |-> 1: ... : ...

To further analyze the system, we define a function **k**-safe, where **k**-safe (n, m) holds iff the marking m does not have any place with more than n tokens:

```
op k-safe : Nat Marking -> Bool .
var M : Marking . vars N N1 N2 : Nat . var P : Place .
eq k-safe(N, empty) = true.
eq k-safe(N1, P |->N2; M) = N2 <= N1 and k-safe(N1, M).
```
We can then quickly (in 5ms) check whether the net is 1-safe when transition t_3 has interval [3, 4]:

```
Maude> search [1] init3 : initClocks(net3(3,4)) : net3(3,4) =>*
                 M : CLOCKS : NET such that not k-safe(1, M).
```

```
Solution 1 (state 27)
M --> "p1" |-> 0 ; "p2" |-> 2 ; "p3" |-> 0 ; "p4" |-> 1 ; "p5" |-> 1
CLOCKS --> "t1" -> 0; "t2" -> 0; "t3" -> 4; "t4" -> 0
NET \leftarrow > \cdots
```
The net is not 1-safe: we reached a state with two tokens in place p_2 . However, the net is 1-safe if t_3 's interval is instead $[2, 3]$:

```
Maude> search [1] init3 : initClocks(net3(2,3)) : net3(2,3) =>*
                  M : CLOCKS : NET such that not k-safe(1, M).
```
No solution.

Further analysis shows that $net3(3,4)$ is 2-safe, but that $net3(3,5)$ is not even 1000-safe.

We can also analyze concrete instantiations of our net by full linear temporal logic (LTL) model checking in Maude. For example, we can define a parametric atomic proposition place p has n tokens, which holds in a state iff its marking has exactly n tokens in place p :

op place_has_tokens : Place Nat -> Prop [ctor] . eq $(P \mid -\ge N1)$; M : CLOCKS : NET) $\mid =$ place P has N2 tokens = $(N1 == N2)$.

Then we can check properties such as whether in each behavior of the system, there will be infinitely many states where p_3 has no tokens and infinitely many states where it holds one token:^{[8](#page-11-0)}

```
Maude> red modelCheck(init3 : initClocks(net3(3,4)) : net3(3,4),
         ([] \Diamond place "p3" has 0 tokens) / ([] \Diamond place "p3" has 1 tokens)).
```
result Bool: true

We know that $net3(3,4)$ can reach markings with two tokens in p_2 ; but is this inevitable (i.e., does it happen in *all* behaviors)?

```
Maude> red modelCheck(init3 : initClocks(net3(3,4)) : net3(3,4),
                         \leftrightarrow place "p2" has 2 tokens).
```
result ModelCheckResult: counterexample(...)

The result is a counterexample showing a path where p_2 never holds two tokens.

We also obtain a "time sampling" specification corresponding to \mathcal{R}_3 by adding a global time component to the state:

⁸ $[1, \diamond, \wedge]$, and \sim are the Maude representations of corresponding (temporal) logic operators \Box ("always"), \diamond ("eventually"), conjunction, and negation.

op _:_:_@_ : Marking ClockValues Net Time -> State [ctor] .

and modifying the tick rule to increase this global clock according to the elapsed time. Furthermore, for time-bounded analysis we add a constraint ensuring that system execution does not go beyond the time bound Δ :

```
crl [executableTick] :
    M : CLOCKS : NET @ GT => M : increaseClocks(M, CLOCKS, NET, 1) : NET @ GT + 1
    if GT < \Delta and --- remove this condition for unbounded analysis
        1 \leq m \text{te}(M, FT, NET).
```
By setting Δ to 1000, we can simulate one behavior of the system net 3(3,5) up to time 1000:

```
Maude> rew init3 : initClocks(net3(3,5)) : net3(3,5) \theta 0.
result State:
"p1" |-> 0 ; "p2" |-> 1 ; "p3" |-> 0 ; "p4" |-> 1 ; "p5" |-> 1 : ... : ... @ 1000
```
We can then check whether $net3(3,4)$ is one-safe in the time interval [5, 10] by setting Δ in the tick rule to 10, and execute following command:

```
Maude> search [1] init3: initClocks(net3(3,4)): net3(3,4) 0 0 =>*
            M : CLOCKS : NET @ GT such that not k-safe(1, M) and GT >= 5.
Solution 1 (state 68)
MARKING --> "p1" |-> 0 ; "p2" |-> 2 ; "p3" |-> 0 ; "p4" |-> 1 ; "p5" |-> 1
...
```
 $GT \rightarrow > 8$

This shows that the non-one-safe marking can be reached in eight time units.

5 Parameters and Symbolic Executions

Standard explicit-state Maude analysis of the theories $\mathcal{R}_0-\mathcal{R}_2$ cannot be used to analyze all possible behaviors of PITPNs for two reasons: (1) The rule tick introduces a new variable T in its right-hand side, reflecting the fact that time can advance by any value $T \leq \text{mte}(\ldots)$; and (2) analyzing parametric nets with uninitialized parameters is impossible with explicit-state Maude analysis of concrete states. (For example, the condition T in INTERVAL in rule applyTransition will never evaluate to true if INTERVAL is not a concrete interval, and hence the rule will never be applied.)

Maude-SE analysis of *symbolic* states with SMT variables can solve both issues, by symbolically representing the time advances T and the net's uninitialized parameters. This enables analysis and parameter synthesis methods for analyzing all possible behaviors in dense-time systems with unknown parameters.

This section defines a rewrite theory $\mathcal{R}_1^{\mathbf{S}}$ that faithfully models PITPNs and that can be symbolically executed using Maude-SE. We prove that (concrete) executions in \mathcal{R}_1 are captured by (symbolic) executions in \mathcal{R}_1^S , and vice versa. We also show that standard folding techniques [\[30\]](#page-25-19) in rewriting modulo SMT are not sufficient for collapsing equivalent symbolic states in $\mathcal{R}_1^{\mathbf{S}}$. We therefore propose a new folding technique that guarantees termination of the reachability analyses of \mathcal{R}_1^S when the state-class graph of the encoded PITPN is finite.

5.1 The Symbolic Rewriting Logic Semantics

We define the "symbolic" semantics of PITPNs using the rewrite theory $\mathcal{R}_1^{\mathbf{S}}$, which is the symbolic counterpart of \mathcal{R}_1 , instead of basing it on \mathcal{R}_0 , since a symbolic "tick" step represents all possible tick steps from a symbolic state. We therefore do not introduce deadlocks not possible in the corresponding PITPN.

 $\mathcal{R}_1^{\bf S}$ is obtained from \mathcal{R}_1 by replacing the sort Nat in markings and the sort PosRat for clock values with the corresponding SMT sorts Integer and Real. (The former is only needed to enable reasoning with symbolic initial states where the number of tokens in a location is unknown). Moreover, conditions in rules (e.g., $M1 \leq$ <code>M2</code>) are replaced with the corresponding SMT expressions of sort Boolean. The symbolic execution of $\mathcal{R}^{\bf S}_1$ in Maude-SE will accumulate and check the satisfiability of the constraints needed for a parametric transition to happen.

We start by declaring the sort Time as follows:

```
sorts Time TimeInf . subsort Real < Time < TimeInf .
op inf : -> TimeInf [ctor] .
```
where Real is the sort for SMT reals. (We add constraints to the rewrite rules to guarantee that only non-negative real numbers are considered as time values.)

Intervals are defined as in \mathcal{R}_0 : op '[_:_'] : Time TimeInf -> Interval. Since Real is a subsort of Time, an interval in $\mathcal{R}_1^{\mathbf{S}}$ may contain SMT variables. This means that a parametric interval $[a, b]$ in a PITPN can be represented as the term [a:Real : b:Real], where a and b are variables of sort Real.

The definition of markings, nets, and clock values is similar to the one in Section [3.1.](#page-5-1) We only need to adjust the following definition for markings:

op _|->_ : Place Integer -> Marking [ctor] .

Hence, in a pair $\eta(p)$ |-> e_I , e_I is an SMT integer expression that could be/include SMT variable(s).

