Abstract— The classical Binary Symmetric Channel has a fixed transition probability. We discuss the Binary Symmetric Channel with a variable transition probability that depends on a Poisson distribution. The error rate for this channel is determined and we also give bounds for the channel capacity. We give a motivation for the model based on the Class-A impulse noise model, as given by Middleton. The channel model can be extended to the Additive White Gaussian Channel model, where the noise variance also depends on a Poisson distribution.

Keywords— BSC, Poisson distribution, BER, Capacity, Noise Variance

# I. INTRODUCTION

The binary symmetric channel (BSC) model [1] is a classical communication model with binary input, binary output and with a fixed transition probability, see Fig. 1.

Figure 1. The binary symmetric channel (BSC)

In this case, we calculate the transition probability, q, for a coherent 2-FSK transmission with hard decision (binary) at the receiver [1] using the Q-function, i.e.

$$q = Q\left(\sqrt{\frac{E_b}{2\times\sigma_g^2}}\right),$$

where  $E_b$  is the signal energy per bit and  $\sigma_g^2$  is the Additive White Gaussian Noise (AWGN) variance, respectively. Q(x) is the probability that a standard normal random variable takes a value larger than x. We use coherent 2-FSK modulation for the rest of this correspondence.

We modify the model in such a way, that the transition probability is varying according to a Poisson distribution, see Fig. 2.

Figure 2. The BSC with variable transition probability

We call this model Channel I. For this model, the transition probability q(k) is given by

$$q(k) = Q\left(\sqrt{\frac{E_b}{2\times\left(\sigma_g^2 + \frac{k\sigma_I^2}{A}\right)}}\right),\tag{1}$$

where k is Poisson-distributed with the property that the average(k) = A and the variance (k) = A. Note: we use the probability  $P(k) = (A^k e^{-A}/k!)$  for a Poisson-distributed variable k. The noise consists of the sum of two independent AWGN noise sources, both with average zero and sum variance  $\sigma_k^2 = \frac{k\sigma_l^2}{A} + \sigma_g^2$ . The source with noise variance  $\sigma_g^2$  can be considered as a background noise, i.e. always present with the same variance. The variance  $\sigma_l^2$  represents the average impulsive noise variance per symbol.

For small values of A, a symbol is disturbed with probability  $P(k=0) \approx (1-A)$  by background noise with variance  $\sigma_g^2$ , or with probability  $P(k=1) \approx A$  by noise with variance  $\sigma_g^2 + \sigma_l^2/A$ , which can be large. For large values of A, k is close to its average value A and the noise variance approaches  $\sigma_g^2 + \sigma_l^2$ .

The motivation for this channel is given by the Class-A impulse noise model as defined by Middleton [2]. Using this model, a symbol is disturbed by AWGN in addition to k AWGN impulses, each with variance  $\frac{\sigma_l^2}{A}$ . Again, k is Poisson distributed with average A. At the 2-FSK demodulator, we take a binary decision and end-up with the binary symmetric channel as given in Fig. 2.

We also consider another channel, Channel II, where the transition probability is given by

$$q(k) = Q\left(\sqrt{\frac{E_b}{2\times(\sigma_g^2 + k\sigma_l^2)}}\right). \tag{2}$$

Note that here the sum noise variance is  $\sigma_g^2 + k\sigma_l^2$ , depending on A only via the parameter k. For small values of A, the noise has the variance  $\sigma_g^2$  with  $P(k=0) \approx (1-A)$  or the variance  $(\sigma_g^2 + \sigma_l^2)$  with  $P(k=1) \approx A$ . For large values of A, k is close to its average value A and thus the variance of the disturbance approaches  $\sigma_g^2 + A\sigma_l^2$ .

In this correspondence, we investigate the average error probability for Channel I and Channel II for various values of A, section II. Based on the calculations, we further look at the channel capacity, section III. We compare the capacity results for informed - and non-informed decoder about the value of k. We conclude in section IV. The Appendix gives an extension of the model to a Gaussian channel with arbitrary input.

### II. ERROR PROBABILITY

To present our results, in the sequel, we set  $\sigma_I^2 = 7.28.10^{-4}$  Watt,  $\sigma_g^2 = 7.28.10^{-7}$  Watt and the energy per bit  $E_b = 7.28.10^{-3}$  Joules [3,4].

