ABSTRACT

The use of Transformer represents a recent success in speech enhancement. However, as its core component, self-attention suffers from quadratic complexity, which is computationally prohibited for long speech recordings. Moreover, it allows each time frame to attend to all time frames, neglecting the strong local correlations of speech signals. This study presents a simple yet effective sparse self-attention for speech enhancement, called ripple attention, which simultaneously performs fine- and coarse-grained modeling for local and global dependencies, respectively. Specifically, we employ local band attention to enable each frame to attend to its closest neighbor frames in a window at fine granularity, while employing dilated attention outside the window to model the global dependencies at a coarse granularity. We evaluate the efficacy of our ripple attention for speech enhancement on two commonly used training objectives. Extensive experimental results consistently confirm the superior performance of the ripple attention design over standard full self-attention, blockwise attention, and dual-path attention (Sep-Former) in terms of speech quality and intelligibility.

Index Terms— speech enhancement, Transformer, spare self-attention

1. INTRODUCTION

The perceived quality and intelligibility of speech signals are inevitably degraded by surrounding background noises in our daily acoustic scenarios. As a solution, speech enhancement improves the quality of speech perception by separating clean speech from degraded noisy speech. Due to some underlying assumptions, traditional speech enhancement methods often lack the ability to suppress non-stationary noises [1–4]. Over the past decade, deep learning has promoted tremendous progress in speech enhancement given the supervision of large-scale training data [5]. A typical method is to optimize a deep neural network (DNN) to predict the spectra of

*Corresponding author

clean speech or a time-frequency (T-F) mask from the T-F spectra of noisy speech. Motivated by the idea of T-F auditory masking, the ideal binary mask (IBM) is introduced for speech enhancement [5]. Subsequently, various T-F masks are proposed, including ideal ratio mask (IRM) [6], complex IRM (cIRM) [7], and phase-sensitive mask (PSM) [8]. DNNs are also optimized to recover the waveform of clean speech directly from the noisy raw waveform in an end-to-end manner [9, 10].

With the ability to model the long-range correlations, long shortterm memory networks (LSTMs) are adopted for speech enhancement [8, 11]. Nevertheless, LSTM network architectures involve a large number of parameters and inherent sequential nature, which excludes its use for many applications. Convolutional neural networks process time frames in parallel and can also capture contextual dependencies by stacking multiple layers. Residual temporal convolution networks (ResTCNs) [12], incorporating 1-D dilated convolution and residual connection, have been applied for speech enhancement with an impressive performance [13–16].

Transformer [17] has recently shown state-of-the-art (SOTA) results in numerous speech tasks, including speech enhancement [18-21]. As a core piece of Transformer, the multi-head self-attention attends to all time steps in parallel, allowing Transformer to model long-term dependencies efficiently. However, the computation complexity of self-attention is quadratic with respect to the sequence length, thus making it infeasible for long speech recordings. In addition, the strong local correlations of speech are ignored. The more recent dual-path transformer (SepFormer) [22] splits the sequence into overlapped chunks and conducts self-attention to intra and inter chunks, for local and global modeling, respectively, which mitigate the issue of quadratic complexity. SepFormer is introduced in [22] for speech separation, demonstrating SOTA performance, and then applied for speech enhancement [20]. We present a sparse attention for speech enhancement, here referred to as ripple attention, which can simultaneously model the local and global correlations in a spectrogram in a simpler and more effective way, without chunking. In particular, the ripple attention consists of fine-grained local attention and coarse-grained global attention. Considering that speech frames usually have a stronger correlation in a local context than in a broad context over time, the local attention restricts each frame to attend to its neighboring frames in a context window at fine granularity, which takes special care of neighboring frames. The dilated attention is applied to the time frames outside the window at a coarse granularity, allowing the model to capture the global dependencies more efficiently. In this paper, we show that our ripple attention outperforms blockwise attention and the SOTA SepFormer on two commonly used training targets, and theoretically analyze the computation cost.

The closest work to ours is Longformer [23] for document processing, where the dilated attention is restricted in a sliding window for local modeling, unlike our model, which applies dilated attention outside the window, for coarse-grained global modeling. Moreover, our speech-oriented attention allows each frame for global modeling instead of only a few task-specific tokens allowed to query all tokens for global modeling.

The rest of this paper is organized as follows. In Section 2, we introduce T-F neural speech enhancement. Section 3 describes our proposed method. Section 4 sets up the experiment and analysis the results. Section 5 gives the conclusion.