Operations on markings and intervals remain the same, albeit with the appropriate SMT sorts. Since the operators in Maude for Nat and Rat have the same signature that those for Integer and Real, the specification needs few adjustments. For instance, the new definition of $M1 \leq M2$ is:

```
vars N1 N2 : Integer .
op _<=_ : Marking Marking -> Boolean .
eq ((P |-> N1) ; M1) <= ((P |-> N2) ; M2) = N1 <= N2 and (M1 <= M2) .
eq empty \leq M2 = true.
where \leq in N1 \leq N2 is a function op \leq = \leq : Integer Integer -> Boolean.
```
Symbolic states in $\mathcal{R}_1^{\mathbf{S}}$ are defined as follows:

```
sort State. op _:_:_:_ : TickState Marking ClockValues Net -> State [ctor]
```
The rewrite rules in $\mathcal{R}_1^{\mathbf{S}}$ act on symbolic states that may contain SMT variables. Although these rules are similar to those in \mathcal{R}_1 , their symbolic execution is completely different. Recall from Section [2](#page-2-0) that Maude-SE defines a theory transformation to implement symbolic rewriting. In the resulting theory \mathcal{R}_1^S , when a rule is applied, the variables occurring in the right-hand side but not in the left-hand side are replaced by fresh variables. Moreover, rules in $\mathcal{R}_1^{\mathbf{S}}$ act on constrained terms of the form $\phi \parallel t$, where t in this case is a term of sort State and ϕ is a satisfiable SMT boolean expression. The constraint ϕ is obtained by accumulating the conditions in rules, thereby restricting the possible values of the variables in t.

The tick rewrite rule in $\mathcal{R}_1^{\mathbf{S}}$ is

```
crl [tick] : tickOk : M : CLOCKS : NET
         => tickNotOk : M : increaseClocks(M, CLOCKS, NET, T) : NET
if (T \ge 0/1 and mte(M, CLOCKS, NET, T).
```
The variable T is restricted to be a non-negative real number and to satisfy the following *predicate* mute, which gathers the constraints to ensure that time cannot advance beyond the point in time when an enabled transition must fire:

```
op mte : Marking ClockValues Net Real -> Boolean .
eq mte(M, empty, NET, T) = true.
eq mte(M, (L -> R1) ; CLOCKS, (L : PRE --> ... in [T1 : inf]) ; NET , T)
= mte(M, CLOCKS, NET, T).
eq mte(M, (L \rightarrow R1); CLOCKS, (L : PRE \rightarrow ... \text{ in } [T1 : T2]); NET, T)
 = active(M, L : ...) ? T <= T2 - R1 : true) and mte(M, CLOCKS, NET, T) .
```
This means that, for every transition L, if the upper bound of the interval in L is inf, no restriction on T is added. Otherwise, if L is active at marking M, the SMT ternary operator C ? E1 : E2 (checking C to choose either E1 or E2) further constrains T to be less than T2 - R1. The definition of increaseClocks also uses this SMT operator to represent the new values of the clocks:

```
eq increaseClocks(M, (L \rightarrow R1); CLOCKS, (L : PRE -- > ... ); NET, T)
  (L -> (active(M, L : PRE ...)) ? R1 + T : R1 ));
   increaseClocks(M, CLOCKS, NET, T) .
```
The rule for applying a transition is defined as follows:

```
crl [applyTransition] :
    TS : M : ((L -> T) ; ClOCKS) : (L : PRE -> ...) ; NET)\Rightarrow tickOk : ((M - PRE) + POST) : updateClocks(...) :
    (L : PRE -- > ... ; NET) if active(...) and (T in INTERVAL).
```
When applied, this rule adds new constraints asserting that the transition L can be fired (predicates active and _in_) and updates the state of the clocks:

```
eq updateClocks((L' -> R1) ; CLOCKS, INTERM-M, (L': PRE --> ...); MET)= (L -> PRE <= INTERM-M ? R1 : 0/1) ; updateClocks(...) .
```

Fig. 2: A simple production-consumption system taken from [\[50\]](#page-26-2).

In the following, $k\text{-safe}(k,m)$ is a predicate stating that the marking m does not have more than k tokens in any place.

Example 2. Let net and m_0 be the Maude terms representing, respectively, the PITPN and the initial marking shown in Fig. [2.](#page-14-0) The term net includes a variable $a:Real$ representing the parameter a. The following command

```
smt-ssearch tickOk : m_0 : initClocks(net) : net =>* TICK : M : CLOCKS : NET
  such that (a:Real >= 0/1 and not k-safe(1, M)) = true
```
answers the question whether it is possible to reach a state with a marking M with more than one token in some place. Maude positively answers this question and the resulting accumulated constraint tells us that such a state is reachable (with 2 tokens in p_2) if a:Real >= 4/1.

Terms of sort Marking in $\mathcal{R}_1^{\mathbf{S}}$ may contain expressions with parameters (i.e., variables) of sort Integer. Let Λ_m denote the set of such parameters and $\pi_m : \Lambda_M \to \mathbb{N}$ a valuation function for them. We use m_s to denote a mapping from places to Integer expressions including parameter variables. Similarly, clocks_s denotes a mapping from transitions to Real expressions (including variables). We write $\pi_m(m_s)$ to denote the ground term where the parameters in markings are replaced by the corresponding values $\pi_m(\lambda_i)$. Similarly for $\pi(clocks_s)$. We use $[\![\mathcal{N}]\!]_{\mathcal{R}^{\mathbf{S}}_1}$ to denotes the above rewriting logic representation of nets in $\mathcal{R}^{\mathbf{S}}_1$.

Let t_s be a term of sort State in \mathcal{R}_1^S and assume that $\phi \parallel t_s \leadsto_{\mathcal{R}_1^S} \phi' \parallel t_s'$. By construction, if for all $t \in \llbracket \phi \rrbracket$ ts] all markings (sort Integer), clocks and parameters (sort Real) are non-negative numbers, then this is also the case for all $t' \in [\![\phi' \parallel t'_{s}]\!]$. Note that there is a one-to-one correspondence for ground terms in $\mathcal{R}_1^{\bf S}$ (sorts <code>Marking, ClockValues,</code> etc) satisfying that condition with (ground) terms in $\mathcal{R}_1.$ We use $t \approx \in [\![\phi\!] \mid t_s]\!]$ to denote that there exists a $\mathcal{R}_1^{\mathbf{S}}$ term $t' \in [\![\phi\!] \mid t_s]\!]$ and t is its corresponding term in \mathcal{R}_1 .

The following theorem states that the symbolic semantics matches all the behaviors resulting from a concrete execution of \mathcal{R}_1 with arbitrary parameter valuations π and π_m . Furthermore, for all symbolic executions with parameters, there exists a corresponding concrete execution where the parameters are instantiated with values consistent with the resulting accumulated constraint.

Theorem 4 (Soundness and Completeness). Let N be a PITPN and m_s be a marking possibly including parameters.

(1) Let ϕ be the constraint $\bigwedge_{\lambda_i \in A} (0 \leq \lambda_i^- \leq \lambda_i^+) \wedge \bigwedge_{\lambda_i \in A_m} (0 \leq \lambda_i)$. If

 $\phi \parallel \texttt{tickOk}: m_s : clocks_s : [\![N]\!]_{\mathcal{R}_1^S} \leadsto_{\mathcal{R}_1^S}^* \phi' \parallel TS' : m'_s : clocks_s': [\![N]\!]_{\mathcal{R}_1^S}$ then, there exists π and π_m $s.t. \ \texttt{tickOk}: \pi_m(m_s) : clocks: [\![\pi(\mathcal{N})]\!]_{\mathcal{R}_0} \longrightarrow_{\mathcal{R}_1}^* TS': \pi_m(m'_s): clocks': [\![\pi(\mathcal{N})]\!]_{\mathcal{R}_0} \text{ where } \phi' \wedge \bigwedge_{\lambda_i \in \Lambda} \lambda_i =$ $\pi(\lambda_i) \wedge \bigwedge_{\lambda_i \in A_m} \lambda_i = \pi_m(\lambda_i)$ is satisfiable, clocks $\approx \in [\![\phi\!\! \mid \text{clocks}]$ and clocks' $\approx \in [\![\phi'\!] \mid \text{clocks}'_s]\!]$.

