Abstract

Recent measurements of Jupiter's gravitational moments by the Juno spacecraft and seismology of Saturn's rings suggest that the primordial composition gradients in the deep interior of these planets have persisted since their formation. One possible explanation is the presence of a double-diffusive staircase below the planet's outer convection zone, which inhibits mixing across the deeper layers. However, hydrodynamic simulations have shown that these staircases are not long-lasting and can be disrupted by overshooting convection. In this letter, we suggests that planetary rotation could be another factor for the longevity of primordial composition gradients. Using rotational mixing-length theory and 3D hydrodynamic simulations, we demonstrate that rotation significantly reduces both the convective velocity and the mixing of primordial composition gradients. In particular, for Jovian conditions at $t \sim 10^8$ yrs after formation, rotation reduces the convective velocity by a factor of 6, and in turn, the kinetic energy flux available for mixing gets reduced by a factor of $6^3 \sim 200$. This leads to an entrainment timescale that is more than two orders of magnitude longer than without rotation. We encourage future hydrodynamic models of Jupiter and other gas giants to include rapid rotation, because the decrease in the mixing efficiency could explain why Jupiter and Saturn are not fully mixed.

Key words: UAT Keywords: Jupiter (873), Saturn (1426), Solar system gas giant planets (1191), Planetary interior (1248), Hydrodynamics (1963), Hydrodynamical simulations (767), Convective zones (301)

1. Introduction

The history of the solar system is written in the interiors of the giant planets. In particular, since Jupiter accounts for 75% of the Solar System's planetary mass, understanding its interior (or more precisely, determining the distribution and total mass of heavy elements within the planet) can provide important clues on the first stages of the formation of the solar system (see the recent review by Miguel & Vazan 2023). Traditionally, Jupiter has been considered a fully convective planet, with a well-defined interface separating a dense core made of heavy elements and the hydrogen-helium envelope (Pollack et al. 1996). However, new data from the Juno mission indicates that Jupiter does not have a well-defined central core of heavy elements, nor is it homogeneously mixed (e.g., Bolton et al. 2017b,a; Wahl et al. 2017; Debras & Chabrier 2019; Howard et al. 2023). Interestingly, ring seismology suggests that Saturn is likewise not homogeneously mixed (Mankovich & Fuller 2021). These new observational constraints on the internal structure of gas giants require updates to formation and evolution models (Helled et al. 2022). Composition gradients decrease the efficiency of the heat transport throughout the planet's interior and thus affect its cooling, and mass-radius relationship at a given age (e.g., Chabrier & Baraffe 2007; Leconte & Chabrier 2012, 2013).

Primordial composition gradients are expected to naturally result from planet formation (e.g., Helled & Stevenson 2017; Müller et al. 2020; Stevenson et al. 2022) or collisional events during the planet's evolution (Liu et al. 2019), but the persistence of composition gradients against strong convectivemixing over evolutionary timescales is poorly understood. One mechanism for maintaining a composition gradient appears in one-dimensional evolution models, where convective staircases (i.e., multiple convective layers separated by thin, stably-stratified, diffusive interfaces) form underneath the outer convective envelope, preventing mixing deeper in the interior (e.g., Vazan et al. 2015, 2018; Stevenson et al. 2022). However, 3D simulations of layered convection in incompressible flows have shown that convective staircases fully mix on short timescales (e.g., Wood et al. 2013; Garaud 2018). Recently, Fuentes et al. (2022) explored the formation of a convective staircase beneath a growing convection zone, and found that compositional mixing across the interface between the convection zone and the stable region prevents the formation of the staircase. Similar results were found by Anders et al. (2022) in the context of stellar convection, concluding that compositional gradients are ineffective barriers against convective mixing over evolutionary timescales.

Rotation is another factor that could prevent convective mixing in Jupiter and other gas giants. Experiments and nu-

merical simulations of thermal convection have shown that rotation reduces the convective velocities when the flow has small Rossby number, Ro, the ratio of the rotation period to the convective turnover time (e.g., Stevenson 1979; Fernando et al. 1991; Barker et al. 2014; Dietrich & Wicht 2018; Aurnou et al. 2020; Hindman et al. 2020). Further, numerical experiments wherein rapidly-rotating convection zones grow via entrainment have shown that the vertical transport of buoyancy and kinetic energy across the convective layer, and thus the entrainment rate, are reduced by rotation (Julien et al. 1996a). Convective flows in Jupiter and other gas giants can be significantly slow compared to rotation (Ro $\leq 10^{-6}$, e.g. Guillot et al. 2004), so the effects of rotation on the erosion of primordial composition gradients are likely to be significant. Indeed, Leconte & Chabrier (2012) suggested that rotation would hamper convection and impede the mixing of heavy elements.