2. PROBLEM FORMULATION

Taking the short-time Fourier transform (STFT), the noisy waveform is transformed into T-F domain: X[l, k] = S[l, k] + D[l, k], where l is the time frame index and k is the frequency bin index. S[l, k], D[l, k] and X[l, k] represent the coefficients of clean speech, noise, and noisy speech, respectively. A typical T-F neural speech enhancement optimizes a DNN to predict a T-F mask, $\widehat{M}[l, k]$, to separate the clean speech, $\widehat{S}[l, k] = \widehat{M}[l, k] \cdot X[l, k]$. Without the loss of generality, we adopt two commonly used T-F masks, IRM [6] and PSM [8], to validate our proposed sparse self-attention mechanism.

$$\operatorname{IRM}[l,k] = \sqrt{\frac{|S[l,k]|^2}{|S[l,k]|^2 + |D[l,k]|^2}}$$
(1)

where $|\cdot|$ denotes the spectral magnitude.

$$PSM[l,k] = \frac{|S[l,k]|}{|X[l,k]|} \cos[\theta_{S[l,k]-X[l,k]}]$$
(2)

where $\theta_{S[l,k]-X[l,k]}$ indicates the phase difference between the STFT coefficients of clean and noisy speech [8].

3. SPEECH ENHANCEMENT WITH RIPPLE SPARSE SELF-ATTENTION

3.1. Network Architecture

Fig.1 (a) illustrates the overall architecture of our sparse selfattention backbone network. The STFT magnitude spectrum of noisy speech $|\mathbf{X}| \in \mathbb{R}^{L \times K}$ is the input to the network, where *L* is the number of time frames and *K* is the number of frequency bins. The input is first projected by Conv1D, a 1-D convolution layer of kernel size 1 that involves a frame-wise layer normalization with the ReLU as activation function, which produces a latent T-F representation with a size of d_{model} . The produced latent representation is then fed into *B* stacked sparse self-attention blocks, and each block consists of two subblocks: a sparse multi-head attention (MHA) module and a two-layer fully connected feed-forward network (FNN). A residual connection is applied around each subblock, followed by frame-wise layer normalization. The output layer of the network is a 1-D convolution layer of kernel size 1 and the sigmoid activation function is applied to output the estimated mask.

3.2. Sparse Self-Attention

Fig.1 (b) illustrates the workflow of the ripple sparse multi-head attention, which takes as input a set of queries ($\mathbf{Q} \in \mathbb{R}^{L \times d_{model}}$), keys ($\mathbf{K} \in \mathbb{R}^{L \times d_{model}}$), and values ($\mathbf{V} \in \mathbb{R}^{L \times d_{model}}$). A total of *h* attention heads are employed in the sparse multi-head attention, where the head index is denoted as $i = \{1, 2, 3, ..., h\}$, allowing the model

Fig. 1. Illustration of (a) the ripple sparse self-attention backbone network and (b) the sparse multi-head self-attention module. The key idea is to introduce a sparse attention mask to sparsify $L \times L$ attention matrix.

to pay attention to different aspects of information. For *i*-th head, firstly a linear projection is applied to **Q**, **K**, and **V**, respectively: $Q_i = \mathbf{Q}\mathbf{W}_i^Q$, $K_i = \mathbf{K}\mathbf{W}_i^K$, and $V_i = \mathbf{V}\mathbf{W}_i^V$, with dimensions d_k , d_k , and d_v , respectively, where $\mathbf{W}_i^Q \in \mathbb{R}^{d_{model} \times d_k}$, $\mathbf{W}_i^K \in \mathbb{R}^{d_{model} \times d_k}$, and $\mathbf{W}_i^V \in \mathbb{R}^{d_{model} \times d_v}$ are learned parameter matrices. For each head, the scaled dot-product attention is utilized to compute the attention scores. The output is given as:

$$A_i = \operatorname{softmax}\left(\frac{Q_i K_i^{\top}}{\sqrt{d_k}} \odot M\right) V_i \tag{3}$$

where $d_k = d_v = d_{model}/h$, $M \in \{0, 1\}^{L \times L}$ denotes the attention mask used to sparsify the attention matrix, where $M_{ij} = 1$ indicates that frame *i* is allowed to attend to frame *j*, 0 otherwise. The operation \odot is defined as:

$$(P \odot M)_{ij} = \begin{cases} P_{ij} & \text{if } M_{ij} = 1\\ -\infty & \text{if } M_{ij} = 0 \end{cases}$$
(4)

The outputs for each attention head are then concatenated and linearly projected:

$$MultiHead (\mathbf{Q}, \mathbf{K}, \mathbf{V}) = Concat(A_1, ..., A_h)\mathbf{W}^O$$
(5)

where $\mathbf{W}^O \in \mathbb{R}^{d_{model} \times d_{model}}$. The two-layer FFN takes the output of the first subblock and performs two linear transformations with a ReLU activation function in the first layer. Detailed descriptions of our ripple sparse attention pattern are given in the next section.

