Abstract

High-content cellular imaging, transcriptomics, and proteomics data provide rich and complementary views on the molecular layers of biology that influence cellular states and function. However, the biological determinants through which changes in multi-omics measurements influence cellular morphology have not yet been systematically explored, and the degree to which cell imaging could potentially enable the prediction of multi-omics directly from cell imaging data is therefore currently unclear. Here, we address the question of whether it is possible to predict bulk multi-omics measurements directly from cell images using Image2Omics – a deep learning approach that predicts multi-omics in a cell population directly from high-content images stained with multiplexed fluorescent dyes. We perform an experimental evaluation in gene-edited macrophages derived from human induced pluripotent stem cell (hiPSC) under multiple stimulation conditions and demonstrate that Image2Omics achieves significantly better performance in predicting transcriptomics and proteomics measurements directly from cell images than predictors based on the mean observed training set abundance. We observed significant predictability of abundances for 5903 (22.43%; 95% CI: 8.77%, 38.88%) and 5819 (22.11%; 95% CI: 10.40%, 38.08%) transcripts out of 26137 in M1 and M2-stimulated macrophages respectively and for 1933 (38.77%; 95% CI: 36.94%, 39.85%) and 2055 (41.22%; 95% CI: 39.31%, 42.42%) proteins out of 4986 in M1 and M2-stimulated macrophages respectively. Our results show that some transcript and protein abundances are predictable from cell imaging and that cell imaging may potentially, in some settings and depending on the mechanisms of interest and desired performance threshold, even be a scalable and resource-efficient substitute for multi-omics measurements.

Figure 1: An overview of the Image2Omics approach presented in this work. We generated cell imaging data for a cellular system under a wide range of CRISPR perturbations and exposed to multiple stimuli (top left; in this work: M1- and M2-polarised macrophages). We then trained a machine learning model (Image2Omics; right) using the paired samples where both imaging and multi-omics (transcriptomics and proteomics) were available to learn how to predict the multi-omics layers directly from high-content images alone.

Introduction

Transcriptomics, proteomics and high-content imaging are rich and complementary tools for interrogating state and function of cellular systems at high-resolution across multiple layers of biology [1, 2, 3, 4]. However, measuring transcriptomics and proteomics – even with optimised technologies [5, 6, 7] - is resource- and time-intensive [8] and often the main bottleneck when conducting studies aiming to elucidate molecular biology. High-content imaging on the other hand is a high-throughput technology that can generate measurements at scale in a cost- and time-effective manner [9, 10, 11, 12]. Given that molecular biology and cell morphology¹ regulate each other in a complex interplay [13, 14, 15, 16], we hypothesise that high-content images of cells under controlled conditions contain information that enables the approximate reconstruction of the underlying molecular state. However, to the best of our knowledge, whether and to what degree the various multi-omics layers can be reconstructed from high-content imaging data has not yet been established. The ability to reconstruct molecular biological measurements with multi-omics technologies could aid in optimising experimental throughput while potentially retaining the same information content at lower resource expenditure.

¹For brevity, throughout this work, we refer to cell morphology as a term that includes both image-derived morphological as well as protein localisation features from antibody staining.

Establishing the predictability of multi-omics from cell images is difficult because (i) both cell images and multi-omics layers are rich in information content and manually interpreting their contents for associations with underlying omics markers is infeasible and prone to over- and mis-interpretation of mechanisms, and (ii) a sufficiently representative set of reference images with omics annotations is necessary to evaluate prediction performance across the diversity of cell states in a target cell population. Morphological features corresponding to high-level function, such as elongated shapes in M1/M2-polarized macrophages [17] and the various characteristic shapes adopted by microglia in healthy and diseased conditions [18], are established in literature, but - to the best of our knowledge - no comprehensive map relating cellular morphology and protein localisation to the underlying molecular biology exists to date.

The translatability between transcriptomics measurements and high-content imaging has previously been studied in the single-cell context by [19] - where multi-domain autoencoders are used to translate between single-cell imaging and transcriptomics readouts - and by [20], wherein a model for generating nuclear and whole-cell morphology from single-cell gene expression profiles was developed. Outside of high-content cell imaging, the predictability of transcriptomics was previously demonstrated from hematoxylin and eosin (H&E) stained histopathology images [21, 22, 23], from positron emission tomography (PET) data [24], from computerized tomography (CT) data [25], from computerized tomography angiography (CTA) data [26] and from imaging flow cytometry data [27]. In addition, [28, 29] introduced methods for integrating single-cell multi-omics measurements and imaging data [30, 31], and a large-scale dataset of paired gene expression and morphological profiles of cells under perturbations was released by [32]. However, to the best of our knowledge, the predictability of multi-omics measurements directly from high-content cell imaging data has not yet been studied.

In this work, we demonstrate that transcriptomics and proteomics measurements can be predicted directly from high-content imaging data using a machine learning model, Image2Omics, trained on paired multi-omics measurements and cell images collected in hiPSC-derived macrophage populations under two stimulation conditions and under 152 CRISPR-based perturbations to cover a diverse range of cellular states. To the best of our knowledge, this work is the first to demonstrate that the prediction of multi-omics from cell imaging can be achieved with symmetric mean average percentage errors (SMAPE) across transcriptome and proteome as low as respectively 5.46% (95% CI: 4.47%, 7.85%) and 9.95% (95% CI: 8.52%, 12.16%) across predictable transcript and protein abundances, respectively, under M1 stimulation and 11.39% (95% CI: 10.27%, 12.90%) and 7.21% (95% CI: 6.24%, 8.64%) across predictable transcript and protein abundances under M2 stimulation is possible. Our results imply that high-content imaging data is predictive of transcriptomics and proteomics measurements, and may - in some settings and depending on the mechanisms of interest - be an appropriate substitute for multi-omics measurements, particularly if a paired omics and imaging dataset in the same cell population under comparable conditions is available.