(2) Let π be a parameter valuation and π_m a parameter marking valuation. Let ϕ be the constraint $\bigwedge_{\lambda_i\in\Lambda}(\lambda_i=1)$ $\pi(\lambda_i)) \wedge \bigwedge_{\lambda_i \in \Lambda_m} (\lambda_i = \pi_m(\lambda_i)).$ If

tickOk : $\pi_m(m_s)$: clocks : $[\![\pi(\mathcal{N})]\!]_{\mathcal{R}_0} \longrightarrow_{\mathcal{R}_1}^* TS'$: m' : clocks' : $[\![\pi(\mathcal{N})]\!]_{\mathcal{R}_0},$ then

 $\phi \parallel \texttt{tickOk} : m_s : clocks_s : [\![\mathcal{N}]\!]_{\mathcal{R}_1^S} \longrightarrow^*_{\mathcal{R}_1^S} \phi' \parallel TS' : m'_s : clocks' : [\![\mathcal{N}]\!]_{\mathcal{R}_1^S} \textit{ where } m' \approx \in [\![\phi' \parallel m'_s]\!] ,$ $clocks \approx \in [\![\phi \parallel clocks_s]\!]$ and $clocks' \approx \in [\![\phi' \parallel clocks's]\!]$.

The symbolic counterpart $\mathcal{R}_2^{\mathbf{S}}$ of the theory \mathcal{R}_2 can be defined similarly.

5.2 A New Folding Method for Symbolic Reachability

Reachability analysis should terminate for both positive and negative queries for nets with finite parametric state-class graphs. However, the symbolic state space generated by smt-search is infinite even for such nets, so that smt-search will not terminate when the desired states are unreachable. The problem is that smt-search stops exploring from a symbolic state only if it has already visited the same state. Due to the fresh variables created in $\mathcal{R}_1^{\bf S}$ whenever the tick rule is applied, symbolic states representing the same set of concrete states are not the same, even though they are logically equivalent, as exemplified below.

Example 3. The following command, trying to show that the PITPN in Fig. [2](#page-14-0) is 1-safe if $0 \le a < 4$, does not terminate.

 $smt-ssearch$ tickOk : m_0 : 0-clock(net) : net =>* TICK : M : CLOCKS : NET such that (a:Real >= $0/1$ and a:Real < 4 and not M <= k-safe $(1,M)$) = true.

Furthermore, the command

 $smt-ssearch$ tickOk : m_0 : 0-clock(net) : net =>* TICK : M : CLOCKS : NET such that (a:Real >= 0/1 and a:Real < 4 and $M \le m_0$ and $m_0 \le M$) = true.

searching for reachable states where $M = m_0$ will produce infinitely many (equivalent) solutions, including, e.g., the following constraints:

```
Solution 1: #p5-9:Integer === 1 and #t3-9:Real + a:Real - #t2-9:Real <= 0/1 and ...
Solution 2: #p5-16:Integer === 1 and #t3-16:Real + a:Real - #t2-16:Real <= 0/1 and ...
```
where a variable created by smt -search starts with # and ends with a number taken from a sequence to guarantee freshness. Let $\phi_1 \parallel t_1$ and $\phi_2 \parallel t_2$ be, respectively, the constrained terms found in Solution 1 and Solution 2. In this particular output, $\phi_2 \parallel t_2$ is obtained by further rewriting $\phi_1 \parallel t_1$. The variables representing the state of markings and clocks (e.g., #p5-9 in t_1 and #p5-16 in t_2) are clearly different, although they represent the same set of concrete values ($[\![\phi_1 \parallel t_1]\!] = [\![\phi_2 \parallel t_2]\!]$). Since constrains are accumulated when a rule is applied, we note that ϕ_2 equals $\phi_1 \wedge \phi_2'$ for some ϕ_2' , and $vars(\phi_1 \parallel t_1) \subseteq vars(\phi_2 \parallel t_2)$.

The usual approach for collapsing equivalent symbolic states in rewriting modulo SMT is subsumption [\[30\]](#page-25-19). Essentially, we stop searching from a symbolic state if, during the search, we have already encountered another symbolic state that subsumes ("contains") it. More precisely, let $U = \phi_u \parallel t_u$ and $V = \phi_v \parallel t_v$ be constrained terms. Then $U \subseteq V$ if there is a substitution σ such that $t_u = t_v \sigma$ and the implication $\phi_u \Rightarrow \phi_v \sigma$ holds. In that case, $\llbracket U \rrbracket \subseteq \llbracket V \rrbracket$. A search will not further explore a constrained term U if another constrained term V with $U \subseteq V$ has already been encountered. It is known that such reachability analysis with folding is sound (does not generate spurious counterexamples [\[6\]](#page-24-14)) but not necessarily complete (since $\llbracket U \rrbracket \subseteq \llbracket V \rrbracket$ does not imply $U \sqsubseteq V$).

Example 4. Let ϕ_1 and ϕ_2 be the resulting constraints in the two solutions found by the second smt-search command in Example [3.](#page-15-0) Let σ be the substitution that maps #pi-9 to #pi-16 and #tj-9 to #tj-16 for each place p_i and transition t_j . The SMT solver determines that the formula $\neg(\phi_2 \Rightarrow \phi_1 \sigma)$ is satisfiable (and therefore $\phi_2 \Rightarrow \phi_1 \sigma$ is not valid). Hence, a procedure based on checking this implication will fail to determine that the state in the second solution can be subsumed by the state found in the first solution.

The satisfiability witnesses of $\neg(\phi_2 \Rightarrow \phi_1 \sigma)$ can give us some ideas on how to make the subsumption procedure more precise. Assume that ϕ_1 carries the information $R = T_0$ for some clock represented by R and T_0 is a tick variable subject to $\phi = (0 \le T_0 \le 2)$. Assume also that in ϕ_2 , the value of the same clock is $R' = T_1 + T_2$ subject to $\phi' = (\phi \wedge T_1 \geq 0 \wedge T_2 \geq 0 \wedge T_1 + T_2 \leq 2)$. Let $\sigma = \{R \mapsto R'\}$. Note that $(R' = T_1 + T_2 \wedge \phi \wedge \phi')$ does not imply $(R = T_0 \wedge \phi)\sigma$ (take, e.g., the valuation $T_1 = T_2 = 0.5$ and $T_0 = 2$). The key observation is that, even if R and R' are both constrained to be in the interval $[0, 2]$ (and hence represent the same state for this clock), the assignment of R' in the antecedent does not need to coincide with the one for R in the consequent of the implication.

In the following, we propose a subsumption relation that solves the aforementioned problems. Let $\phi \parallel t$ be a constrained term where t is a term of sort State. Consider the abstraction of built-ins $(t^{\circ}, \sigma^{\circ})$ for t, where t° is as t but it replaces the expression e_i in markings $(p_i \mapsto e_i)$ and clocks $(l_i \rightarrow e_i)$ with new fresh variables. The substitution σ° is defined accordingly. Let $\Psi_{\sigma^{\circ}} = \bigwedge_{x \in dom(\sigma^{\circ})} x = x\sigma^{\circ}$. We use $(\phi \parallel t) \Downarrow_{\text{now}}$ to denote the constrained term $\phi \wedge \Psi_{\sigma} \circ \| t^{\circ}$. Intuitively, $(\phi \| t) \Downarrow_{\text{now}}$ replaces the clock values and markings with fresh variables and the boolean expression $\Psi_{\sigma^{\circ}}$ constrains those variables to take the values of clocks and marking in t. From [\[45\]](#page-25-17) we can show that $[\![\phi\] \!]$ t] = $[\![(\phi\] \!]$ t) $\Downarrow_{\text{now}}]$.