In this Letter, we examine how rotation modifies the rate of mixing of a stable fluid layer by a neighboring convection zone. In Section 2, we use mixing-length theory to argue that rotation reduces the convective velocity and the kinetic energy flux available for mixing. Then, in Section 3 we use the scalings from rotating mixing length theory to show that rotation decreases the rate of entrainment and mixing at the boundary between the stable and unstable layers. In Section 4, we use 3D numerical simulations to support the predictions from the previous sections. Finally, in Section 5 we discuss the implications of our results for Jupiter and other gas giants.

2. Mixing-length theory for rotating convection

In this section, we summarize the mixing-length scalings for the convective velocity and kinetic energy flux in nonrotating and rotating flows.

In the absence of rotation, convective motions are nearly isotropic with a characteristic length scale, ℓ , that is roughly the depth of the convection zone (e.g., in a laboratory experiment) or a pressure scale height (e.g., in stellar and planetary interiors). Further, the velocity scale of the convective flows is approximately the overturning buoyant "freefall" velocity, $U_{\rm NR} = \sqrt{g\alpha\delta T_{\rm NR}\ell}$, where the subscript NR means no rotation, g is the acceleration due to gravity, and $\alpha = -(\partial \ln \rho/\partial T)|_C$ is the coefficient of thermal expansion at constant composition C, and $\delta T_{\rm NR}$ is the characteristic temperature perturbation of convective parcels. The heat flux carried by the convective motions is $F_H \sim \rho c_P \delta T_{\rm NR} U_{\rm NR}$, where ρ is the mass density, and c_P is the specific heat capacity at constant pressure. Then, the convective velocity can be estimated as

$$U_{\rm NR} \sim \left(\frac{\alpha g F_H \ell}{\rho c_P}\right)^{1/3}$$
 (1)

Typical values for Jupiter's deep interior at $t \sim 10^8$ yrs after formation, when the convective luminosity is high enough so that a large fraction of the planet is expected to be mixed, $\ell \sim H_P \sim 10^9$ cm (a pressure scale height), $c_P/\alpha g \sim 10^{10}$ cm, $\rho \sim 1~{\rm g~cm}^{-3}$, and $F_H \sim 6 \times 10^5~{\rm cgs}$ (e.g., Cumming et al.

2018; Helled et al. 2022), give $U_{\rm NR} \sim 40~{\rm cm~s^{-1}}$ (and accordingly, the convective turnover time is $\ell/U_{\rm NR} \sim 0.8~{\rm yr}$).

In the limit of rapid rotation, convection is quasi-geostrophic, and convective flows are set by a balance between the Coriolis, inertial, and buoyancy (Archimedean) forces (called CIA balance, e.g., Stevenson 1979). In this limit, a new length scale, ℓ_{\perp} , associated with motions perpendicular to the rotation vector, Ω , emerges (e.g., Barker et al. 2014; Aurnou et al. 2020; Vasil et al. 2021). From CIA balance, one obtains

$$\frac{2\Omega U_{\rm R}}{\ell} \sim \frac{U_{\rm R}^2}{\ell_{\perp}^2} \sim \frac{\alpha g \delta T_{\rm R}}{\ell_{\perp}},\tag{2}$$

where the subscript R means *rotating* and Ω is the angular frequency of the rotation vector. Using the definition of the heat flux $F_H \sim \rho c_P \delta T_R U_R$, and eliminating δT_R and ℓ_\perp from Equations (2), it follows that

$$U_{\rm R} \sim \left(\frac{g\alpha F_H}{\rho c_P}\right)^{2/5} \left(\frac{\ell}{2\Omega}\right)^{1/5} \sim U_{\rm NR} \left(\frac{U_{\rm NR}}{2\Omega\ell}\right)^{1/5},$$
 (3)

Plugging in the previous values for Jupiter, together with $2\pi/\Omega \sim 10$ hours, we obtain $U_{\rm R} \sim 6~{\rm cm~s^{-1}}$. Rotation therefore reduces the convective velocity by a factor of ~ 6 ; then, the convective turnover time increases by a factor of ~ 6.6 , giving $\ell/U_{\rm R} \sim 5~{\rm yrs}$.