Results

Image2Omics. Image2Omics is a machine-learning model trained to predict bulk transcriptomics and proteomics directly from high-content images. Image2Omics uses a multiple instance learning approach to train a ResNet architecture deep convolutional neural network that takes in cell-centered patches as input and produces a latent representation of the cell images from which transcript and protein abundance measurements are predicted (see Section 5.3). To collect the training and test data for developing and evaluating Image2Omics, arrayed wetlab experiments were conducted in hiPSC-derived [33] macrophages that were stimulated to M1 and M2 states and perturbed with clustered regularly interspaced short palindromic repeats (CRISPR) knockouts to induce a diverse range of transcriptomic and proteomic states. Measurements were subsequently taken for bulk proteomics, bulk transcriptomics, and high-content imaging (see Section 5.1 for details). We empirically evaluated the performance of Image2Omics for predicting bulk transcriptomics and proteomics measurements from high-content imaging data by comparing the predictions of Image2Omics to measured ground truth observations in held-out test set across 10 different random splits (see Section 5.4).

Predictability by gene product. We evaluated the degree to which the abundance of each gene product (transcripts and proteins) can be predicted directly from cellular images by comparing the prediction performance of Image2Omics to the Mean Predictor baseline. Mean Predictor is defined as a model that predicts the mean abundance value of the same gene product in the training data irrespective of inputs. We calculated the r^2 correlation between the ground truth and predicted abundances of gene products in the test set to determine the magnitude of the predictability improvement of the gene product abundances stemming from the use of the cellular imaging data (Figure 2). In addition, for each gene product, we performed a one-sided Mann-Whitney-Wilcoxon test with $\alpha < 0.05$ to determine whether Image2Omics produces a statistically significant improvement in predictability over the Mean Predictor (Figure 3). Out of all gene products that met minimal expression thresholds, we found that gene products are significantly predictable from cellular images in respectively 22.43% (95% CI: 8.77%, 38.88%) and 22.11% (95% CI: 10.40%, 38.08%) of cases for transcripts in M1 and M2 polarised macrophages and 38.77% (95% CI: 36.94%, 39.85%) and 41.22% (95% CI: 39.31%, 42.42%) of cases for proteins in M1 and M2 polarised macrophages (Figure 3). We also found that, compared to transcript abundances, more protein abundances are significantly predictable by Image2Omics - across all gene products, protein abundances are more predictable than transcripts and those predictions are more often significant (Figure 3). A selection of the top and bottom 10 gene products with the respectively lowest and highest r^2 values and SMAPEs for predicting gene product abundances achieved by Image2Omics is presented in Table 4.

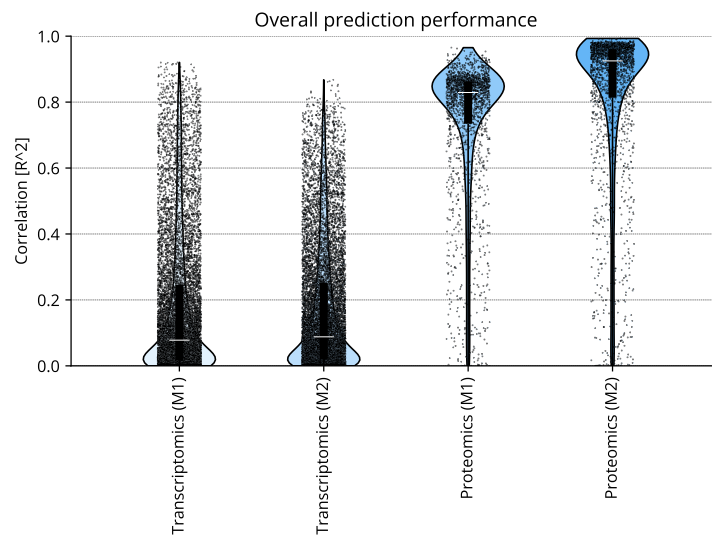

Figure 2: Correlation coefficients (r^2 ; y-axis) between observed protein and transcript abundances and those predicted by Image2Omics on held out test set samples in M1 and M2 polarised states (higher = more predictable). Dots correspond to transcript or protein markers and violins indicate the distribution of correlation coefficients across the transcriptome and proteome in M1 and M2 states. A number of selected genes from the top and bottom 10 for each stimulus and gene product with the respectively lowest and highest prediction errors are available in Table 4.

Figure 3: Charts displaying the percentage of transcripts (top) and proteins (bottom) in M1 (left column) and M2 (right column) polarised states that are significantly ($p < 0.05$) more predictable ($SMAPE_{Image2Omics} < SMAPE_{mean}$) from image data on held-out test data using Image2Omics than using the mean observed abundance in the training set (purple), the percentage of non significant marker proteins and transcripts (light pink) and those filtered out due to low or no observed expression in the experiment (light grey). We found that imaging data was informative to enable significant predictability of the majority of abundance levels in M1 and M2 conditions and in both proteomics and transcriptomics. A larger fraction of abundances was significantly predictable from cellular imaging when predicting proteomics than in transcriptomics.

Predictability by subcellular localisation. We also evaluated the prediction error measured by r^2 broken down by subcellular localisation of the gene product as catalogued in the Human Protein Atlas (<https://www.proteinatlas.org/>) [34]. We observed that gene products localised in cytosol and nucleoplasm and vesicles were overall associated with higher SMAPEs compared to those localised in nucleoli and endoplasmatic reticulum – a pattern that held across both protein and transcript abundances as well as macrophage polarisation states (Figure 4).