Note that the only variables occurring in $(\phi \parallel t) \Downarrow_{\text{now}}$ are those for parameters (if any) and the fresh variables in $dom(\sigma^{\circ})$ (representing the symbolic state of clocks and markings). For a constrained term $\phi \parallel t$, we use $\exists (\phi \parallel t)$ to denote the formula $(\exists X)\phi$ where $X = vars(\phi) \setminus vars(t)$.

Definition 6 (Relation \preceq). Let $U = \phi_u \parallel t_u$ and $V = \phi_v \parallel t_v$ be constrained terms where t_u and t_v are terms of sort **State**. Moreover, let $U \Downarrow_{\text{now}} = \phi_u' \parallel t_u'$ and $V \Downarrow_{\text{now}} = \phi_v' \parallel t_v'$, where $\text{vars}(t_u') \cap \text{vars}(t_v') = \emptyset$. We define the relation \preceq on constrained terms so that $U \preceq V$ whenever there exists a substitution σ such that $t'_u = t'_v \sigma$ and the formula $\exists (U \Downarrow_{\textit{now}}) \Rightarrow \exists (V \Downarrow_{\textit{now}}) \sigma$ is valid.

The formula $\exists (U \Downarrow_{\text{nov}})$ hides the information about all the tick variables as well as the information about the clocks and markings in previous time instants. What we obtain is the information about the parameters and the values of the clocks and markings "now". Moreover, if t_u and t_v above are both tickOk states (or both tickNotOk states), and they represent two symbolic states of the same PITPN, then t'_u and t'_v always match $(\sigma$ being the identity on the variables representing parameters and mapping the corresponding variables created in $V \Downarrow_{\text{now}}$ and $U \Downarrow_{\text{now}}$.

Theorem 5 (Soundness and Completeness). Let U and V be constrained terms in \mathcal{R}_1^S representing two symbolic states of the same PITPN. Then, $\llbracket U \rrbracket \subseteq \llbracket V \rrbracket$ iff $U \preceq V$.

We have implemented a new symbolic reachability analysis based on the folding relation in Definition [6.](#page-16-0) Building on the theory transformation defined in Maude-SE, we transform the theory \mathcal{R}_1^S into a rewrite theory \mathcal{R}_1^{fS} that rewrites terms of the form $S: \phi \parallel t$ where S is a set of constrained terms (the already visited states). Theory \mathcal{R}_1^{fS} defines the sort SetState for ;-separated sets of constrained terms and an operator subsumed($\phi \parallel t$, S) that reduces to true iff there exists $\phi' \parallel t' \in S$ s.t $\phi \parallel t \preceq \phi' \parallel t'$. A rule $l: q \longrightarrow r$ if ψ in \mathcal{R}_1^S is transformed into the following rule in \mathcal{R}_1^{fS} .

 $l: S: \operatorname{PHI} \parallel q^{\circ} \longrightarrow (S; \phi_{r} \parallel r) : \phi_{r} \parallel r$ if smtCheck $(\phi_{r}) \wedge \operatorname{not}$ subsumed $(\phi_{r} \parallel r, S)$

where PHI is a Boolean variable, S is a variable of sort SetState, $(q^{\circ}, \sigma^{\circ})$ is an abstraction of built-ins for q and $\phi_r = (\text{PHI} \text{ and } \psi \text{ and } \Psi_{\sigma^{\circ}})$. Note that the transition happens only if the new state $\phi_r \parallel r$ is not subsumed by an already visited state in S. The theory \mathcal{R}_2^f is similarly obtained from \mathcal{R}_2^S .

In \mathcal{R}_1^{fS} , for an initial constraint ϕ on the parameters, the command

search $[n,m]$: empty: $\phi \parallel t \Rightarrow S : \phi' \parallel t'$ such that smtCheck($\phi' \land \Phi$) answers the question whether it is possible to reach a symbolic state that matches t' and satisfies the condition Φ . In the following, we use $\text{init}(net, m_0, \phi)$ to denote the term empty : $\phi \parallel \text{tick} \times m_0$: $\text{initClocks}(net)$: net.

Example 5. Consider the PITPN in Fig. [2.](#page-14-0) Let m_0 be the marking in the figure and $\phi = 0 \le a < 4$. The command

search init(net , m_0 , ϕ) =>* S : $\phi' \parallel$ (TICK : M : CLOCKS : NET) such that smtCheck $(\phi'$ and not k-safe $(1, M)$).

terminates returning No solution, showing that the net is 1-safe if $0 \le a < 4$.

The following result shows that if the set of reachable state classes in the symbolic semantics of $\mathcal N$ (see [\[2\]](#page-24-2)) is finite, then so is the set of reachable symbolic states using the new folding technique.

Corollary 1. For any PITPN N and state class (M, D) , if the transition system $(C, (M, D), \Rightarrow)$ is finite, then so is $\left(T_{\Sigma,State},init(\mathcal{N},M,D), \rightsquigarrow_{\mathcal{R}^{fs}_1} s$.

It is worth noting that the new folding relation in Def. [6](#page-16-0) and Theorem [5](#page-16-1) is applicable to any rewrite theory R that satisfies the requirements for rewriting with SMT [\[45\]](#page-25-17), briefly explained in Sec. [2.2.](#page-4-0)

6 Parameter Synthesis and Symbolic Model Checking

This section shows how Maude-SE can be used for a wide range of formal analyses beyond reachability analysis. We show how to use Maude-SE for solving parameter synthesis problems, model checking the classes of non-nested timed temporal logic properties supported by the state-of-the-art PITPN tool Roméo, reasoning with parametric initial states where the number of tokens in the different places is not known, and analyzing nets with user-defined execution strategies. We thereby provide analysis methods that go beyond those supported by Roméo, while supporting almost all forms of analysis provided by Roméo.

6.1 Parameter Synthesis

A state predicate is a boolean expression whose atomic propositions include tests on the values of markings (e.g., k-safe(1, m)) and clocks (e.g., $c_1 < c_2$). EF-synthesis is the problem of computing parameter values π such that there exists a run of $\pi(\mathcal{N})$ that reaches a state satisfying a given state predicate ϕ . The safety synthesis problem $AG\neg\phi$ is the problem of computing the parameter values for which states satisfying ϕ are unreachable.

search in the theory \mathcal{R}_1^{fS} (see Section [5.2\)](#page-15-1) provides semi-decision procedures for solving these parameter synthesis problems (which are undecidable in general). As illustrated below, the resulting constraint computed by search can be used to synthesize the parameter values that allow such execution paths. The safety synthesis problem $AG\neg\phi$ can be solved by finding all solutions for $EF\phi$ and then negating the resulting constraint.

Example 6. Example [2](#page-14-1) shows an EF-synthesis problem: find values for the parameter a such that a state with at least two tokens in *some* place can be reached. If $\phi = 0 \le a$, the command

search [1] init(net, m_0 , ϕ) =>* S : PHI' || (TICK : M : CLOCKS : NET) such that $smtCheck(PHI'$ and not $k-safe(1, M)$).

returns one solution and the resulting constraint ϕ' , instantiating the pattern PHI', can be used to extract the parameter values as follows. Let X be the set of SMT variables in ϕ' not representing parameters. A call to the quantifier elimination procedure (qe) of the SMT solver Z3 on the formula $\exists X.\phi'$ reduces to a:Real $\geq 4/1$, giving us the desired values for the parameter a.

To solve the safety synthesis problem $AG\neg\phi$, we have used Maude's meta-programming facilities [\[16\]](#page-24-5) to implement a command safety-syn(net, m_0 , ϕ_0 , ϕ) where m_0 is a marking, ϕ_0 a constraint on the parameters and ϕ a constraint involving the variables M and CLOCKS as in the search command in Example [6.](#page-17-1) This command iteratively calls search to find a state reachable from m_0 , with initial constraint ϕ_0 , where ϕ does not hold. If such state is found, with accumulated constraint ϕ' , the search command is invoked again with initial constraint $\phi_0 \wedge \neg \phi'$. This process stops when no more reachable states where ϕ does not hold are found, thus solving the $AG\neg\phi$ synthesis problem.