Fig. 2. Illustration of the full self-attention pattern and the ripple sparse attention pattern (with sequence length L = 12).

3.3. Ripple Sparse Attention Mask

Fig. 2 shows an example of the full-attention mask and our ripple sparse-attention mask. The colored squares (with the row index i and column index j) correspond to the mask value $M_{ij} = 1$, which indicates that frame i attends to frame j and the corresponding attention score is involved. The blank squares correspond to $M_{ij} = 0$, which indicates that the attention score is masked or discarded. As illustrated in Fig. 2 (a), full attention computes the correlations between all time frames, which leads to $O(L^2)$ complexity that limits its use for long audio recordings. In addition, it also inhibits local correlations among nearby frames. To tackle these issues, we propose a ripple sparse attention that involves fine-grained local and coarse-grained global modeling, enabling the model to capture both local and global dependencies more efficiently and effectively.

Since the speech signal comes with strong local correlations, our ripple attention employs a fine-grained local attention that controls each frame to attend to the frames within the context window. Specifically, given a sliding window with a length of w frames, each time frame only attends to $\frac{1}{2}w$ frames on the left and right sides (green squares in Fig. 2 (b)), which achieves linear complexity O(Lw). To allow the model to capture the global dependencies, our attention employs dilated self-attention for the frames outside the local context window at a coarse granularity. The dilated self-attention is only computed between positions that are d time frames away from each other, which has $O(L\lfloor \frac{L-w}{d} \rfloor)$ complexity. This is analogous to dilated CNNs where the window has dilation rate gaps d (blue squares in Fig. 2 (b)).

4. EXPERIMENTS

4.1. Datasets and Feature Extraction

Following the datasets setup in [21], we employ the Librispeech [24] train-clean-100 set (28 539 utterances) as the clean speech data in the training set. The noise data contains a total of 6 909 noise recordings, which are from seven datasets: the coloured noise recordings [18], the noise set in the MUSAN corpus [25], the Nonspeech noises [26], the QUT-NOISE dataset [27], the Environmental Noise dataset [28, 29], the RSG-10 dataset [30], and the Urban Sound dataset [31]. We randomly exclude 1000 clean speech utterances and noise recordings to yield 1000 noisy/clean pairs as the validation set, where a segment randomly selected from one noise recording is mixed with one clean speech at an SNR value (randomly chosen from [-10, 20] dB, in 1 dB increments). Four real-world noises (babble voice, F16, and factory welding excluded from RSG-10 dataset [30] and street music excluded from the Urban Sound dataset [31]) are used for testing. We randomly chose ten clean speech utterances from the Librispeech test-clean-100 set for each noise recording, and mix each clean speech utterance with a noise segment randomly selected from the noise recording at SNRs of -5, 0, 5, 10 and 15 dB, which yields 200 noisy speech for testing. All audio signals in the experiment are sampled at 16 kHz. For the spectral analysis, we employ a square-root-Hann window of length 32 ms (50% overlapping) and a 512-point STFT, which leads to the 257-point STFT magnitude spectrum.

4.2. Experimental Setup

As baselines, we compare our ripple attention with standard full self-attention [17–19, 32] and two recent sparse attention patterns, blockwise attention [33] (for document processing) and SepFormer (SOTA efficient self-attention model for speech enhancement) [20,

22] to demonstrate its effectiveness and superiority. All models employ B = 4 transformer layers (same model size) and adopt the following parameters: H = 8, $d_{model} = 256$, and $d_{ff} = 1024$. Self-attention was found to tend to model short-term dependencies in the lower layers [34]. Inspired by this, unlike [35] as well as baseline models, the proposed model applies only local band attention to the first two layers. We investigate the performance of our ripple attention under different configurations for the window size w and the dilation rate d: w = 12 and $d = \{16, 24, 50\}$. Blockwise attention splits the input sequence into nonoverlapping blocks of size 50 and processes each block separately. For SepFormer baseline [22], the intra- and inter-chunk transformer blocks include two transformer layers, respectively, and the size of the chunk (or block) is set to 50 (with 50% overlap) as suggested in [20].