Predictability by pathway membership and abundance. We also evaluated whether and to what degree there are linear associations between select properties of genes (pathway membership, localisation and abundance levels) and their predictability as measured by the r^2 correlation coefficient between Image2Omics predicted and experimentally observed test set abundance levels. With the exception of M1 transcriptomics, we observed that abundances are more predictable for on average more highly expressed protein products, and that membership in a variety of pathways is associated with differences in predictability of protein and transcript abundances (Figure 5).

Qualitative analysis of feature importance. To better understand the factors associated with better prediction performance for individual gene products, we qualitatively investigated the cellular images corresponding to a selection of the abundance predictions, the prediction performance of Image2Omics for those images, and feature attribution heatmaps that indicate areas of focus for the model (Figure 6). By visual analysis, we found that Image2Omics focused on the general cell shape with an apparent enhanced emphasis on the nucleus - a finding that was robust across perturbations, stimulation conditions and predicted omics marker type. In addition, we found that the generated attribution maps were distributing weight across larger parts of the image in image tiles that contained multiple cells in addition to the cell that the tile was centred on, which indicates that Image2Omics in some cases attempted to leverage information distributed across cells in a single tile.

Cell image embedding. In addition, we evaluated the ability of the image-based feature embedding learnt by the image-embedding component of Image2Omics to differentiate between perturbations and functional states of cell populations (Figure 7). We found that the image-based feature embedding learnt by Image2Omics is able to differentiate between various cell conditions and captures rich information on cell function and state – implying that its ability to predict omics markers is closely linked to its capability to accurately identify cell states and conditions.

Discussion

The ability to predict omics markers directly from cellular images could be of high utility for applications in cell-based assays where the use of omics technologies

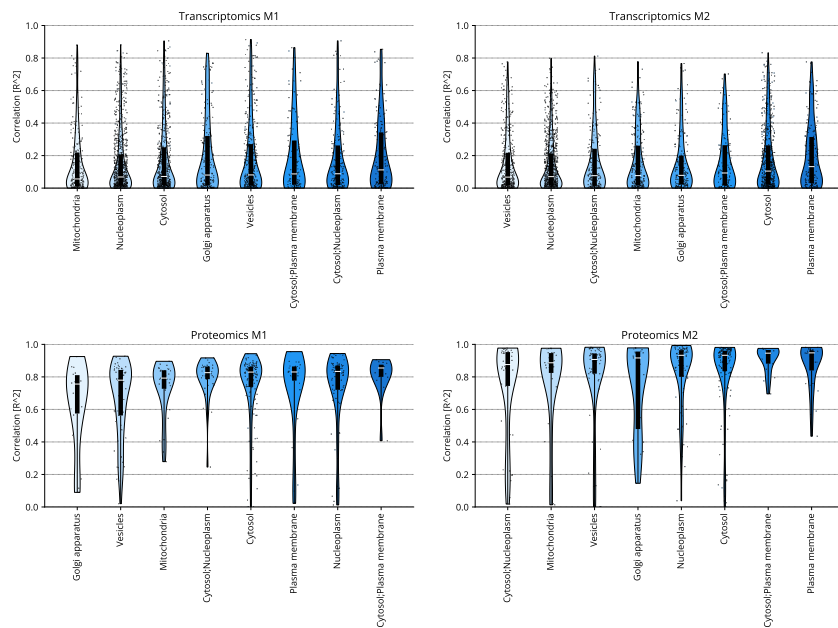

Figure 4: Performance in predicting measured transcript (top) and protein (bottom) abundances from image data alone measured in terms of correlation (measured in r^2 ; y-axis, lower is better) on held-out test images of M1 (left column) and M2 (right column) macrophages broken down by subcellular location (x-axis) sorted from best (left) to least (right) predictable on average for the top 8 largest subcellular localisation categories. We find that gene products with subcellular location in nucleoli are associated with lower predictability than those located in the cytosol and nucleoplasm, and that this pattern holds both across cell states and omics layers. Note that gene products without known subcellular location are not shown here. Performance is calculated over all perturbed and unperturbed cell states to cover a diverse range of cellular states.