Example 7. Consider the PITPN in Fig. [3,](#page-21-0) taken from [\[48\]](#page-26-3), with a parameter a and three parametric transitions with intervals $[a : a]$, $[2a : 2a]$, and $[3a : 3a]$. Roméo can synthesize the values of the parameter a making the net 1-safe, subject to initial constraint $30 \le a \le 70$. The same query can be answered in Maude:

safety-syn(net, m_0 , a:Real >= 30/1 and a:Real <= 70/1, k-safe(1,M)).

The first counterexample found assumes that $a \leq 48$. If $a > 48$, search does not find any counterexample. This is the same answer that Roméo found.

Roméo only supports properties over markings. The state predicates in the commands above can include also conditions on the clock values.

Our symbolic theories allow for parameters (variables of sort Integer) in the initial marking. This opens up the possibility of using Maude-SE to solve synthesis problems involving parametric initial markings. For instance, we can determine the initial markings that make the net k-safe and/or alive:

Example 8. Consider a parametric initial marking m_s for the net in Fig. [2,](#page-14-0) with parameters x_1, x_2 , and x_3 denoting the number of tokens in places p_1 , p_2 , and p_3 , respectively, and the initial constraint ϕ_0 stating that $a \ge 0$ and $0 \le x_i \le 1$. The execution of the command safety-syn(net, m_s, ϕ_0 , k-safe(1,M)) determines that the net is 1-safe when $x_1 = x_3 = 0$ and $0 \le x_2 \le 1$.

Analysis with strategies. Maude's strategy facilities [\[15\]](#page-24-12) allow us to analyze PITPNs whose executions follow some user-defined strategy. As exemplified below, such strategies may affect the outcome of parameter synthesis analysis.

Example 9. We execute the net in Fig. [2](#page-14-0) with the following strategy $t3-first$: whenever transition t_3 and some other transition are enabled at the same time, then t_3 fires first. This execution strategy can be specified as follows:

```
t3-first := (applyTransition[L <- "t3"] or -else all)!
```
Running srew init(*net*, m_0 , $a \ge 0$) using t3-first in \mathcal{R}_1^{fS} finds all symbolic states reachable with this strategy, and all of them are 1-safe. Therefore, all parameter values $a \geq 0$ guarantee the desired property with this execution strategy.

6.2 Analyzing Temporal Properties

This section shows how Maude-SE can be used to analyze the temporal properties supported by Roméo [\[26\]](#page-25-3), albeit in a few cases without parametric bounds in the temporal formulas. Roméo can analyze the following temporal properties:

```
\mathbf{Q} \phi \mathbf{U}_J \psi \mathbf{Q} \mathbf{F}_J \phi \mathbf{Q} \mathbf{G}_J \phi \mathbf{Q} \phi \phi \phi \phi \phi
```
where $\mathbf{Q} \in \{\exists, \forall\}$ is the existential/universal path quantifier, ϕ and ψ are state predicates on markings, and J is a time interval [a, b], where a and/or b can be parameters and b can be ∞ . For example, $\forall F_{[a,b]}$ ϕ says that in each path from the initial state, a marking satisfying ϕ is reachable in some time in [a, b]. The bounded response $\phi \rightarrow \epsilon_b \psi$ denotes the formula $\forall G(\phi \implies \forall F_{[0,b]} \psi)$ (each ϕ -marking must be followed by a ψ -marking within time b).

Since queries include time bounds, we use the theory \mathcal{R}_2^{fS} , and $init(net, m_0, \phi)$ will denote the term empty : ϕ | tickOk : m_0 : initClocks(net) : net ω 0/1.

State predicates, including inequalities on markings and clocks, and also a test whether the global clock is in a given interval are defined as follows:

```
ops _>=_ _>_ _<_ _<=_ _==_ : Place Integer -> Prop .
ops \rightharpoonup = \rightharpoonup \rop in-time : Interval -> Prop .
eq S : C || (TICK : M ; (P |-> N1) : CLOCKS : NET) @ G-CLOCK |= P >= N1'
    = smtCheck(C \text{ and } N1 \geq N1'). --- similarly for >, <, < and ==
eq S : C || (TICK : M : CLOCKS : NET) @ G-CLOCK |= in-time INTERVAL
    = smtCheck(C and (G-CLOCK in INTERVAL )) .
```
Atomic propositions (sort Prop) are evaluated on symbolic states represented as constrained terms S : $\phi \parallel t$. Since they may contain variables, a call to the SMT is needed to determine whether the constraint ϕ entails the proposition.

Some of the temporal formulas supported by Roméo can be easily verified using the reachability commands presented in the previous section. The property $\exists F_{[a,b]} \psi$ can be verified using the command:

```
search [1] init(net, m_0, \phi) =>* S : PHI' \parallel TICK : M : CLOCKS : NET @ G-CLOCK
   such that STATE' |= \psi and G-CLOCK in [a : b].
```
where ϕ states that all parameters are non-negative numbers and $STATE'$ is the expression to the right of \Rightarrow *. a and b can be variables representing parameters to be synthesized; and ψ can be an expression involving CLOCKS. For example,

search [1] init (net, m_0, ϕ) =>* S' : PHI' \parallel TICK : (M ; "p1" \mid -> P1) : (CLOCKS ; "t2" -> C2) : NET @ G-CLOCK such that $STATE'$ |= P1 > 1 and C2 < 2/1 and G-CLOCK in [a : b].

checks whether it is possible to reach a marking, in some time in $[a, b]$, with more than one token in place p_1 , when the value of the clock of transition t_2 is $\lt 2$.

The dual property $\forall G_{[a,b]} \phi$ can be checked by analyzing $\exists F_{[a,b]} \neg \phi$.

Example 10. Consider the PITPN in Example [7](#page-18-1) with (interval) parameter $\phi = 30 \le a \le 70$. The property $\exists F_{[b,b]}(\neg 1-safe)$ can be verified with the following command, which determines that the parameter b satisfies $60 \le b \le 96$.

```
search [1] init(net, m_0, \phi) \implies S : \text{PHI'} \parallel \text{TICK} : M : \text{CLOCKS} : \text{NET} \text{ @ G-CLOCK}such that STATE' |= b:Real >= 0/1 and (G-CLOCK in [b:Real : b:Real])
                               and not (k\text{-safe}(1,\texttt{M})).
```
The bounded response $\phi \leadsto_{\leq b} \psi$ formula can be verified using a simple theory transformation on $\mathcal{R}_{0}^{\mathbf{S}}$ followed by reachability analysis. The theory transformation adds a new constructor for the sort State to build terms of the form C_{ϕ} : M: Clocks: Net, where C_{ϕ} is either noClock or clock(τ); the latter represents the time (τ) since a ϕ -state was visited, without having been followed by a ψ -state. The rewrite rules are adjusted to update this new component as follows. The new tick rule updates clock(T1) to clock(T1 + T) and leaves noClock unchanged. The rule applyTransition is split into two rules:

```
crl [applyTransition] : clock(T) : M ... => NEW-TP : M' ...
```

```
if NEW-TP := if STATE' |= \psi then noClock else clock(T) fi \wedge ...
```

```
crl [applyTransition] : nOClock : M ... => NEW-TP : M' ...
```

```
if NEW-TP := if STATE' |= \phi and not STATE' |= \psi
```

```
then clock(0/1) else noClock fi \wedge ...
```
In the first rule, if a ψ -state is encountered, the new " ϕ -clock" is reset to noClock. In the second rule, this " ϕ -clock" starts running if the new state satisfies ϕ but not ψ . The query $\phi \rightsquigarrow_{\leq b} \psi$ can be answered by searching for a state where a ϕ -state has not been followed by a ψ -state before the deadline b:

search [1] \ldots =>* S : PHI' \parallel clock(T) : \ldots such that T > b .

Reachability analysis cannot be used to analyze the other properties supported by Roméo ($\mathbf{Q} \phi \mathbf{U}_J \psi$, and $\forall F_J \phi$ and its dual $\exists G_J \phi$). While developing a full SMT-based timed temporal logic model checker is future work, we can combine Maude's explicit-state model checker and SMT solving to solve these (and many other) queries. On the positive side, and beyond Roméo, we can use full LTL, and also allow conditions on clocks in state propositions.