The error probability for Channel I (Fig.2) depends on k and can be formulated as

$$BER(channel\ I) = \sum_{k=0}^{\infty} \frac{e^{-A}A^k}{k!} \times Q\left(\sqrt{\frac{E_b}{2 \times \left(\sigma_g^2 + \frac{k\sigma_I^2}{A}\right)}}\right). \quad (3)$$

Since the Q function is convex for  $k \geq I$ , we cannot use the average noise variance  $\sigma_g^2 + \sigma_l^2$  to calculate the  $BER(channel\ I)$ . Instead, we use the properties of the Poisson distribution and first calculate the variance of  $(\sigma_g^2 + \frac{k\sigma_l^2}{A})$ , which is equal to  $(\frac{\sigma_l^4}{A})$  [3,4]. Hence, for <u>large</u> values of A (or small values of  $\sigma_l^2$ ), this variance goes to zero, see Fig. 3.

Figure 3. Normalized probability density function of the noise variance for different values of A

For large A, the relevant contributing probabilities in (3) are close to P(k = A). As result, the  $BER(channel\ I)$  approaches:

$$\lim_{A \to \infty} BER(Ch\ I) = Q\left(\sqrt{\frac{E_b}{2 \times (\sigma_g^2 + \sigma_I^2)}}\right). \tag{4}$$

For small values of A, the value of the Q function approaches  $\frac{1}{2}$ . Hence, in this limiting case, the error rate approaches

$$\lim_{A\to 0} BER(Ch. I) = e^{-A}Q\left(\sqrt{\frac{E_b}{2\times(\sigma_g^2)}}\right) + \frac{A}{2}, \quad (5)$$

which is close to the error rate for the AWGN channel with variance  $\sigma_g^2$ . For small  $\sigma_g^2$ , the BER is approximately equal to A/2, see Fig. 4. Note that

$$Q\left(\sqrt{\frac{E_b}{2\times(\sigma_g^2)}}\right) (k = 0) \leq Q\left(\sqrt{\frac{E_b}{2\times(\sigma_g^2 + \sigma_l^2)}}\right).$$

Figure 4. BER versus A, (3)

For our particular choice of  $E_b$  and  $\sigma_I^2$ , an error floor appears for in between values of A, see Fig. 5. The *SNR* is defined as  $10log_{10}$  ( $E_b/\sigma_g^2$ ) dB, with variable  $\sigma_g^2$ .

Figure 5. BER versus SNR of a 2-FSK system for different values of A

As another varying channel, we can look at the channel II where the noise variance equals  $\sigma_g^2 + k\sigma_l^2$ , which depends on k and it is again connected to the Poisson distribution with parameter A. The BER is given by

$$BER(Ch. II) = \sum_{k=0}^{\infty} \frac{e^{-A_A k}}{k!} \times Q\left(\sqrt{\frac{E_b}{2 \times (\sigma_g^2 + k\sigma_l^2)}}\right). \quad (6)$$

For <u>large</u> values of A, the relevant values of k are large and thus, we expect  $Q\left(\sqrt{\frac{E_b}{2\times(\sigma_g^2+k\sigma_I^2)}}\right)\approx \frac{1}{2}$  and

$$\lim_{A \to \infty} BER(Ch.II) = 1/2.$$
 (7)

For <u>small</u> values of A,  $P(k = 0) = e^{-A} \approx 1 - A$ , and thus we expect the BER to be close to

$$\lim_{A\to 0} BER(Ch.II) =$$

$$(1 - A)Q\left(\sqrt{\frac{E_b}{2\times(\sigma_g^2)}}\right) + AQ\left(\sqrt{\frac{E_b}{2\times(\sigma_g^2 + \sigma_I^2)}}\right). \tag{8}$$

The value of  $\sigma_g^2$  is small compared to  $\sigma_I^2$ , and thus for small A, the BER(Ch.II, small~A) is approximately equal to  $AQ\left(\sqrt{\frac{E_b}{2\times(\sigma_g^2+\sigma_I^2)}}\right)$ . In Fig. 6, we illustrate the BER for channel II.

Figure 6. The BER for channel II as a function of A.

The *BER* can be used to estimate the channel capacities for Channel I and Channel II, section III.

# III. CAPACITY

In Information theory, the channel capacity is an important part of channel evaluation, [5,6]. For the binary symmetric channel, the capacity is C = 1 - H(q), where H(q) is the binary entropy function, with a maximum value of 1. Channel I and Channel II are symmetric and thus the capacity achieving input probability distribution  $P(in) = (\frac{1}{2}, \frac{1}{2})$ . In general, the capacity is given by H(Y) - H(Y/X), where X

and Y are the input - and output - random variables, respectively. For these two channels and  $P(in) = (\frac{1}{2}, \frac{1}{2})$ , the output probability distribution is  $P(out) = (\frac{1}{2}, \frac{1}{2})$ . Hence, to find the capacity, we have to find the entropy H(Y/X) = H(Noise). When receiver and transmitter are <u>not</u> informed about the value of k, the H(Noise) = H(BER). The channel capacity is then C = 1 - H(BER).