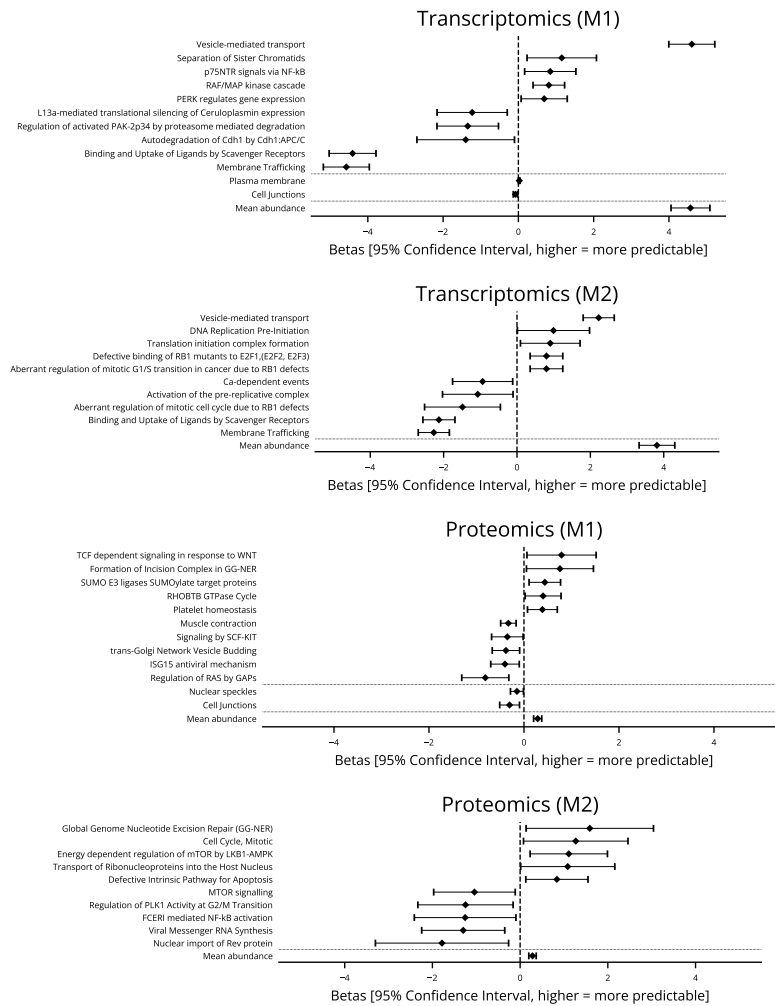

Figure 5: Forest plots indicating the associations (y axis) with a significantly ($p < 0.05$) higher/lower predictability of protein and transcript abundances on held-out test data (x-axis; measured in linear regression beta coefficients; higher = more predictable) in M1 and M2 conditions including pathway membership of the predicted gene (first section from the top; top 5 pathways associated with lower and higher predictability pathways shown), sub-cellular localisation of the gene (second section from the top or empty if no significant association), and mean abundance levels observed in the training set (bottom-most section). We found that - with the exception of M1 transcriptomics - abundances are more predictable for on average more highly expressed protein products, and that membership in a variety of pathways is associated with differences in predictability of protein and transcript abundances.

Figure 6: Selected gene products (from top to bottom: PDCD6IP, TFPI2, DDI2, HLA-A) and the associations between the actual measured abundances and the predicted abundances based on the imaging data from the held-out test fold (leftmost column), sample cell-centred image patches (centre column) and the assigned attributions that visualise the importance assigned to pixels in the original image by the model to make its prediction (rightmost column). We note that it is important to consider the performance of the predictive model when interpreting attribution maps as emphasised features' relevance may be insignificant when the model's predictive performance is poor.

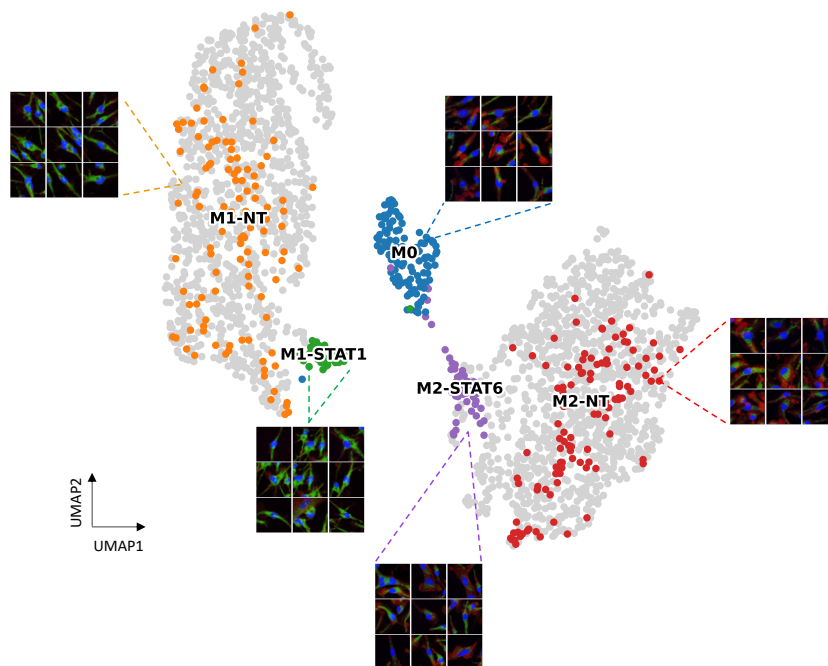

Figure 7: Learned morphological feature embeddings in a 2-dimensional Uniform Manifold Approximation, Projection for Dimension Reduction (UMAP) [35] space as derived from high-content cell imaging (left-hand plot). The learned morphological embedding is well able to distinguish between selected genetic perturbations that have emphasised morphological effects (other colors with callouts) - indicating that morphological features recapitulate differences in cell state as intended by the model training (Section 5.3) and that the cell imaging embeddings carry rich information on cell function and state. Plate batch effects were removed using the CORrelation ALignment (CORAL) algorithm [36].

to measure molecular markers may not always be technically feasible or cost-effective in terms of time and resources. In contrast, high-content cellular imaging is a scalable and cost-effective alternative that is amenable to high-throughput and automated experimentation. As demonstrated in this study, high-content imaging data contains rich information on cellular state and function that is at least partially overlapping with that generated via omics readouts. In addition, unlike measurement protocols for omics technologies that require the dissolution of cells (such as, e.g., RNAseq), cellular imaging has the additional advantage of being a non-destructive method for obtaining protein and transcript abundance measurements from cells and could thus enable the tracking of omics marker evolution in the same cell population over time. Image-based prediction of omics markers could have particular utility for iterative experimental exploration campaigns [37] in a fixed set of conditions and cell types where sufficient training data with paired omics and imaging are available. Given the shared information content in cellular images and omics measurements, potential avenues for future work could be in exploring the inverse task of generating images from multi-omics measurements [20, 38]. It is important to note that the predictions of Image2Omics are associational based on observed patterns in its training data, and – although interpreting models such as Image2Omics can help us better understand the interplay between cell morphology and molecular measurements – uncovering the causal molecular mechanisms [39, 40] that give rise to changes in cellular morphology and gene product localisation (and vice-versa) remain open challenges.