The timed temporal operators can be defined on top of the (untimed) LTL temporal operators in Maude (\leq) , [] and U) :

```
op <_>_ : Interval Prop -> Formula .
op _U__ : Prop Interval Prop -> Formula .
op [_]_ : Interval Prop -> Formula .
vars PR1 PR2 : Prop .
eq < INTERVAL > PR1 = <> (PR1 /\ in-time INTERVAL).
eq PR1 U INTERVAL PR2 = PR1 U (PR2 \land in-time INTERVAL).
eq [ INTERVAL ] PR1 = \sim (< INTERVAL > (\sim PR1)).
```
For this fragment of non-nested timed temporal logic formulas, it is possible to model check universal and existential quantified formulas as follows:

```
op A-model-check : State Formula -> Bool . --- Universal queries
op E-model-check : State Formula -> Bool . --- Existential queries
eq A-model-check(STATE, F) = modelCheck(STATE, F) == true .
eq E-model-check(STATE, F) = modelCheck(STATE , \tilde{F} ) =/= true
```
7 Benchmarks

We have compared the performance of our Maude-with-SMT analysis with that of Roméo (version 3.8.6) on three case studies. We compare the time it takes for different rewrite theories to solve the synthesis problem $\mathsf{EF}(p > n)$ (i.e., place p holds more than n tokens), for different places p and $0 \leq n \leq 2$, and to check whether the net is 1-safe. The models used in our experiments are: the producer-consumer [\[50\]](#page-26-2) system in Fig. [2,](#page-14-0) the scheduling [\[48\]](#page-26-3) system in Fig. [3,](#page-21-0) and the tutorial system in Fig. [4](#page-21-1) taken from the Roméo website. The model tutorial was modified to produce two tokens in transition startOver, thus leading to infinite behaviors. The details of each model can be found in Table [1.](#page-21-2)

We ran all the experiments on a Dell Precision Tower 3430 with a processor Intel Xeon E-2136 6-cores @ 3.3GHz, 64 GiB memory, and Ubuntu 20.04. Each experiment was executed using Maude in combination with two different SMT solvers: Yices and Z3. We use a timeout of 10 minutes.

Fig. [5](#page-22-0) shows the execution times of Roméo and Maude in log-scale, for the three case studies. (The data for each experiment can be found in Appendix [A\)](#page-26-4). Each point in the figures represents the time taken by Roméo and Maude to analyze the properties $\mathsf{EF}(p > n)$ and $\mathsf{AG}(\neg \mathsf{1}\text{-safe})$. The execution of $\mathcal{R}_1^{\mathbf{S}}$ outperforms $R_0^{\mathbf{S}}$ in some cases and the use of Yices2 shows better times when compared to Z3. For negative queries (e.g., $\mathsf{EF}(p>2)$ is false for scheduling and producer-consumer), as expected, we have timeouts for $\mathcal{R}_0^{\mathbf{S}}$ and $\mathcal{R}_1^{\mathbf{S}}$. In those cases, \mathcal{R}_1^{fS} completes the analysis before the timeout. Currently, Maude-SE supports existential quantified queries only with Z3 and \mathcal{R}_1^{fS} can be only executed with that SMT solver. In the near future, Maude-SE will integrate the support for quantifiers in Yices2 and we expect a better performance for \mathcal{R}_1^{fS} . We finally note that, in some reachability queries, Maude-SE outperforms Roméo. More interestingly, our approach terminates in cases where Roméo does not. Our results are proven valid when injecting them in the model and running Roméo with these additional constraints. This phenomenon happens when the search order leads Roméo in the exploration of an infinite branch with an unbounded marking.

Table 1: Description of the models used in the benchmarks (Fig. [5\)](#page-22-0).

Fig. 4: Case study tutorial.

Fig. 5: Execution times for Roméo and Maude, in log-scale. Theory \mathcal{R}_0^S using Z3 (\circ), theory \mathcal{R}_0^S using Yices (\circ), theory $\mathcal{R}_1^{\mathbf{S}}$ using Z3 (\Box), theory $\mathcal{R}_1^{\mathbf{S}}$ using Yices (\Box), and $\mathcal{R}_1^{f\mathbf{S}}$ using Z3 (\diamondsuit). Point $\hat{\mathbf{X}}$ is the property 1-safe.

8 Related Work

Tool support for parametric time Petri nets. We are not aware of any other tool for analyzing parametric time(d) Petri nets than Roméo [\[26\]](#page-25-3).

Petri nets in rewriting logic. Formalizing Petri nets algebraically [\[31\]](#page-25-20) was one of the inspirations behind rewriting logic. Different kinds of Petri nets are given a rewriting logic semantics in [\[46\]](#page-25-18), and in [\[37\]](#page-25-21) for timed nets. In contrast to our paper, these papers focus on the semantics of such nets, and do not consider execution and analysis; nor do they consider inhibitor arcs or parameters. Capra [\[13,](#page-24-15)[12\]](#page-24-16), Padberg and Schultz [\[43\]](#page-25-22), and Barbosa et al. [\[11\]](#page-24-17) use Maude to formalize dynamically reconfigurable Petri nets (with inhibitor arcs) and I/O Petri nets. In contrast to our work, these papers target untimed and non-parametric nets, and do not focus on formal analysis, but only show examples of standard (explicit-state) search and LTL model checking.

Symbolic methods for real-time systems in Maude. We develop a symbolic rewrite semantics and analysis for parametric time automata (PTA) in [\[4\]](#page-24-9). The differences with the current paper include: PTAs are very simple structures compared to PITPNs (with inhibitor arcs, no bounds on the number of tokens in a state), so that the semantics of PITPNs is more sophisticated than the one for PTAs, which does not use "structured" states, equations, or user-defined functions; defining a new rewrite theory for each PTA in [\[4\]](#page-24-9) compared to having a single rewrite theory for all nets in this work; obtaining desired symbolic reachability properties using "standard" folding of symbolic states for PTAs compared to having to develop a new folding mechanism for PITPNs; analysis in [\[4\]](#page-24-9) do not include model checking temporal logic formulas; and so on.

In addition, a variety of real-time systems have been formally analyzed using rewriting with SMT, including PLC ST programs [\[23\]](#page-25-23), virtually synchronous cyber-physical systems [\[20,](#page-24-18)[21,](#page-24-19)[22\]](#page-24-20), and soft agents [[32\]](#page-25-24). These papers differ from our work in that they use guarded terms [\[9,](#page-24-21)[10\]](#page-24-13) for state-space reduction instead of folding, and do not consider parameter synthesis problems.

9 Concluding Remarks

We have provided a "concrete" rewriting logic semantics for PITPNs, and proved that this semantics is bisimilar to the semantics of such nets in [\[47\]](#page-25-1). However, this model is non-executable; furthermore, explicitstate Maude analysis using Real-Time Maude-style "time sampling" leads to unsound analysis for dense-time systems such as PITPNs. We therefore *systematically transformed* this model into a "symbolic" rewrite model which is amenable to sound and complete symbolic analysis using Maude combined with SMT solving.

We have shown how almost all formal analysis and parameter synthesis supported by the PITPN tool Roméo can be performed using Maude-with-SMT. In addition, we have shown how Maude-with-SMT can provide additional capabilities for PITPNs, including synthesizing initial markings (and not just firing bounds) from parametric initial markings so that desired properties are satisfied, full LTL model checking, and analysis with user-defined execution strategies. We have developed a new "folding" method for symbolic states, so that symbolic reachability analysis using Maude-with-SMT terminates whenever the corresponding Roméo analysis terminates.