Ten clean speech utterances are included in one mini-batch for one training step, and the noisy mixture is generated by mixing each clean speech utterance in the mini-batch with one segment randomly selected from one randomly chosen noise recording at an SNR value randomly chosen integer from the range of [-10, 20] dB. The loss function is the mean squared error between the ground truth and the predicted mask. For each epoch, we randomly shuffle the order of the clean speech utterances. The Adam optimizer with parameters as in [17], i.e., $\beta_1 = 0.9$, $\beta_2 = 0.98$, and $\epsilon = 10^{-9}$ is adopted for training. The gradient clipping is adopted to clip gradient values to between [-1, 1]. As the training of transformer is sensitive to the learning rate [17, 18], we follow the warm-up training strategy [17], where the learning rate [rr, rs], we follow the warm up training stategy [17], where the learning rate is adjusted according to the rule: $lr = d_{model}^{-0.5} \cdot \min(n_step^{-0.5}, n_step \cdot wup_steps^{-1.5})$, where n_step and wup_steps denote the number of training steps and warm-up training steps, respectively. Following [18], $wup_steps = 40\,000$ is adopted for warm-up training. It should be noted that compared to the training strategy in [20], we find that the warm-up training strategy shows better results in our dataset.

4.3. Training & Validation Loss

The training and validation loss curves of different models are illustrated in Fig. 3, where each of the models is trained for 150 epochs with IRM as the training objective. Compared to standard full selfattention, our ripple attention patterns (with different dilation rates) consistently produce obvious lower training and validation loss, indicating the effectiveness of the ripple attention design. The lower loss than the blockwise attention and SepFormer further demonstrates the superiority of our attention pattern.

Fig. 3. The (a) training and (b) validation loss curves.

4.4. Results and Discussion

The PESQ [36] and ESTOI [37] are adopted to evaluate the perceptual quality and intelligibility of speech, respectively. Three composite metrics [38] are used to evaluate the mean opinion scores

Attention	Block Size	Window Size (w)	Dilation Rate (d)			IRM			PSM				
Pattern					Inpu	it SNR	(dB)			Input SNR (dB)

Tables 1 and 2 report the comparison results of PESQ and ES-TOI scores for the five SNR levels, respectively. Among the two training objectives, overall, PSM shows better performance than IRM. Our ripple self-attention patterns consistently improve over the unprocessed noisy recordings in terms of PESQ and ESTOI under all SNR levels. Taking the 5 dB SNR as a case, the ripple attention (w = 12, d = 24) with IRM provides 0.89 and 18.68% gains on PESO and ESTOI, respectively. It is also clear to observe that our ripple attention significantly improves PESQ and ESTOI scores of the full self-attention across all SNR conditions. In the case of 5 dB SNR, our sparse attention (w = 16, d = 24) with PSM improves full self-attention by 0.15 in PESQ and 2.36% in ESTOI. Additionally, our attention consistently outperforms blockwise attention and SepFormer, which further confirms the superiority of the sparse attention design. For instance, our attention (w = 12, d = 24) with PSM provides 0.13 and 0.11 PESQ gains and 2.45% and 2.06% ESTOI gains over blockwise attention and SepFormer, respectively, for 5 dB SNR case. Table 3 reports the comparison results of CSIG, CBAK, and COVL scores averaged across all SNR levels, showing performance trends similar to the results in Tables 1 and 2. On average, our ripple attention (w = 12, d = 50) with PSM improves CSIG by 0.10, 0.12, and 0.05, CBAK by 0.05, 0.08, and 0.03, and COVL by 0.10, 0.13, and 0.06 over full attention, blockwise attention, and SepFormer, respectively.

Fig. 4. The comparison (theoretical value) of multiply–accumulate operations (MACs) at various sequence lengths.

In Fig. 4, we theoretically analyze the computation costs required by different attention patterns at various sequence lengths. The computation cost is measured in terms of multiply-accumulate operations (MACs). Among the three sparse self-attention patterns, the blockwise attention shows lower MACs. In addition, we can also find that our proposed attention patterns consistently exhibit lower MACs than SepFormer. Taking the performance and computation cost into account, our proposed ripple sparse attention provides a better trade-off than blockwise attention and SepFormer.

5. CONCLUSION

In this study, we propose a novel sparse self-attention for speech enhancement, termed ripple attention, which comprises a local band attention and a dilated attention. Local attention captures strong local correlations of speech signals at fine granularity, and the dilated attention allows the network model to capture global dependencies at coarse granularity. Our ripple sparse attention mechanism is investigated under different configurations of window size and dilation rate. Extensive speech enhancement experiments on two training objectives (IRM and PSM) show that our ripple attention consistently outperforms standard full self-attention, blockwise attention, and SepFormer in all cases, confirming the superiority of the design of our sparse attention.