The ability of Image2Omics to predict omics measurements across a wide range of gene products from cellular imaging data implies that at least some of the information on cellular state and function contained in cellular images is overlapping with that described by omics measurements. The results presented in this study therefore demonstrate that gene products’ proteomics and transcriptomics measurements can indeed be predicted with significantly better performance with cellular imaging data than in its absence, with considerable prediction performance in many cases – as implied by the known interplay between cellular morphology and protein localisation and molecular biology [13, 14, 15, 16]. However, for these predictions to reach practical utility, it is likely necessary to reach a certain minimal performance threshold for predicting a defined set of markers that depends on the use-case of interest. Given that not all gene products are strongly predictable from cellular images and that certain categories of markers appear to be on average associated with higher prediction errors (for example, cytosol-localised gene products as shown in Figure 4), imaging-based omics prediction by Image2Omics cannot be considered a general substitute of omics measurements. The measured prediction performance for the gene products of interest in the cellular population of interest can, however, serve as a guideline to which omics layers for which gene products could potentially be substituted by predictions based on cellular imaging data.

Limitations. A major limitation of the Image2Omics approach to predicting omics measurements directly from cellular images is that sufficient training data consisting of paired omics and cellular imaging data for a cell population of interest, or alternatively a pre-trained model initialised with such training data, are required. Similar to other machine-learning domains with shared commons (for example, the HuggingFace model repository (<https://huggingface.co/models>)), a potential approach to combat this limitation could be to create a central resource of shared pre-trained omics prediction models for a variety of cell types that could enable researchers to leverage the previous experimental work of others. A potential barrier to a collaborative effort to generate shared pre-trained Image2Omics models could be the difficulty of standardising and pooling imaging data collected under different experimental configurations and using different equipment. In addition, although the presented experimental evaluation in this work considered a wide range of extreme cell states induced by genetic perturbations and different experimental stimulations, additional experiments are needed to substantiate the robustness of Image2Omics predictions - including testing across different donors, in single cells rather than batches and across a wider range of stimuli, perturbations and cell types than presented in this study, so that the predictability of various omics modalities across biological and experimental contexts can be fully determined.

In summary, we developed Image2Omics – a new deep learning method for predicting bulk transcriptomics and proteomics directly from cell images. We demonstrated that image information is predictive of multi-omics for 5903 (22.43%; 95% CI: 8.77%, 38.88%) and 5819 (22.11%; 95% CI: 10.40%, 38.08%) transcripts out of 26137 in M1 and M2-stimulated macrophages respectively and for 1933 (38.77%; 95% CI: 36.94%, 39.85%) and 2055 (41.22%; 95% CI: 39.31%, 42.42%) proteins out of 4986 in M1 and M2-stimulated macrophages respectively with SMAPEs as low as 5.46% (95% CI: 4.47%, 7.85%) and 9.95% (95% CI: 8.52%, 12.16%) respectively across predictable transcript and protein abundances under M1 stimulation and 11.39% (95% CI: 10.27%, 12.90%) and 7.21% (95% CI: 6.24%, 8.64%) respectively across predictable transcript and protein abundances under M2 stimulation. To the best of our knowledge, this is the first study that quantifies the predictability of transcriptomics and proteomics from high-content cellular images across a wide range of cellular states and under perturbations. Our results imply that high-throughput cellular imaging assays could, in some settings and depending on the mechanisms of interest, be a scalable and cost-effective alternative to direct multi-omics measurements, and also highlight a rich interplay between information contained in cellular images and the underlying molecular state of a cell population. We believe our results warrant future studies on the predictability of additional multi-omics layers (for example, metabolomics and secretomics) from cellular images and on the predictability of multi-omics across additional cell types that are amenable to paired imaging and multi-omics workflows.

Materials and methods

Data Acquisition

A library of 156 genes were knocked out in the induced pluripotent stem cell (iPSC) derived macrophages using a high throughput CRISPR (clustered regularly interspaced short palindromic repeats)-Cas9 (CRISPR associated protein 9) method [41]. Macrophages were then cultured for recovery for 6 days in 384 well plates (PerkinElmer PhenoPlate™ 384-well microplates, cat. no. 6057302). The resulting cells were stimulated for 24 hours with cytokines IFN- γ and LPS (M1-activating stimuli) or IL-4 (M2-activating stimuli). Plates were then processed for staining. Briefly, culture media (50 μ L per well) was removed using a Bravo automated liquid handler (Agilent) from each well and dispensed into a white plate (Greiner V-bottom 384-well plate, cat. no. 781280) to be utilised for cytokine readout. 50 μ L of live cell MitoTracker staining solution (MitoTracker orange (Invitrogen™, cat. no. M7510) diluted in prewarmed (37 °C) media for a final concentration of 200 nM) was immediately added into each well using a multidrop (Multidrop Combi Reagent Dispenser, Thermo Scientific). Plates were incubated in dark for 30 minutes at 37 °C, 95% relative humidity and 5% CO₂, before MitoTracker staining solution was removed with Bravo. Cells were then fixed with 30 μ L, 4% paraformaldehyde (Alfa Aesar, cat. no. J61899) per well and left for 20 minutes at room temperature in dark. Plates were washed three times with PBS-tween (0.1% v/v tween 20 (Sigma-Aldrich, cat. no. P9416) in Dulbecco's Phosphate Buffered Saline (PBS, Sigma-Aldrich, cat. no. D8537)) using a plate washer (Biotek 405 TS Microplate washer, Agilent). Cells were permeabilized adding 50uL permeabilization solution (0.1% v/v Triton X-100 (Sigma-Aldrich, cat. no. T8787) in PBS) in to each well using multidrop at medium speed and incubated at room temperature (RT) for 20 minutes. After permeabilization solution was removed, plates were washed three times with PBS-tween using plate washer and 50uL of blocking solution (0.1% v/v tween 20 and 2% v/v goat serum (Biowest cat. no. S2000-500) in PBS), was added into each well using multidrop at a medium speed. Plates were sealed and left in dark at RT for 2 hours. Blocking solution was removed using plate washer and 30uL per well primary antibody mix (1:1000 anti-CD38 (Thermo cat. no. MA1-19316) for M1 or 1:1000 anti-MAOA (Abcam cat. no. ab240031) for M2, in blocking solution) was added. Plates were sealed and stored at 4 °C in a dark fridge overnight. Following day, after three times washing with PBS-tween, a secondary antibody mixture (1:1000 nuclear stain (Hoechst 33342 Thermo H3570), 1:500 Alexa Fluor 488 (for CD38 (Thermo cat. no. A11001) or for MAOA (Thermo cat. no. A32731)) and 1:400 actin stain (Thermo cat. no. A22287) in blocking solution) of 30 μ L per well was added using multidrop at medium speed. Following 2 hours of incubation at RT, plates were washed with PBS-tween using the plate washer three times and left in 50uL PBS per well for imaging analysis.