Although the effect of rotation on the convective velocity could be considered minor in the sense that the resulting turnover time is still many orders of magnitude smaller than the age of the planet, the important quantity for entrainment is the kinetic energy flux, which is reduced by a much larger factor. This can be seen from the ratio between the kinetic energy flux $F_{\rm K} \sim (1/2) \rho U_{\rm conv}^3$ associated with the convective motions and the thermal heat flux carried by convection. Without rotation, Equation (1) gives $F_{\rm K,NR}/F_H=(1/2)\rho U_{\rm NR}^3/F_H\sim (\alpha g\ell/c_P)$. In the limit of rapid rotation, Equation (3) gives

$$\frac{F_{\rm K,R}}{F_H} \sim \left(\frac{\alpha g \ell}{c_P}\right) \left(\frac{U_{\rm R}}{2\Omega \ell}\right)^{1/2} \sim {\rm Ro}^{1/2} \frac{F_{\rm K,NR}}{F_H} \,, \tag{4}$$

where $Ro = U_R/2\Omega\ell \ll 1$ is the Rossby number of the flow based on the rotationally-constrained convective velocity. Then, for a given heat flux, rotation reduces the kinetic energy flux by a factor of $Ro^{1/2} \ll 1$. Using the values above for Jupiter, we estimate $Ro \sim 10^{-5}$, and consequently, the kinetic energy flux available to mix the fluid is reduced by a factor of $\sim 4 \times 10^{-3}$. This reduction is important because the energy source for the upward transport and mixing of heavier material is the kinetic energy of the convective motions. We investigate this in more detail in Section 3.

3. Entrainment in rapidly rotating flows

Mixing of material (entrainment) across convective boundaries (e.g., a core-envelope interface) has been investigated with great detail in laboratory experiments and numerical simulations (e.g., Turner 1968; Fernando 1987; Molemaker & Dijkstra 1997; Fuentes & Cumming 2020). In those studies, a convection zone advances into a stable region, and the returning flows from overshooting convection entrain fluid with the chemical composition of the stable layer. This material rapidly mixes, so the convection zone grows over time (see Anders & Pedersen 2023, for a review of boundary mixing processes). By reducing the convective velocities, rotation reduces the entrainment (mixing) efficiency, and consequently, decreases the growth rate of the convective layer.

Consider a plane-parallel fluid layer of depth H, stably-stratified with composition decreasing linearly with height, $C_0(z) = |dC_0/dz|(H-z)$. Note that C could represent the spatial variation in mass fraction of heavy elements, or the mean molecular weight of the fluid, as would be induced by salt in water or heavy elements in hydrogen. Then, a heat flux F_0 escapes through the top of the stable layer, such that convection is driven from above and mixes the composition gradient from top to bottom. For simplicity, we adopt the Boussinesq approximation (Spiegel & Veronis 1960), wherein the fluid density is constant everywhere except for buoyant perturbations, which is a decent approximation in the vicinity of a convective boundary.

We now estimate the rate of entrainment dh/dt, where h(t) is the depth of the convection zone at time t. Lifting and mixing a quantity ΔC of heavy fluid requires an energy expenditure $\Delta E=(1/6)\rho_0\beta\Delta Cgh^2$ (see, e.g., Fuentes & Cumming 2020), where mass conservation dictates that $\Delta C=0.5|dC_0/dz|h$. Here, ρ_0 is the density of the layer, and $\beta=(\partial\ln\rho/\partial C)_T$ is the coefficient of compositional expansion (both quantities assumed constant). Differentiating ΔE with respect to time, we write the rate of change of potential energy due to mixing as $d(\Delta E)/dt=(1/4)\rho_0\beta|dC_0/dz|gh^2h$. We adopt the entrainment hypothesis, which states that the rate of change of potential energy across the layer is set by the kinetic energy flux of the convective motions $F_{\rm KE}=(1/2)\rho_0U_{\rm conv}^3$ (Linden 1975). It follows that

$$\frac{1}{4}\rho_0\beta g \left| \frac{dC_0}{dz} \right| h^2 \frac{dh}{dt} \approx \frac{1}{2}\rho_0 U_{\text{conv}}^3.$$
 (5)

Equation (5) assumes that all the kinetic energy is used to do work and lift material from below, and that thermal effects do not significantly affect the rate of change in the potential energy across the layer (a good approximation since $\alpha \Delta T \ll \beta \Delta C$).

We see that given U_{conv} , Equation (5) can be integrated to obtain h(t). Without rotation, we use $\rho = \rho_0$, $F_H = F_0$, and $\ell = h$ and assume $U_{\text{conv}} \approx U_{\text{NR}} \propto \ell^{1/3}$ (Equation 1), to obtain (within a factor of order unity due to the assumptions above)¹

$$h_{\rm NR}(t) \approx 2 \left(\frac{\alpha g F_0}{\rho_0 c_P N^3}\right)^{1/2} (Nt)^{1/2} ,$$
 (6)

where $N = \sqrt{g\beta|dC_0/dz|}$ is the buoyancy frequency. From Equation (6), the rate at which the convection zone expands inward depends on how quickly it cools down (which sets the convective velocity magnitude) and on the magnitude of the initial composition gradient.