Suppose that the receiver is informed about the value of k (state of the channel), then the capacity is given by

$$C_{informed} = P(k = 0)C(k = 0) + P(k = 1)C(k = 1) + ...$$

$$= 1 - P(k = 0)H(q(k = 0)) - P(k = 1)H(q(k = 1)) + ...$$

$$= 1 - \sum_{k=0}^{\infty} P(k) H(q(k))$$
(9)

$$\geq 1 - H(\overline{q(k)})$$
 (using the entropy convexity) (10)

where 
$$q(k) = Q\left(\sqrt{\frac{E_b}{2\times\left(\sigma_g^2 + \frac{k\sigma_I^2}{A}\right)}}\right)$$
 and  $\overline{q(k)} = BER$  as given

in (3) for channel I and (6) in channel II.

Fig. 7 illustrates the capacities for Channel I for different values of A for informed and non-informed receiver.

Figure 7. Capacity for Channel I as a function of A.

For large values of A, the capacity is determined by (4), since the variance of  $(\frac{k\sigma_I^2}{A}) = (\frac{\sigma_I^4}{A})$ , which goes to 0 for large A. Hence, information at the receiver about k does not help since all relevant values of k are close to the average A and thus the BER is equal to (4).

For small values of A, the information at the receiver does help. The value of  $\sum_{k=0}^{1} P(k) H(q(k)) \approx A$ , whereas  $H(\overline{q(k)}) \approx H(A/2)$ . Note, that (1-A) > 1 - H(A/2) for A < 1. As an example, we calculate (9) and (10) when A = 0.01. In this case, for the given noise variances, we obtain  $1 - \sum_{k=0}^{\infty} P(k) H(q(k)) \approx 0.99$  and  $1 - H(\overline{q(k)}) \approx 0.96$ .

Remark: From Fig. 7, we can see that for the non-informed receiver the capacity for A = 0.02 is the same as for the informed receiver at A = 0.2. Hence, in order to obtain the same performance, we have to increase  $E_b$  for the non-informed model with a factor of 10. This shows the importance of channel information at the receiver. Noise

mitigation is an important topic. In [7], we find an approach using noise estimation at the receiver.

Fig. 8 illustrates the capacities for Channel II for different values of A for informed and non-informed receiver. The values of (9) and (10) are very close together. The gain by using information at the receiver is negligible. For small A,

(8) approaches 
$$AQ\left(\sqrt{\frac{E_b}{2\times(\sigma_g^2+\sigma_l^2)}}\right)$$
. For large  $A$ , the variance gets small and thus, all values of  $k$  are close to the average  $A$  leading to a BER approaching  $\frac{1}{2}$  and a capacity close to 0.

Note: This channel capacity analysis concerns the particular case of a discrete symmetric channel, on which the capacity expression is a function of *BER*, and cannot exceed a value of 1. Further details of the channel capacity for a general AWGN channel are provided in the Appendix.

Figure 8. Capacity for Channel II as a function of A.

# V CONCLUSION

We introduce a variation of the Binary Symmetric Channel (BSC), where the transition probability is determined by a Poisson distribution with characteristic parameter A. Two different types of channels are described. We give the Bit Error Rate (BER) and the channel capacity for informed and non-informed receiver about the strength of the noise that determines the transition probability. Using the BER, we also comment on the channel capacities for both cases. We extend the model to the AWGN channel.

## APPENDIX

The Binary Symmetric channel can be generalized to the un-quantized Additive White Gaussian Noise channel with noise variance  $(\sigma_g^2 + \frac{k\sigma_I^2}{A})$ , see Fig. 9.

Figure 9. General AWGN channel.

The average variance is  $\sigma_{AV} = \sigma_g^2 + \sigma_l^2$  and the average input power spectral density is P/2B, where P and B are the transmitted signal power and bandwidth, respectively.

Calculating the channel capacity means that for a given noise probability distribution p(n) the input distribution p(x) has to be found which maximizes

C = 
$$\sup_{p(x): \overline{x^2} \le P/2B} [H(Y) - H(N)] \text{ bits/transmission}, (10)$$

where H(Y) and H(N) are the output- and - noise entropy, respectively. Note that H(N) = H(Y/X). For an AWGN source with fixed variance  $\sigma_g^2$ ,  $H(N) = \frac{1}{2}log_2(\sigma_G^2)$  bits. Unfortunately, it is not always possible to find an explicit expression for the optimum input distribution that maximizes C, [6].