Data preprocessing. Low-expressed genes/proteins were filtered out by setting a threshold on the normalized counts. If the normalized counts are greater than zero in less than 50 out of 384 wells (13 %) in each plate, the gene/protein was eliminated from the analysis.

High-throughput 3' RNA-seq

The protocol was developed based on the DRUG-seq protocol [5]. In brief, cells in 384 well plates were washed with ice-cold PBS on BRAVO (Agilent Technologies). 18ul lysis buffer (50mM Tris-HCL pH8.0, 75mM KCL, 6%Ficoll PM-400, 0.15%Triton-100, 0.5unit/ul Thermo Fisher SUPERaseIn) was added by Dragonfly (SPT Labtech) to lyse the cells directly in each well. Plates were sealed and shake at 900rpm for 10mins. The lysate plate can be stored in -80 for up to 3 months. To start the reverse transcription (RT) 1ul bar-coded RT primers at 10nM were added to 5ul RT reaction mix (1uM TSO 5'-AAGCAGTGGTATCAACGCAGAGTGAATrGrGrG-3', 0.1mM dNTP, 0.2Mm GTP, 0.4unit/ul Thermo Fisher RNaseOUT, 2unit/ul Thermo Fisher Maxima H Minus Reverse Transcriptase, 1:20000 ERCC mix1) together with 15ul cell lysate. Plates were incubated at 42°C for 90 mins followed by 10 cycles at 50°C for 2 minutes, 42°C for 2 minutes, together with a final incubation at 85°C for 5 minutes. RT reaction mix from each well were pooled into a single sample purified with the Agencourt RNAClean XP beads (Beckman Coulter). cDNA was amplified using primer 5'- AAGCAGTGGTATCAACGCAGAGT-3', beads purified, and tagmented using TDE1 enzyme and buffer kits (Illumina). Individual libraries were indexed and sequenced on illumina Nova-seq 6000. Library was loaded at 2nM with read 1 at 20 cycles, index 1 at 8 cycles, index 2 at 0, and read 2 at 76 cycles.

Proteomics

Cells in 384-well plates were washed 3 times with PBS using a Bravo automated liquid handler (Agilent Technologies) to remove the residual culture media. Subsequently, 90 μ L of 80% acetone were added to the cell pellets and the plates were incubated at -20 C for 2h to precipitate the proteins. After centrifugation at 6000 g for 15 min, supernatants were removed and protein pellets were resuspended in 20 μ L digestion buffer (100 mM TEAB (pH 8.5) containing 0.625 mM TCEP, 2.5 mM chloroacetamide, 3.125 ng/ μ L trypsin, and 3.125 ng/ μ L LysC) followed by over-night incubation at room temperature in an orbital shaker set to 1200 rpm. Peptides were dried in vacuo and labeled with TMTpro isobaric mass tags in 100 mM TEAB (pH 8.5) 50% DMSO at room temperature for 1h. The reaction was stopped in 2.5% hydroxylamine and samples were subsequently pooled and purified using C18SCX stage-tips as described [42]. TMT-labeled samples were subjected IMAC enrichment using prefilled Fe(III) cartridges (Agilent) and the flow-through was further processed with a high pH reversed-phase peptide fractionation kit (Thermo Fisher Scientific) to yield 3 fractions prior to LC-MS/MS analysis.

LC-MS/MS analysis of proteomics samples

Fractionated and lyophilized samples were resuspended in 0.05% trifluoroacetic acid in water and 30 % of each sample was injected into an Ultimate3000 nanoRLSC (Dionex) coupled to a Exploris (Thermo Fisher Scientific) mass spectrometer (Thermo Fisher Scientific). Peptides were separated on custom-made 50 cm \times 100 μ m (ID) reversed-phase columns (C18, 1.9 μ m, Reprosil-Pur, Dr. Maisch) at 55 $^{\circ}$ C. Gradient elution was performed from 2 % acetonitrile to 40 % acetonitrile in 0.1 % formic acid and 3.5 % DMSO over 65 min at a flow rate of 350 nL/min. Samples were online injected into the mass spectrometer. The Q Exactive Plus was operated in a data-dependent top 10 acquisition method. MS spectra were acquired using 70,000 resolution and an ion target of 3×10^6 for MS1 scans. Higher energy collisional dissociation (HCD) scans were performed with 35 % NCE at 35,000 resolution (at m/z 200), and ion target setting was set to 2×10^5 to avoid coalescence [42]. The instrument was operated with Tune 2.4 and Xcalibur 3.0 build 63. Phosphoproteomics samples were run unfractionated using a 120 min gradient and otherwise identical settings.