On the other hand, in the limit of rapid rotation we should use $U_{\rm conv} \approx U_{\rm R} \propto \ell^{1/5}$ (Equation 3), and integration of Equation (5) gives

$$h_{\rm R}(t) \approx \left(\frac{24}{5}\right)^{5/12} \left(\frac{\alpha g F_0}{\rho_0 c_P N^3}\right)^{1/2} \left(\frac{N}{2\Omega}\right)^{1/4} (Nt)^{5/12} ,$$
 (7)

01

$$h_{\rm R}(t) \approx \left[0.96 \left(\frac{N}{2\Omega} \right)^{1/4} (N t)^{-1/12} \right] h_{\rm NR}(t) \,.$$
 (8)

We can see that rotation slows down the propagation of the convection zone, it reduces the power-law index from 0.5 to approximately 0.41, but the most significant effect comes from the prefactor $(N t)^{-1/12}$, which can be very small over long timescales.

It is instructive to compare the mixing timescales in both cases. From Equations (6) and (7), the time required for convection to mix a stable layer of vertical size L (i.e., h(t) = L) is

$$\tau_{\rm NR} \approx N^{-1} \left(\frac{\rho_0 c_P N^3 L^2}{4\alpha g F_0} \right) \,, \tag{9}$$

in the non-rotating case, and

$$\tau_{\rm R} \approx \frac{5}{24} N^{-1} \left(\frac{\rho_0 c_P N^3 L^2}{\alpha g F_0} \right)^{6/5} \left(\frac{2\Omega}{N} \right)^{3/5} \approx \frac{5}{6} {\rm Ro}^{-1/2} \, \tau_{\rm NR} \,,$$
(10)

in the rotating case. Therefore, the mixing timescale increases approximately by a factor of $(5/6)\text{Ro}^{-1/2}$, a commensurate change to the decrease in the kinetic energy flux—compare Equations (4) and (10).

In a system like Jupiter where Ro $\sim 10^{-5}$ at $t \sim 10^8$ yrs after formation, this corresponds to a mixing timescale that is more than two orders of magnitude longer. This difference is substantial, e.g., for $L \sim 10^9$ cm, $N^2 \sim g/H_P \sim 10^{-6}$ s⁻², Equations (9) and (10) give $\tau_{\rm NR} \sim 10^8$ yrs and $\tau_{\rm R} \sim 10^{10}$ yrs, i.e., for the rotating case the mixing timescale would be more than the age of the Solar System.

4. Numerical experiments and results

In the following, we use two hydrodynamic simulations (with and without rotation) to test the theory above. We model 3D thermal convection in a plane-parallel binary mixture of fluid (heavy and light elements). The domain initially consists of two layers: a convection zone of uniform composition, on top of a region stabilized by a composition gradient. The top of the convection zone is constantly cooled so that convection propagates downwards. We focus on how rotation affects the mixing of heavy material at the lower convective boundary.

In our simulations, as in our derivation above, we assume that the length scale of the fluid motions is much smaller

¹ A full derivation including the mixing efficiency, interfacial heat transport, and thermal effects on the density can be found in Fuentes & Cumming (2020).

Figure 1. Volume renderings of the z component of the vorticity $\omega = \nabla \times u$ for the non-rotating case (left) and rotating case (right). For both cases, the snapshots are shown at times when the bottom of the convection zone has expanded beyond the initial location (from z = 1 to 0.75). The Rossby number in the rotating case is Ro_{sim} ≈ 0.065 , computed using the averaged flow velocity in the convection zone, and thickness of the convection zone.

Figure 2. Horizontally-averaged profiles of composition \overline{C} , convective composition flux \overline{wC} , and the kinetic energy flux in the vertical direction $(1/2)\overline{wu^2}$ (left, middle, and right panel, respectively). The overline denotes that variables are averaged over the horizontal directions. Note that $u^2 = u^2 + v^2 + w^3$, where u, v, and w are the x, y, and z components of the velocity. The results are shown at at a times where the convection boundary is located at z = 0.75 (i.e., h = 1.25) for both runs. This time corresponds to t = 3750 for the non rotating case, and t = 11500 for the rotating case. The background colors distinguish between the convection zone and the stable region.

than a density scale height, so that the effects of curvature can be ignored and the Boussinesq approximation is valid (Spiegel & Veronis 1960). Although the density in giant planets can vary by many orders of magnitude, this approximation fully captures nonlinear mixing near the convective boundary, which is the focus of our study. In the rotating case, we consider uniform rotation throughout the fluid, and assume that gravity and rotation are aligned and point in the z direction, $\Omega = \Omega \hat{z}$, and $g = -g\hat{z}$, i.e., the simulation is at a polar latitude. The density of the fluid depends on both composition and temperature fluctuations. In what follows, all results are presented in dimensionless form. For details on the numerical setup, nondimensionalization, and code, we refer the reader to Appendices A and B.