We have compared the performance of Roméo and our Maude-with-SMT methods on a number of benchmarks, which show that Maude combined with the SMT solver Yices in many cases outperforms Roméo, whereas Maude combined with Z3 is significantly slower. We also experienced that Roméo sometimes did not find (existing) solutions and the output of some executions included the message "maybe", showing that Roméo was computing an approximation. As mentioned in Section [7,](#page-20-0) this can be caused by the search exploration mechanism implemented in Roméo. Maude's search commands use a breadth-first strategy, thus guaranteeing completeness (if a given state is reachable, it will be eventually found). Moreover, operations on constraints are delegated to state-of-the-art SMT solvers. We also point out that Maude's specifications are very close to their corresponding mathematical definitions. Hence, it is easier to check the correctness of the implementation and, together with Maude's meta-programming features, it is easy to develop, test and evaluate different analysis algorithms.

This paper has not only provided new features for PITPNs. It has also shown that even a model like our Real-Time Maude-inspired PITPN interpreter—with functions, equations, and unbounded markings—can easily be turned into a symbolic rewrite theory for which Maude-with-SMT provides very useful sound and complete analyses even for dense-time systems.

In future work we should: implement the needed Maude-SE's bindings for quantifiers in Yices2, thus improving the performance of analysis with \mathcal{R}_1^{fS} ; extend Maude's LTL model checker to a full SMT-based (with folding) timed LTL and CTL model checker, thus covering all the analysis provided by Roméo; develop a richer timed strategy language for controlling the executions of PITPNs; and explore theory transformations for the sound and complete symbolic analysis of Real-Time Maude specifications.

A Data for the benchmarks

Table 2: times for $\mathsf{EF}(p>0)$

Table 3: times for $\mathsf{EF}(p>1)$

B Proofs of the Results

B.1 Proof of Theorem [1](#page-9-0)

Proof. (i) By definition $a_0 = (M_0, J) \approx (\llbracket M_0 \rrbracket_{\mathcal{R}_0} : \text{initClocks}(\llbracket \mathcal{N} \rrbracket_{\mathcal{R}_0}) : \llbracket \mathcal{N} \rrbracket_{\mathcal{R}_0}$, since all clocks are 0 in $initClocks(...)$, so that these clocks satisfy all the constraints in Definition [5](#page-9-1) since $I = J$ in the initial state. (ii) Follows from the following two lemmas.

Lemma 1. If $(M, I) \to (M', I')$ and $(M, I) \approx (\llbracket M \rrbracket_{\mathcal{R}_0} : \text{clocks} : \llbracket \mathcal{N} \rrbracket_{\mathcal{R}_0})$ then there is a clocks' such that $([M]_{\mathcal{R}_0} : clocks : [\![\mathcal{N}]\!]_{\mathcal{R}_0}) \mapsto ([\![M']\!]_{\mathcal{R}_0} : clocks' : [\![\mathcal{N}]\!]_{\mathcal{R}_0}) \text{ and } (M',I') \approx ([\![M']\!]_{\mathcal{R}_0} : clocks' : [\![\mathcal{N}]\!]_{\mathcal{R}_0}).$

Proof. Since $(M, I) \to (M', I')$, we have that there exists an intermediate pair $(M, I'') \in (T \cup \mathbb{R}_+)$ such that $(M, I) \stackrel{\delta}{\rightarrow} (M, I'')$ and $(M, I'') \stackrel{t_f}{\rightarrow} (M', I').$

For the first step $(\stackrel{\delta}{\to})$, since $(M, I) \stackrel{\delta}{\to} (M, I'')$, there exists a δ such that $\forall t \in T$, either $I''(t) = I(t)$ or $\hat{I}I''(t) = \max(0, \hat{I}I(t) - \delta)$ and $I''(t)\hat{I} = I(t)\hat{I} - \delta$. In both cases we have that $\forall t \in T, I''(t)\hat{I} \geq 0$. Now, letting $T = \delta$, it must be the case that $T \leq m$ the $(\llbracket M \rrbracket_{\mathcal{R}_0}$, clocks, $\llbracket \mathcal{N} \rrbracket_{\mathcal{R}_0}$). This is because m to $(\llbracket M \rrbracket_{\mathcal{R}_0}$, clocks, $[\![\mathcal{N}]\!]_{\mathcal{R}_0}$ is defined to be equal to the minimum difference between $J(t)$ ^{\uparrow} and the clock value of t

Table 4: times for $\mathsf{EF}(p>2)$

Table 5: 1-safe time verification

out of all $t \in T$. That is, it is the maximum time that can elapse before an enabled transition reaches the right endpoint of its interval. In other words, an upper limit for δ . Hence, the tick-rule can be applied to $(\llbracket M \rrbracket_{\mathcal{R}_0} : clocks : [\llbracket \mathcal{N} \rrbracket_{\mathcal{R}_0})$ with all enabled clocks having their time advanced by δ .

For the second step $\stackrel{t_f}{\rightarrow}$, since $(M, I'') \stackrel{t_f}{\rightarrow} (M', I')$, the transition t_f is active and $\uparrow I''(t_f) = 0$. Since $\uparrow I(t_f) = 0$, the clock of transition t_f must be in the interval $[\uparrow J(t_f), J(t_f)\uparrow]$ by definition of (M, I'') . This is precisely the condition for applying the applyTransition-rule to the resulting state of the previous tick-rule application.

Lemma 2. If $([\![M]\!]_{\mathcal{R}_0} : \mathit{clocks} : [\![\mathcal{N}]\!]_{\mathcal{R}_0}) \mapsto b$ and

 $(M, I) \approx (\llbracket M \rrbracket_{\mathcal{R}_0} : clocks : \llbracket \mathcal{N} \rrbracket_{\mathcal{R}_0}),$ then there exists a state $(M', I') \in \mathcal{A}$ such that $(M, I) \rightarrow (M', I')$ and $(M', I') \approx b.$

Proof. Since $(\llbracket M \rrbracket_{\mathcal{R}_0} : \text{clocks} : \llbracket \mathcal{N} \rrbracket_{\mathcal{R}_0}) \mapsto b$, we have that there exists an intermediate state $(M : \text{CLOCKS} : \text{NET}) \in$ $T_{\Sigma,\texttt{State}}$ such that $(\llbracket M \rrbracket_{\mathcal{R}_0} : \textit{clocks} : \llbracket \mathcal{N} \rrbracket_{\mathcal{R}_0}) \stackrel{\texttt{tick}}{\longrightarrow} (\tt{M} \: : \: \texttt{CLOCKS} \: : \: \tt{NET}) \: \texttt{and} \: (\tt{M} \: : \: \texttt{CLOCKS} \: : \: \tt{NET}) \stackrel{\texttt{applyTransaction}}{\longrightarrow}$ b. For the first step $\left(\stackrel{\text{tick}}{\longrightarrow}\right)$, since $(\llbracket M \rrbracket_{\mathcal{R}_0} : clocks : \llbracket \mathcal{N} \rrbracket_{\mathcal{R}_0}) \stackrel{\text{tick}}{\longrightarrow} (\mathbb{M} : \text{CLOCKS} : \text{NET}),$ there is a T <= mte($[M]_{\mathcal{R}_0}$, clocks, $\hat{N}|_{\mathcal{R}_0}$). Now, as in the previous lemma, since the mte is an upper limit for δ , we have that there exists a time transition $(M, I) \stackrel{\delta}{\to} (M, I'')$ with δ equal to the T used in the above tick-rule application so that $(M : \text{CLOCKS} : \text{NET}) = (\llbracket M \rrbracket_{\mathcal{R}_0} : \text{clocks} : \llbracket \mathcal{N} \rrbracket_{\mathcal{R}_0}).$ For the second step $\left(\stackrel{\text{applyTransaction}}{\longrightarrow} \right)$, since $(\llbracket M \rrbracket_{\mathcal{R}_0} : clocks : \llbracket \mathcal{N} \rrbracket_{\mathcal{R}_0}) \stackrel{\text{applyTransition}}{\longrightarrow} b$, there must be a transition t_f which is active and whose clock is in the interval $[\uparrow J(t_f), J(t_f)\uparrow]$. By definition of clocks on (M, I'') , This is precisely the condition for the discrete step t_f to (M, I'') . Hence, $(M, I'') \stackrel{t_f}{\rightarrow} (M', I')$ and $([M]_{\mathcal{R}_0} : \text{clocks} : [\![\mathcal{N}]\!]_{\mathcal{R}_0}) \stackrel{\text{applyTransition}}{\longrightarrow} ([\![M']\!]_{\mathcal{R}_0} : \text{clocks} : [\![\mathcal{N}]\!]_{\mathcal{R}_0}).$

B.2 Proof of Theorems [2](#page-9-2) and [3](#page-10-2)

Theorem [2](#page-9-2).