Protein Identification and quantification

Raw data were processed using an in-house pipeline based on the isobar quant package [43]. Mascot 2.5 (Matrix Science, Boston, MA) was used for protein identification. In a first search 30 ppm peptide precursor mass and 30 mDa (HCD) mass tolerance for fragment ions was used for recalibration followed by search using a 10 ppm mass tolerance for peptide precursors and 20 mDa (HCD) mass tolerance for fragment ions. Enzyme specificity was set to trypsin with up to three missed cleavages. The search database consisted of the SwissProt sequence database (SwissProt Human release December 2018, 42 423 sequences) combined with a decoy version of this database created using scripts supplied by Matrix Science. Carbamidomethylation of cysteine residues and TMT modification of lysine residues were set as fixed modification. Methionine oxidation, and N-terminal acetylation of proteins, and TMT modification of peptide N-termini were set as variable modifications. For phosphoproteomics samples, serine, threonine, and tyrosine phosphorylation was set as variable modification. Unless stated otherwise, we accepted protein identifications as follows. (i) For single-spectrum to sequence assignments, we required this assignment to be the best match and a minimum Mascot score of 30 and a $10\times$ difference of this assignment over the next best assignment. Based on these criteria, the decoy search results indicated $<1\%$ false discovery rate (FDR). (ii) For multiple spectrum-to-sequence assignments and using the same parameters, the decoy search results indicate $<0.1\%$ FDR. All identified proteins were quantified; FDR for quantified proteins was below 1%.

Reporter ion intensities were read from raw data and multiplied with ion accumulation times (in milliseconds) to yield a measure proportional to the number of ions; this measure is referred to as ion area. Spectra matching to peptides were filtered according to the following criteria: mascot ion score >15 ,

Figure 8: Typical confocal fluorescence images of actin mitochondria, nuclei and their overlay from left to right, respectively. Each row shows a different stimulation of the non-targeted (NT) control gRNA for visual comparison.

signal-to-background of the precursor ion >4 , and signal-to-interference >0.5 [44]. Fold-changes were corrected for isotope purity as described and adjusted for interference caused by co-eluting nearly isobaric peaks as estimated by the signal-to-interference measure [45]. Protein quantification was derived from individual spectra matching to distinct peptides by using a sum-based bootstrap algorithm; 95% confidence intervals were calculated for all protein fold-changes that were quantified with more than three spectra.

Automated High-Content Imaging

High-content imaging (HCI) facilitates screening multiple cells at subcellular resolution to detect intensity, texture and morphology related phenotypic variation [1]. A PerkinElmer Opera Phenix high content screening system coupled with a collaborative robot designed for pharmaceutical screening (the plate::handlerTM FLEX, PerkinElmer) was used to image the 384-well plates in spinning disk confocal mode. A 20x water immersion objective (NA=1.0) was used to collect 16 fields of view from each well utilising four fluorescence channels and a bright field (BF) channel comprising nuclei (excitation: 405 nm, emission: 435 nm-480 nm), CD38 or MAOA (excitation: 488 nm, emission: 500 nm-550 nm), mitochondria (excitation: 561 nm, emission: 570 nm-630 nm), actin (excitation: 640 nm, emission: 650 nm-760 nm) and BF (transmission, emission: 650 nm-760 nm)

Figure 9: An overview of the Image2Omics machine learning pipeline from the raw cell painting image to the final output predictions for transcript and protein abundances.

detection.

Two sCMOS cameras of the system were employed with pixel binning of 2. Each camera acquired a set of 2 fluorescence channels at a time (405 nm and 561 nm, 488 nm and 640 nm) and on a third acquisition, one of the cameras collected the brightfield (BF) images in transmission mode. Plates were imaged un-sealed but transparent plastic lid on, enabling BF transmission. A set of representative images from each channel of aforementioned phenotypic stain panel including a stimulation marker from both negative and positive control wells can be seen in Figure 8. All fluorescence imaging data was collected, visualized, and analysed for quality control using Perkin Elmer Harmony (version 4.9.2137.273, Revision: 147881, Acapella version: 5.0.1.124082) software installed on the imaging instrument computer. Raw image files were annotated within the software defining plate maps with gene edits, donor codes, cell types and main marker (CD38 for M1 polarized plates or MAOA for M2 polarized plates) names.

Image2Omics

The Image2Omics pipeline, shown in Figure 9, consists of three stages: image preprocessing, backbone pre-training, and fine-tuning for multi-omics prediction. We describe them in detail in the following sections.

Image Preprocessing

All acquired images are first preprocessed by (1) shading correction and (2) creating cell-centered patches. In step (1), following [48], shading correction for images in the i -th plate is done according to

$$I_{corrected}(x, y) = I_{measured}(x, y) / F^i(x, y)$$

$$F^i(x, y) = G_{\sigma} * \left(P_k * \frac{1}{N} \sum_{n=1}^N I_{measured,n}(x, y) \right)$$

where x and y denote pixel coordinates, $I_{corrected}$ and $I_{measured,n}$ are the corrected and measured intensity of the n -th image out of N total images in plate i -th, F_p is the estimated flat-field image for plate i -th, G_{σ} is a Gaussian kernel with standard deviation σ , and P_k is a P -percentile filter with kernel size k . Similar to [49], we set σ to 50 and use a 10th-percentile filter with k of 250.

In step (2), the cell-centered patches are created by identifying and cropping around nuclei centers from the corrected images, producing a 128×128 tile for each nuclei. To identify nuclei centers, we binarize the nucleus images using Otsu’s method and apply Laplace of Gaussian filter on the binarized image.

Backbone Pre-training

A deep convolutional neural network backbone is pre-trained to discriminate genetic perturbations from the processed images. Specifically, we use a *ResNet18* backbone with three modifications: (i) we replace the *Average Pooling* and *Flatten* operations with a single *Global Average Pooling* layer to support arbitrary input image size, (ii) two dense layers of sizes 1024 and 128 are added following *Global Average Pooling*, and (iii) we add an additional *Mean Aggregation* layer to enable multiple instance learning. Specifically, an embedding h^k for a perturbation in well k is calculated as

$$H_i^k = mResNet18(x_i^k)$$

$$H^k = \frac{1}{N} \sum_{i=1}^N H_i^k$$

where $x_i^k \in \mathbb{R}^{128 \times 128 \times 3}$ and $H_i^k \in \mathbb{R}^{128}$ denote the i -th cell-centered patch of well k and its corresponding embedding, $mResNet18$ is the ResNet18 architecture with modifications (i) and (ii), and $H^k \in \mathbb{R}^{128}$ is the aggregated embedding from N cell-centered patches in well k .