Figure 1 shows 3D snapshots of the z component of the vorticity for both the non-rotating and rotating simulations. Initially, in both cases, the convection zone spans the upper half of the domain, $z \in [1,2]$. After significant evolution ($t \sim 3750$ for the non-rotating case, and $t \sim 11500$ for the rotating case), the bottom of the convection zone has advanced

to z=0.75, mixing the primordial composition gradient. Note that in the rotating case, it takes approximately 3 times longer for the zone to increase its vertical extent by $\Delta h=0.25$. We show later that this difference agrees with Equation (10). Rotation visibly alters the flow morphologies. In the nonrotating case, the characteristic flow length scale is similar in all directions, while in the rotating case, the horizontal length scale of the flow is much smaller than the vertical scale (as expected from the Taylor-Proudman theorem, e.g., Proudman 1916; Taylor 1917).

Figure 2 shows horizontally-averaged profiles of the composition (left), vertical convective composition flux (middle), and vertical kinetic energy flux (right); fluxes are depicted at the same instant in time as displayed in Figure 1. Rotation does not affect the composition profile, which is homogeneous in the convection zone with a transition to the primordial linear distribution in the stable region. This is expected because mass conservation requires that the amount of material transported and mixed in the convection zone depends only on the thickness of the convective layer, $\Delta C = 0.5 |dC_0/dz|h$. The

initial composition in the convection zone is C = 0.5, and with $|dC_0/dz| = 1$ and $\Delta h = 0.25$ giving $\Delta C = 0.125$, the expected evolved convection zone composition is C = 0.625, which is what we observe (see left panel). In the rotating case, both the convective composition flux and the kinetic energy flux are smaller by a factor of ≈ 3 when compared with the values of the non-rotating case (see middle and right panels), supporting both our hypotheses that rotation decreases the vertical transport of dense material and that this reduction is related to the kinetic energy flux. Although we only focus on the compositional transport and kinetic energy flux, it is worth mentioning that the thermal structure of the fluid across the box is similar to that of the composition. The only difference is that in the non-rotating case, the convection zone tends to be isothermalized by strong turbulence, while in the rotating case, a small temperature gradient tends to be sustained in the convection zone (this has been reported in previous studies of thermal convection in rotating flows, see, e.g., Julien et al. 1996b; Cheng et al. 2020).

We expect from the entrainment rates calculated in Section 3 that the convection zone will grow more rapidly in the nonrotating case than the rotating case. We quantify this difference by measuring the size of the convection zone h as a function of time. We define the bottom of the convection zone as the location where the convective composition flux is maximized (see Figure 2, middle), so that h is the distance between that location and the top of the box. Figure 3 (a) shows h vs. time for the two cases; as expected, h in the non-rotating case grows more rapidly than in the rotating case. We fit a power-law function of the form $h(t) = [h_0^{1/n} + K(t - t_0)]^n$, where h_0 is the size of the convection zone at initial time t_0 , and K is a constant. In both simulations, we demand that $h_0 = 1$, since initially the upper half of the box is mixed. The time t_0 is formally the time when the convection zone starts to grow. This only occurs after the convective turbulence is fully established. The initial state in our simulations is one of quiescence. In the non-rotating case, the convection continues to form and equilibrate up to $t_0 = 225$ and only then does entrainment of the stable fluid begin. The convection in the rotating case takes longer to be established, $t_0 = 325$.We find $K \approx 1.61 \times 10^{-4} (6.62 \times 10^{-5})$ and $n \approx 0.49 (0.4)$ in the non-rotating (rotating) case. These values are close to what is predicted by the simplified model in Section 3, where the predicted powerlaw index is n = 1/2 = 0.5 for the nonrotating case, and $n = 5/12 \approx 0.41$ for the rotating case. In dimensionless form, the predicted values of the prefactor are $K = 4(R_o/Pe_{\rm ff}) \sim 10^{-4}$ for the non-rotating case, and $K = (24/5)R_o (\text{Ro}_{\text{ff}}/\text{Pe}_{\text{ff}}^2)^{3/5} \sim 2 \times 10^{-5}$ for the rotating case, where the input dimensionless parameters R_{ρ} , Pe_{ff}, and Ro_{ff}, are the density ratio, and the Peclet and Rossby numbers based on the free-fall velocity, respectively. The reader is referred to Appendix A for more details on the nondimensionalization.