An interesting question is whether information about the strength of the noise,  $\frac{k\sigma_I^2}{A}$ , at the receiver and/or the transmitter has an influence on the capacity of the channel. This approach has led to interesting results for the capacities of memory systems, [8]. We look at the four possible different situations of informed or non-informed transmitter and –receiver, respectively (where \* can be + or -):

1. The capacity C(+,\*): the transmitter knows the value of k. In this case, the transmitter can use the water-filling principle which maximizes the output entropy to  $H(N) = H(P/2B + \sigma_{AV}^2)$  bits;

2. The capacity C(\*,+): The <u>receiver knows</u> the value of *k*. The entropy of the noise at the output is given by

$$H(N) = \sum_{k=0}^{\infty} P(k)H(\sigma_g^2 + \frac{k\sigma_I^2}{A}) \le H(\sigma_{AV}^2)$$
 bits;

3. The capacity C(\*,-): the receiver does not know the value of k and thus,

$$H(N) = H\left[\sum_{k=0}^{\infty} P(k) \left(\sigma_g^2 + \frac{k\sigma_I^2}{A}\right)\right] = H(\sigma_{AV}^2)$$
 bits;

4. The capacity C(-,\*): The transmitter does not know the value of *k* and always uses the maximum input power spectral density P/2B. The output entropy is given by

$$H(Y) = \sum_{k=0}^{\infty} P(k)H(P/2B + \sigma_g^2 + \frac{k\sigma_l^2}{A}) bits.$$

In conclusion, the respective capacities C(+,+), C(-,+), C(-,-), and C(+,-) are given by:

C(+,+) = 
$$H$$
 (P/2B +  $\sigma_{AV}^2$ ) +  
- $\sum_{k=0}^{\infty} P(k) [H(\sigma_g^2 + \frac{k\sigma_I^2}{A})] b/\text{tr}; (11)$ 

$$C(+,-) = H(P/2B + \sigma_{AV}^2) - H(\sigma_{AV}^2) b/tr;$$
 (12)

$$C(-,+) = \sum_{k=0}^{\infty} P(k) [H(P/2B + \sigma_g^2 + \frac{k\sigma_l^2}{A}) + -H(\sigma_g^2 + k\frac{\sigma_l^2}{A})] b/tr;$$
(13)

$$C(-,-) = \sum_{k=0}^{\infty} P(k) [H(P/2B + \sigma_g^2 + \frac{k\sigma_I^2}{A}) + H(\sigma_{AV}^2) \text{ b/tr.}.$$
 (14)

Figure 10. C(+,+) & C(+,-) versus parameter A.

For <u>large values of A</u>, the variance of  $\frac{k\sigma_I^2}{A}$  goes to zero, k will be close to A and thus C(+,+), C(-,+), C(-,-), and C(+,-) approach, (Figs. 10 and 11).

$$\lim_{A\to 0} C(*,*) = H(P/2B + \sigma_{AV}^2) - H(\sigma_{AV}^2) \text{ b/tr.}$$
 (15)

Figure 11. C(-,+) & C(-,-) versus parameter A.

For <u>small values of A</u>, P(k = 0) and P(k = 1) can be approximated by (I-A) and A, respectively. Using the definition for the entropy, the factor  $\frac{1}{2} log_2(1 + \frac{\sigma_l^2}{\sigma_g^2})$  dominates the difference between informed and non-informed receiver capacity, i.e.

$$\lim_{A \to 0} \left[ C(*,+) - C(*,-) \right) =$$

$$= H(\sigma_{AV}^2) - \sum_{k=0}^{\infty} P(k) \left[ H(\sigma_g^2 + \frac{k\sigma_I^2}{A}) \right] b / \text{tr.}.$$
The difference between  $C(+,*)$  and  $C(-,*) =$ 

$$\lim_{A \to 0} \left[ C(+,*) - C(-,*) \right] = H \left( P/2B + \sigma_{AV}^2 \right) +$$

$$- \sum_{k=0}^{\infty} P(k) \left[ H(P/2B + \sigma_g^2 + \frac{k\sigma_I^2}{A}) b / \text{tr.}.$$

For small values of A, the difference [C(+,\*) - C(-,\*)] is dominated by the factor  $\frac{1}{2} log_2(1 + \frac{\sigma_I^2}{(\frac{P}{2R}) + \sigma_g^2})$ . See Fig. 12.

Figure 12. C(+,-) & C(-,-) versus parameter A.

We conclude that for small A, the difference in capacity is larger for the informed receiver than for the informed transmitter. For large A, the four capacities merge.