We train *mResNet18* using Multiple Instance Triplet Loss, defined as

$$L = \max(0, \|H - H^+\|_2^2 - \|H - H^-\|_2^2 + \alpha)$$

where H , H^+ , and H^- denote the aggregated embedding of the anchor, positive, and negative samples, respectively, and α is the margin term. Intuitively, the loss function optimizes for an embedding space where anchor and positive samples stay close to each other while anchor and negative samples are far apart.

Following [50], we use semi-hard online triplet mining and define positive samples as wells that share same genetic perturbation and stimulation condition. During training, each batch consists of $K = 240$ wells uniformly distributed among 12 randomly sampled genetic perturbations and stimulation conditions. For each well we further randomly sample $N = 12$ instances for multiple instance learning, resulting in an effective batch size of 2880. We also set $\alpha = 0.2$ and use the AdamW optimizer with a learning rate of 0.0001 and weight decay term of 0.01.

Multi-omics Fine-tuning

The pre-trained backbone is fine-tuned for multi-omics prediction tasks. For each combination of omics modality $o \in \{\text{transcriptomics, proteomics}\}$ and

stimulation condition $s \in \{M1, M2\}$, we train a separate model with multiple instance learning following

$$Y_{o,s}^k = f_{\theta_{o,s}} \left(\frac{1}{N} \sum_{i=1}^N mResNet18(x_i^k) \right)$$

where $Y_{o,s}^k$ denote the predictions for well k , f a linear model parametrized by $\theta_{o,s}$, and x_i^k a cell-centered patch defined in 5.3.2.

mResNet18 is initialized with pre-trained weights obtained in 5.3.2 and remained frozen during training. For each batch, we sampled $K = 64$ wells and $N = 64$ patches from each well for an effective batch size of 4096. We again use the AdamW optimizer with a learning rate of 0.00005 and a weight decay term of 0.01 to minimize mean squared error loss between the predicted and actual gene product abundances.

Inference

The fine-tuned multi-omics models are employed for different omics modality and stimulation condition predictions. For each well, we sample $N = 512$ instances and predict the omics readouts using the fine-tuned models. Setting different random seeds can lead to different predictions due to selecting different set of instances. To make the results more robust, the prediction is repeated three times with different random seeds and the final results are the average across them. By choosing a big sample size ($N = 512$), we did not observe a significant variance across seeds.

Evaluation Protocol

Label Calculation

Due to the many-to-many relationship between well replicates in imaging readout and well replicates in multi-omics readout, our label calculation protocol consists of three steps:

1. For each well in the multi-omics readout, find all wells with the same gene perturbation.
2. Randomly sample two wells with the same gene perturbation and take the average of their labels.
3. Use the average from the last step and assign it as a label to the well from the first step.

Since in our dataset, there are two imaging readout plates per multi-omics readout plate, the above steps are repeated twice with two different random seeds to generate an imaging to multi-omics readout pair.

Data splitting

We evaluate Image2Omics by repeating the protocol in 5.3 with 10 random splits. For data splitting, the split is done based on the gene perturbation, where we randomly split the unique 156 gene perturbations into train/validation/test sets following 70/10/20 ratio. Due to using different random seeds for splitting, we will have a different set of wells in train/validation/test sets for each seed.

Metrics

We used Symmetric Mean Absolute Percentage Error (SMAPE) between the predicted and ground-truth gene product abundances over K samples of the test set as the evaluation metric:

$$\text{SMAPE}(O, \hat{O}) = \frac{100\%}{K} \sum_{k=0}^K \frac{|\hat{O}_k - O_k|}{|\hat{O}_k| + |O_k|}$$

We also performed statistical tests to evaluate the adequacy of the proposed model. For the statistical tests, we compared the predictions using our model with a static estimate \bar{O}_i based on the training set, which was the average of the omics abundance value in the training set for the i -th target. The comparison was done by applying Mann Whitney Wilcoxon test on the SMAPE obtained from our model versus the static training set estimate. The null hypothesis for this is $\bar{x}i^1 = \bar{x}i^2$ with $\bar{x}i^1 = \text{SMAPE}(O, \hat{O})$ and $\bar{x}i^2 = \text{SMAPE}(O, \bar{O})$ where K is the total number of images in the test set. The goal of this test was to determine the fraction of targets with significant predictive signal stemming from the cellular images. Rejecting the null hypothesis for a molecular marker would imply that Image2Omics does not have a lower SMAPE than a static training set estimate and that hence the molecular marker is not more predictable when having the cell imaging information available than in its absence.

Data Availability

The cell imaging paired with transcriptomics and proteomics data used in this study will be made available at a public repository upon publication.

Code Availability

The source code for Image2Omics is available at <https://github.com/GSK-AI/image2omics>.

IL6ST	0.02 (95% CI: 0.00, 0.06)	20.71% (95% CI: 18.02%, 23.37%)

Table 3: Comparison of the top 10 and bottom 10 gene products with the respectively lowest and highest r^2 correlations (higher is better) and Symmetric Mean Absolute Percentage Errors (SMAPEs; lower is better, all significant at $\alpha < 0.05$) in predicting ground truth gene product abundances directly from cellular images in the test fold dataset for proteomics in M1 polarised macrophages. 95% confidence intervals (CIs) were calculated via resampling and retraining models with a new random seed across 10 resampled runs. Performance is calculated over all perturbed and unperturbed cell states to cover a diverse range of cellular states.

Proteomics (M1 state)		
Gene symbol	Top 10 r^2	SMAPE (95% CI)