Finally, we measure the Rossby number of the flow, $Ro_{sim} = ||u||/2\Omega h$, where ||u|| and h are the magnitude of the flow velocity averaged within the convection zone and the thickness of the convection zone, respectively. We find

Figure 3. Panel (a): Thickness of the convection zone h as a function of time t. The results are shown for both the rotating and non-rotating cases. The solid lines correspond to the best fits of the form $h(t) = [h_0^{1/n} + K(t - t_0)]^n$ for each case. We obtain $n \approx 0.49$ for the non-rotating case (compared to the analytic prediction n = 0.5) and $n \approx 0.40$ for the rotating case (compared to the analytic prediction $n = 5/12 \approx 0.41$). See text for more details. Panel (b): $\operatorname{Ro}_{\text{sim}}$, $\operatorname{Ro}_{\text{sim}}^{1/2}$, and $F_{K,R}/F_{K,NR}$, as a function of the thickness of the convection zone, h. Note that $\operatorname{Ro}_{\text{sim}}^{1/2}$ has similar values to $F_{K,R}/F_{K,NR}$, giving support to Equation (4).

 $Ro_{sim} \approx 0.065$, which decreases slightly as the convection zone evolves and deepens (see Figure 3b). When compared with the ratio between the kinetic energy flux in the rotating and non-rotating case (as predicted by mixing-length theory, see Equation 4), we find $Ro_{sim}^{1/2}/(F_{K,R}/F_{K,NR}) \approx 0.87$. Finally, our theory (Equation 10) predicts that mixing a depth Δh should take longer in the rotating case by a factor of $(5/6)Ro^{-1/2}$. In our simulations this difference is approximately a factor of 3, close to $(5/6)Ro_{sim}^{-1/2} \approx 3.3$.

5. Summary and Discussion

In this work, we studied the effect of rotation on the compositional transport across the boundary between a convection zone and a stable region (e.g., a core-envelope interface in a gas giant). Mixing length theory predicts that rotation reduces the convective velocity (compare Equations 1 and 3). For Jovian conditions at $t \sim 10^8$ yrs since formation, this corresponds to a velocity reduction of approximately a fac-

tor of 6. Consequently, the kinetic energy flux available for the entrainment and mixing of heavy material gets reduced by a factor of $(U_{\rm NR}/U_{\rm R})^3 \sim {\rm Ro}^{-1/2} \sim 6^3 \sim 200$ (see Equation 4). Using the prescriptions for the convective velocity from mixing-length theory, we derived a simple analytical model for the rate of entrainment and the propagation of a convection zone. The thickness of the outer convection zone follows $h(t) \propto t^{1/2}$ in the non-rotating case (Equation 6), and $h(t) \propto \Omega^{1/4} t^{5/12}$ in the rotating case (Equation 7), supporting the hypothesis that rotation decreases compositional mixing. From this model, the timescale to mix a stable layer of vertical size L is larger by a factor of (5/6)Ro^{-1/2}, where Ro is the Rossby number, when rotation is taken into account in the convective velocity (Equation 10). We ran two numerical experiments (including and not including rotation) of convective entrainment and found a good agreement between the analytic predictions and the simulations (e.g., see Figures 2-3).

The agreement between our numerical simulations and the mixing-length theory predictions is encouraging. The mixing time can increase by two orders of magnitude for Jupiter-like values at $t \sim 10^8$ years after formation. This could significantly reduce the rate of core erosion, preventing strong mixing without the need to invoke a double-diffusive staircase. For example, Moll et al. (2017) derived that the rate at which core mass is transported into the envelope is given by $\dot{M}_{\rm core} = \gamma^{-1} \alpha L_{\rm core}/c_P$, where $L_{\rm core}$ is the luminosity at the core-envelope interface, and γ^{-1} is ratio of the buoyancy flux associated with heavy-element transport to the buoyancy flux associated with heat transport. Using 3D simulations of nonrotating incompressible flows, Moll et al. (2017) constrained $\gamma^{-1} \gtrsim 0.5$ for Jupiter conditions. In the entrainment model investigated in this work, the rate at which mass is transported into the outer convection zone is $\dot{M}_{\rm core} \propto hdh/dt$. Then, it follows that rotation reduces the erosion rate by a factor of $\dot{M}_{\rm core,R}/\dot{M}_{\rm core,NR} = \gamma_{\rm R}^{-1}/\gamma_{\rm NR}^{-1} \approx (N/2\Omega)^{1/2} (24Nt/5)^{-1/6}$ (where we have used Equations 6 and 7). Using values for Jupiter at $t \sim 10^8$ years after formation, we estimate $\gamma_{\rm R}^{-1}/\gamma_{\rm NR}^{-1}\approx 0.01$. Although we have derived this ratio with a rather simple model, the fraction is significantly smaller than unity and illustrates the importance of rotation for convective boundary mixing.