Proof. For the (\Leftarrow) side, it suffices to follow in \mathcal{R}_{0} the same execution strategy as in \mathcal{R}_{1} . For (\Rightarrow) , it suffices to perform the following (reachability-preserving) change in the \mathcal{R}_0 trace: the application of two consecutive tick rules with $T = t_1$ and $T = t_2$ are replaced by a single application of tick with $T = t_1 + t_2$. This is enough to show that the same trace can be obtained in \mathcal{R}_1 .

Theorem [3](#page-10-2).

Proof. From Theorem [2,](#page-9-2) we know that the tickOk/tickNotOk strategy can be followed in \mathcal{R}_0 to produce an equivalent trace. Using that trace, the result follows trivially by noticing that applications of tick in \mathcal{R}_0 with $T = \delta$ ($t \rightarrow \infty$ t') match applications of tick in \mathcal{R}_2 with the same instance of T, thus advancing the global clock in exactly δ time-units.

B.3 Proof of Theorems [4](#page-15-2) and [5](#page-16-1)

Theorem [4](#page-15-2)

Proof. This result is a direct consequence of soundness and completeness of rewriting modulo SMT [\[45\]](#page-25-17). More precisely, from [\[45\]](#page-25-17) we know that: if $\phi_t \parallel t \leadsto^* \phi_u \parallel u$ then $t' \longrightarrow^* u'$ for some $t' \in [\![\phi_t \parallel t]\!]$ and $u' \in [\![\phi_t \parallel t]\!]$ and $u' \in [\![\phi_t \parallel t]\!]$ and $u' \in [\![\phi_t \parallel t]\!]$. $u' \in \llbracket \phi_u \parallel u \rrbracket$; and if $t' \longrightarrow^* u'$ with $t' \in \llbracket \phi_t \parallel t \rrbracket$, then there exists ϕ_u and t_u s.t. $\phi_t \parallel t \leadsto^* \phi_u \parallel u$ with $u' \in [\![\phi_u \parallel u]\!]$.

Theorem [5](#page-16-1)

Proof. Let $U \Downarrow_{\text{now}} = \phi'_u \parallel t'_u$ and $V \Downarrow_{\text{now}} = \phi'_v \parallel t'_v$, where $vars(t'_u) \cap vars(t'_v) = \emptyset$. Let $X_u = vars(\phi'_u) \setminus vars(t'_u)$ and $X_v = \text{vars}(\phi_v') \setminus \text{vars}(t_v')$. By construction, $t_u', t_v' \in T_{\Sigma \setminus \Sigma_0}(X_0), \exists (U \Downarrow_{\text{now}}) = (\exists X_u) \phi_u'$, and $\exists (V \Downarrow_{\text{now}}) =$ $(\exists X_v)\phi'_v$. It suffices to show $\llbracket U \Downarrow_{\text{now}} \rrbracket \subseteq \llbracket V \Downarrow_{\text{now}} \rrbracket$ iff $U \preceq V$. (\Rightarrow) Assume $\llbracket U \Downarrow_{\text{now}} \rrbracket \subseteq \llbracket V \Downarrow_{\text{now}} \rrbracket$. Then, t'_u and t'_v are E-unifiable (witnessed by $w \in \llbracket U \Downarrow_{\text{now}} \rrbracket \cap \llbracket V \Downarrow_{\text{now}} \rrbracket$). Since t'_{v} has no duplicate variables and E only contains structural axioms for $\Sigma \setminus \Sigma_{0}$, by the matching lemma [\[45,](#page-25-17) Lemma 5], there exists a substitution σ with $t'_u = t'_v \sigma$ (equality modulo ACU). Since any built-in subterm

of t_u' is a variable in X_0 , σ is a renaming substitution $\sigma: X_0 \to X_0$ and thus $\llbracket V \Downarrow_{\text{now}} \rrbracket = \llbracket (V \Downarrow_{\text{now}}) \sigma \rrbracket$. Suppose $\exists (U \Downarrow_{\text{now}}) \Rightarrow \exists (V \Downarrow_{\text{now}}) \sigma$ is not valid, *i.e.*, $((\exists X_u) \phi'_u) \wedge (\forall X_v) \neg \phi'_v \sigma$ is satisfiable. Let Y be the set of free variables in $((\exists X_u)\phi_u') \wedge (\forall X_v) \neg \phi_v' \sigma$. Notice that $Y = vars(t_u') = vars(t_v' \sigma)$. Let $\rho: Y \to T_{\Sigma_0}$ be a ground substitution that represents a satisfying valuation of $(\exists X_u)\phi'_u \wedge (\forall X_v)\neg\phi'_v \sigma$. Then, $t'_u \rho \in \llbracket U \Downarrow_{\text{now}} \rrbracket$ but $t'_\n{\alpha} \rho = t'_\n{\alpha} \rho \notin [[(V \Downarrow_{\text{now}}) \sigma] = [V \Downarrow_{\text{now}}],$ which is a contradiction.

(←) Assume $U \preceq V$. There exists a substitution $\sigma : X_0 \to X_0$ such that $t'_u = t'_v \sigma$ and $\exists (U \Downarrow_{\text{now}}) \Rightarrow$ $\exists (V \Downarrow_{\text{now}}) \sigma$ is valid. Let Y be the set of free variables in $\exists (U \Downarrow_{\text{now}}) \Rightarrow \exists (V \Downarrow_{\text{now}}) \sigma$. As mentioned above, $\llbracket V \Downarrow_{\text{now}} \rrbracket = \llbracket (V \Downarrow_{\text{now}}) \sigma \rrbracket$ and $Y = vars(t'_u) = vars(t'_v \sigma)$. Let $w \in \llbracket U \Downarrow_{\text{now}} \rrbracket$. Then, for some ground substitution $\rho_u, w = t'_u \rho_u$ and $\phi'_u \rho_u$ holds. From the assignments in $\rho_u|_Y$, we can build a valuation V making true $\exists (U \Downarrow_{\text{now}})$ and, by assumption, making also true $\exists (V \Downarrow_{\text{now}}) \sigma$. Hence, there exists a ground substitution ρ_v (that agrees on the values assigned in V) such that $\phi'_v \sigma \rho_v$ holds and $\rho_u|_Y = \rho_v|_Y$. Notice that $w = t'_u \rho_u =$ $t'_u(\rho_u|_Y) = t'_v \sigma(\rho_v|_Y) = t'_v \sigma(\rho_v)$. Therefore, $w \in [[(V \Downarrow_{\text{now}}) \sigma]].$

Corollary [1](#page-17-2)

Proof. Assume that $(C,(M, D), \Rightarrow)$ is a finite transition system and, to obtain a contradiction, that there are infinitely many $\rightsquigarrow_{\mathcal{R}^{fs}_1}$ -reachable states from $\text{init}(\mathcal{N}, M, D)$. Since $\left(T_{\Sigma, \text{State}}, \text{init}(\mathcal{N}, M, D), \rightsquigarrow_{\mathcal{R}^{fs}_1}\right)$ is finitely branching, there must be an infinite sequence of the form $U_0 \rightsquigarrow_{\mathcal{R}_1^{fs}} U_1 \rightsquigarrow_{\mathcal{R}_1^{fs}} \cdots$ where, by definition of $\rightsquigarrow_{\mathcal{R}_1^{f}} s, U_j \not\preceq U_i$ for $i < j$. From Theorem [5](#page-16-1) we know that $[[U_j]] \not\subseteq [[\dot{U}_i]]$. By Theorem [4,](#page-15-2) this means that after each transition, more concrete different states are found. Hence, the reachable state classes cannot be finite, thus a contradiction.