Although our numerical experiments are done in a Cartesian box and assume that gravity and rotation are parallel to each other (as expected at the poles of the planet), the reduction in the convective velocity does not depend on the exact geometry or shape of the composition profile. However, numerical simulations with misaligned gravity and rotation have shown that thermal mixing is not uniform across latitude (e.g., Dietrich & Wicht 2018; Currie et al. 2020). A logical next step would be to investigate this problem using spherical geometry and a primordial composition gradient that is more consistent with formation models (e.g., Stevenson et al. 2022).

Our simulations do not include density stratification, as we adopt the Bousinessq approximation which formally limits the vertical scale to be much less than a density scale height. Including density stratification and compressibility will change

the mixing rate by a combination of two effects. First, the potential energy required to mix a region should decrease; while composition is uniformly mixed in the convection zone in both cases, the compressible case mixes the density to the adiabatic gradient, whereas Boussinesq convection mixes the density to a constant value, which requires a greater energy expenditure. Second, stratification increases the asymmetry between upflows and downflows and in turn increases the net kinetic energy flux, so it should matter whether a stable entraining region is at the top or bottom of a convection zone (see e.g., Fig. 4 Meakin & Arnett 2007). At this time we cannot speculate on the net result of those effects. To our knowledge, there are no simulations of convective entrainment accounting for both composition gradients and rotation in a compressible flow. We will investigate this problem in a future paper.

We encourage future work on hydrodynamic models of gas giants, as improved mixing prescriptions at convective boundaries provide a promising avenue for better aligning 1D evolution models with observational inferences of gas giant interiors from NASA's missions Juno and Cassini.

Appendix

A. Fluid equations & Initial Conditions

We study convective entrainment in rapidly rotating flows with composition and temperature gradients. To do so, we adopt the Boussinesq approximation of the fluid equations and evolve both temperature T and composition C. We normalize the fluid equations using as units of length and time the initial size of the convection zone h_0 and the free fall time across it $t_{\rm ff} = h_0/u_{\rm ff}$ (where $u_{\rm ff} = \sqrt{\alpha g h_0 \Delta T_F}$, g is the acceleration due to gravity, and $\alpha = -(\partial \ln \rho / \partial T)|_C$ is the coefficient of thermal expansion). Further, for the characteristic temperature scale we utilize $\Delta T_F = F_0 h_0 / \rho_0 \kappa_T c_P$, with ρ_0 being the background density, F_0 the cooling energy flux at the surface of the convection zone, κ_T the thermal diffusivity, and c_P the specific heat at constant pressure. The units of temperature and composition are respectively $[T] = \Delta T_F$, and $[C] = \Delta C_0$ (i.e., the initial composition change across the stable region). The corresponding normalizations for the kinetic, heat and composition fluxes are $[F_K] = (1/2)\rho_0 u_{\rm ff}^3$, $[F_H] = \rho c_P u_{\rm ff} \Delta T_F$, and $[F_X] = \rho_0 u_{\rm ff} \Delta C_0$, respectively.

The nondimensional equations are

$$\nabla \cdot \boldsymbol{u} = 0 \tag{A1}$$

$$\partial_t \boldsymbol{u} + \boldsymbol{u} \cdot \nabla \boldsymbol{u} + \nabla \boldsymbol{\varpi} + \operatorname{Roff}^{-1} \hat{\boldsymbol{z}} \times \boldsymbol{u} = \left(T - \frac{C}{R_{\rho}} \right) \hat{\boldsymbol{z}} + \frac{\operatorname{Pr}}{\operatorname{Pe}_{\mathrm{ff}}} \nabla^2 \boldsymbol{u},$$
(A2)

$$\partial_t T + \boldsymbol{u} \cdot \boldsymbol{\nabla} T = \frac{1}{\text{Pe}_{\text{ff}}} \boldsymbol{\nabla}^2 T,\tag{A3}$$

$$\partial_t C + \boldsymbol{u} \cdot \boldsymbol{\nabla} C = \frac{\tau_0}{\text{Pe}_{\text{ff}}} \boldsymbol{\nabla}^2 \overline{C} + \frac{\tau}{\text{Pe}_{\text{ff}}} \boldsymbol{\nabla}^2 C', \tag{A4}$$

where u = (u, v, w) is the velocity field, and ϖ is the reduced pressure. Overbars denote horizontal averages and primes denote fluctuations around that average, such that e.g., $C = \overline{C} + C'$. Note that we reduce diffusion on \overline{C} by choosing $\tau_0 < \tau$ to ensure its evolution is due to advection.

In the equations above, there are 5 dimensionless numbers that characterize the evolution of the flow. These are the freefall Rossby number, Peclet number, density ratio, Prandtl number, and inverse Lewis number, which are defined respectively as

$$Ro_{ff} = \frac{u_{ff}}{2\Omega h_0}, Pe_{ff} = \frac{u_{ff}h_0}{\kappa_T}, R_{\rho} = \frac{\alpha\Delta T_F}{\beta\Delta C_0}, Pr = \frac{v}{\kappa_T}, \tau = \frac{\kappa_C}{\kappa_T},$$
(A5)

where Ω is the rotation rate, $\alpha \equiv (\partial \ln \rho / \partial T)|_C$ and $\beta \equiv (\partial \ln \rho / \partial C)|_T$ are respectively the coefficient of thermal and compositional expansion/contraction, ν is the kinematic viscosity, and κ_T and κ_C are the thermal and compositional diffusivity, respectively. Note that R_ρ is the ratio between the destabilizing and stabilizing effect of the thermal and compositional buoyancy.

The initial structure of the fluid is composed of two layers, defined across $z \in [0, 2]$, where the temperature and

composition are respectively

$$T(z) = 2 - z$$
, $C_0(z) = \begin{cases} 0.5 & z > 1 \\ 2 - z & z < 1 \end{cases}$ (A6)

Step functions are not well represented in pseudospectral codes, so we use a smoothed Heaviside function centered at $z = z_0$,

$$H(z; z_0, d_w) = \frac{1}{2} \left(1 + \operatorname{erf} \left[\frac{z - z_0}{d_w} \right] \right). \tag{A7}$$

where erf is the error function; to construct $C_0(z)$ in Equation. A6, we set

$$C_0(z) = (2-z)[1-H(z;1,0.05)] + \frac{1}{2}H(z;1,0.05).$$
 (A8)

We fix the flux of temperature and composition at the top of the domain and we fix their values at the bottom of the domain, so the boundary conditions for temperature and composition are $\partial_z T(z=2)=-1$, T(z=0)=2, $\partial_z C(z=2)=0$, and C(z=0)=2. The boundary conditions for the velocity are stress free at the upper boundary $(\hat{z} \cdot \boldsymbol{u} = \hat{x} \cdot \partial_z \boldsymbol{u} = \hat{y} \cdot \partial_z \boldsymbol{u} = 0)$ at z=2 and no-slip at the lower boundary in the stable fluid $(\boldsymbol{u}=\boldsymbol{0})$ at z=0.

The simulations in this work use $Pe_{ff} = 4.4 \times 10^3$, $R_o^{-1} = 10$, Pr = τ = 0.5, and τ_0 = 10⁻³. We set the Coriolis force to be identically zero in the non-rotating case ($Ro_{ff} = \infty$), while in the rotating case $Ro_{\rm ff}=0.81$. Under Jovian conditions, $Ro_{\rm ff}=O(10^{-5})$, $Pe_{\rm ff}=O(10^{10})$ $\tau\approx Pr=O(10^{-2})$, and $R_{\rho}^{-1}=O(10)$ (see e.g., Guillot et al. 2004; French et al. 2012), but we make clear that the density ratio is very uncertain given our ignorance on the compositional and thermal stratification in the deep interiors of the gas giants.) Our simulations are as turbulent as possible and are qualitatively in the same regime as gas giants (Ro_{ff} < 1, Pe_{ff} \gg 1, Pr < 1, τ < 1, R_{ρ}^{-1} > 1). It is worth mentioning that although the input Rossby number Roff is close to unity, the Rossby number computed from the simulated flows is much smaller (≈ 0.065). It would be possible to decrease the Rossby number, but the time that would be required for the convection zone to mix material would be significantly longer and beyond our computational resources.

B. Simulation Details

We time-evolve equations A1-A4 using the Dedalus pseudospectral solver (Burns et al. 2020) version 3^2 using timestepper SBDF2 (Wang & Ruuth 2008) and CFL safety factor 0.2. All variables are represented using a Chebyshev series with 512 terms for $z \in [0, L_z]$, with $L_z = 2$, and Fourier series in the periodic x and y directions. In the non-rotating case, $x \in [0, L_x]$, $y \in [0, L_y]$, with $L_x = L_y = 3$, and each direction has 192 terms. In the rotating case, $L_x = L_y = 2$,

² We use the code in the master branch of the https://github.com/DedalusProject/dedalus repository, and use the commit with short-sha 29f3a59.

and each direction has 128 terms. To avoid aliasing errors, we use the 3/2-dealiasing rule in all directions. To start our simulations, we add random noise temperature perturbations sampled from a normal distribution with a magnitude of 10^{-5} to the initial temperature field. The Python scripts used to run the simulations in this work are available online as a Git repository³, and backed up in a Zenodo repository (Anders et al. 2023).
